Later work showed that animals also can learn behaviors to stimulate other sites through ICSS (e.g., the locus coeruleus, midbrain central gray, cerebellum, trigeminal motor nucleus, substantia nigra, caudate nucleus, and nucleus accumbens) (Phillips, 1984). The diversity of these sites has not been fully elucidated. Many of them are known to lie along the trajectory of catecholamine-containing neurons. Although this includes both norepinephrine and dopamine projections, most pharmacologic data can be interpreted in terms of dopaminergic mechanisms (Box 43.3; Fig. 43.6). In particular, very high rates of responding for ICSS were found in the ventral tegmental area, ventral striatum (including the nucleus accumbens

to which dopamine neurons project), and limbic system. However, of several possibly independent neural systems that may subservise rewarding brain stimulation, only some depend on dopamine. The difficulty in interpreting the role of striatal dopamine in ICSS lies in distinguishing motor from reward effects (Box 43.3). The phenomenon of human drug dependence and the discovery in the early 1960s of drug self-administration in animals opened the way to an analysis of the neurochemical basis of reinforcement.

### The Mesolimbic Dopamine System Plays a Key Role in Incentive Motivation

Wise (1982) proposed that natural reinforcers are perceived as rewards because they increase activity of the mesolimbic dopamine system. If the hypothesis of Wise is correct, the mesolimbic dopamine system should mediate natural rewards, such as food and sex.

BOX 43.3

PSYCHOPHYSICS OF HEDONISM AS MEASURED BY BRAIN STIMULATION REWARD

Electrical stimulation of the brain can be used as positive reinforcement of learned behaviors. An apparatus is set up so that when an animal presses a lever, its brain is stimulated. Alternatively, a threshold procedure can be used where a lever or wheel response is required. An advantage of using electrical stimulation to measure motivation is that the strength of the reward can be titrated easily by adjusting the amount of current delivered for each response. If the current is adjusted too low (i.e., below the threshold for reinforcement), then the animals will not press the lever. As current is increased, the relationship between the rate of lever pressing and the strength of current typically follows a sigmoidal curve called rate-intensity function. In the threshold procedure, a series of discrete trials are presented at different current intensities, and the responses within a certain cutoff period are recorded. Current levels are lowered and

raised to capture the threshold current (Fig. 43.2). Pharmacologic manipulation of catecholamine neurotransmitter systems can lower thresholds (e.g., treatment with amphetamines or cocaine) or raise thresholds (e.g., treatment with the dopamine receptor antagonist pimozide). Such changes mean the amount of electrical current required to support lever presses varies, whereas the latency to respond is unchanged. Thus, these drugs affect reward processes rather than motor function. The threshold of reinforcement also can be measured by allowing rats to adjust the strength of the current. In this setup, a process is employed in which rats press lever one to produce ICSS, but each lever-one press also reduces the intensity of the current. To reset current intensity, rats must press lever two. Such "self-titration" experiments yield conclusions similar to those based on threshold and rate-intensity functions.

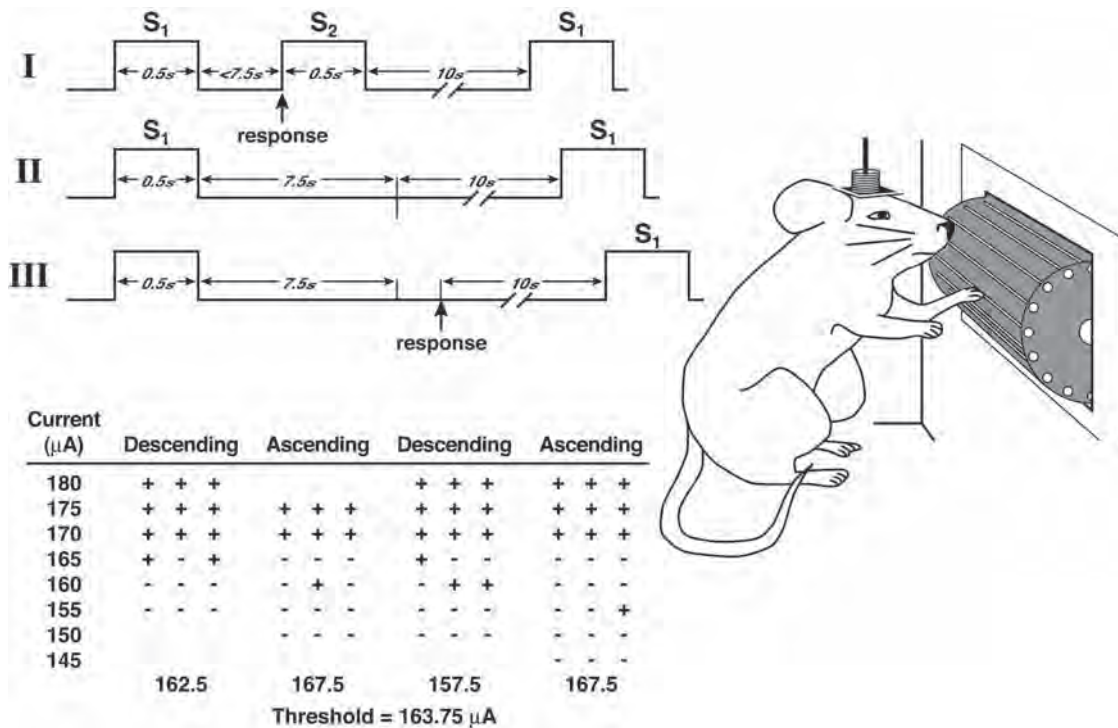

FIGURE 43.6 Intracranial self-stimulation threshold procedure. Panels I, II, and III illustrate the timing of events during three hypothetical discrete trials. Panel I shows a trial during which the rat responded within the 7.5s following the delivery of the noncontingent stimulus (positive response). Panel II shows a trial during which the animal did not respond (negative response). Panel III shows a trial during which the animal responded during the intertrial interval (negative response). For demonstration purposes, the intertrial interval was set at 10s. In reality, the interresponse interval had an average duration of 10s and ranged from 7.5–12.5s. The table depicts a hypothetical session and demonstrates how thresholds were defined for the four individual series. The threshold of the session is the mean of the four series' thresholds. Taken with permission from Markou and Koob (1992).

In fact, depletion of dopamine in the nucleus accumbens does not impair consummatory behavior in rats (unlike dopamine depletion from the caudate-putamen), but it does reduce incentive-motivational responses. For example, proceptive behaviors (such as "ear wiggling," hopping, and darting, all of which serve to solicit the attention of the male) are reduced in female rats with dopamine depletions. Also, depletion of dopamine from the nucleus accumbens decreases locomotor excitement of hungry rats in the presence of food (Koob *et al.*, 1978). Intriguingly, consummatory behaviors, including eating of high incentive foods, appears to be mediated by distinct mechanisms within the nucleus accumbens that depend upon opiate receptors (Kelley and Berridge, 2002).

Mesolimbic dopamine also may control behavior motivated by reward. When a neutral light predicts a primary reinforcer (e.g., water), rats will learn a new behavior (e.g., lever-pressing) to turn on the light, which thus has rewarding properties of its own and is called a conditioned reinforcer. Taylor and Robbins showed that microinjections of D-amphetamine into the nucleus accumbens, but not the caudate, increased the frequency of this behavior (Robbins *et al.*, 1989). This increased frequency of response suggested that amphetamine enhanced the motivational properties of this reward-related stimulus (i.e., the light, which was related to the reward, water). Amphetamine itself was well known to suppress eating and drinking; thus, the increased frequency of behavior was not due to increased thirst, for example. Furthermore, amphetamine did not increase the frequency of responding for a randomly paired stimulus. Finally, amphetamine-induced facilitation was blocked completely by dopamine depletion in the nucleus accumbens (but not by dopamine depletion in the caudate). These results indicated that increased activity in the mesolimbic dopamine system could enhance the motivational properties of stimuli predictive of natural rewards (Robbins *et al.*, 1989). Another way of describing this activational role of the dopamine system is to suggest that it mediates "incentive salience" (Berridge and Robinson, 1998).

### The Amygdala Also Has a Role in Appetitive Conditioning and Motivation

There is growing evidence that the amygdala subserves positive emotional functions, as well as negative functions such as fear. For example, monkeys with lesions of the temporal pole, including the amygdala, poorly learn new stimulus/reward associations, suggesting an altered emotional response to reward. In rats, excitotoxic, axon-sparing lesions of the amygdala

diminish the capacity of stimuli associated with reward to motivate behavior. Such lesions also impair responses that are rewarded with access to female rats. However, mating *per se* is unaffected, in contrast with the effect of medial preoptic area lesions (Everitt *et al.*, 2000; see above). This separation of control of consummatory and learned aspects of sexual behavior indicates that motivated sequences of behavior are constructed through the coordination of neural systems that are at least partly independent. Lesions of the basolateral amygdala also impair the phenomenon of place preference in which experimental animals will consistently return to locations—generally in a well-defined environmental enclosure—where they were previously given reward. In contrast, selective lesions of the central nucleus of the amygdala impair the learning of Pavlovian conditioned approach responses. Thus, different nuclei of the amygdala clearly function in associative processes that contribute to appetitive behavior.

### Motivated Behavior Is Controlled in Part by Learning

The ventral striatum, including the nucleus accumbens, is part of a system that receives afferents from several limbic cortical structures, including the basolateral amygdala, the hippocampal formation, and the prefrontal cortex, and projects to structures such as the lateral hypothalamus and ventral pallidum (Fig. 43.7). Output from the pallidum is routed in several different ways, including to brain stem motor regions and looping back to the prefrontal cortex through the mediodorsal thalamus. This circuit (limbic cortex-ventral striatum-ventral pallidum), in principle, could provide "a neural mechanism by which motivation gets translated into action" (Mogenson *et al.*, 1980). To understand the function of this circuit, Mogenson and colleagues used electrophysiological experiments to demonstrate interactions among its components (e.g., between the amygdala and the nucleus accumbens).

As described earlier, the basal and lateral amygdala convey associative information about stimuli that predict the occurrence of reinforcers. The recipients of this information are systems that select responses. A link between the amygdala and the ventral striatum is important in the translation of emotion (and motivational effects of stimuli) to behavioral output, or action (Everitt *et al.*, 2000). In some circumstances, therefore, reinforcement involves glutamatergic inputs from these limbic afferents to the striatum. These inputs interact with the ascending dopamine system, and together they determine the output of the ventral striatal  $\gamma$ -aminobutyric acid (GABA)-ergic medium spiny

**FIGURE 43.7** Representation of limbic cortical and associated striatal circuitry, with tentative localization of functions involved in drug addiction. (A) Key structures include the medial prefrontal cortex (mPFC), which also includes the anterior cingulate (AC), orbitofrontal cortex (OFC), hippocampus (Hippo), ventral striatum (VS), nucleus accumbens, dorsal striatum (DS), globus pallidus (GP), amygdala (AMYG), and thalamus (Thal). Redrawn from Salloway *et al.* (2001) with permission. (B) Limbic cortical-striatopallidal circuitry. (i) Processing of conditioned reinforcement and delays by basolateral amygdala and of contextual information by hippocampus. (ii) Goal-directed actions involve interaction of the prefrontal cortex with other structures, possibly including the nucleus accumbens and dorsomedial striatum. (iii) “Habits” depend on interactions between the prefrontal cortex and dorsolateral striatum. (iv) “Executive control” depends on prefrontal cortex and includes representation of contingencies, representation of outcomes, and their value and subjective states (craving and, presumably, feelings) associated with drugs. (v) Drug craving involves activation of the orbital and anterior cingulate cortex, and temporal lobe including the amygdala in functional imaging studies. (vi) Connections between dopaminergic neurons and striatum reflect “spirals”—serial interactions organized in a ventral-to-dorsal cascade. (vii) Reinforcing effects of drugs may engage stimulant, Pavlovian instrumental transfer, and conditioned reinforcement processes in the nucleus accumbens shell and core and then engage stimulus-response habits that depend on the dorsal striatum. (viii) The extended amygdala is composed of several basal forebrain structures including the bed nucleus of the stria terminalis, the centromedial amygdala, and more controversially, the medial portion (or shell) of the nucleus accumbens. A major transmitter in the extended amygdala is corticotropin-releasing factor, which projects to the brain stem, where noradrenergic neurons provide a major projection reciprocally to the extended amygdala. Activation of this system is closely associated with the negative emotional state that occurs during withdrawal. Green/blue arrows, glutamatergic projections; orange arrows, dopaminergic projections; pink arrows, GABAergic projections; Acb, nucleus accumbens; BLA, basolateral amygdala; VTA, ventral tegmental area; SNc, substantia nigra pars compacta; VGP, ventral globus pallidus; DGP, dorsal globus pallidus; BNST, bed nucleus of the stria terminalis; CeA, central nucleus of the amygdala; NE, norepinephrine; CRF, corticotropin-releasing factor; PIT, Pavlovian instrumental transfer.

neurons that project to the globus pallidus (ventral pallidum) (Chapter 31). The nucleus accumbens has turned out to be a heterogeneous structure. Its medial “shell” and lateral “core” can be distinguished anatomically, neurochemically, and functionally. The shell region is considered by some to be part of an “extended amygdala” encompassing the central nucleus of the amygdala and the bed nucleus of the stria terminalis (Heimer *et al.*, 1995; see later). The basolateral amygdala projects predominantly to the nucleus accumbens core subregion and to specific parts of the dorsal striatum. These connections are paralleled by other corticostriatal “loops” (Chapter 31 and 52) (e.g., between different parts of the neocortex that project topographically to different sectors of the dorsal striatum). Moreover, there appears to be the possibility of “cross-talk” between these systems, arising from anatomical con-

nections that potentially allow communication from the amygdala-ventral striatal circuitry to the cortico-dorsal striatal loops (Haber *et al.*, 2000). In functional terms, the ventral striatum has been linked to the initial acquisition of drug-seeking and drug-taking behavior, and the subsequent cascade of loop circuitry involving the dorsal striatum to the gradual acquisition of S-R habits that help to give drug addiction its “compulsive” quality (Everitt and Robbins, 2005).

## ADDICTION

### Introduction

Drug abuse is one of the world’s major public health problems. For example, statistics from the 2005 *National Household Survey on Drug Abuse* of the National Institute on Drug Abuse of the United States reveal that approximately 20 million Americans aged 12 and older were past-month users of illicit drugs 126 million were past-month users of alcohol. Furthermore, 22 million past-month users of illicit drugs or alcohol could be classified with substance dependence or abuse in the past year. In addition, 60 million were current smokers (Substance Abuse and Mental Health Services Administration, 2006). The cost of drug abuse to society is staggering. Total economic costs of alcohol abuse per year in the United States is listed as 166.5 billion dollars, smoking 138 billion dollars, and that of illicit drugs 109.9 billion dollars. This totals over 400 billion dollars in lost productivity due to illness or death, health care expenditures, motor vehicle crashes, social welfare, and so on (Robert Wood Johnson Foundation, Princeton, New Jersey, 2001).

### Addiction Cycle

Drug addiction, also known as substance dependence, is a chronically relapsing disorder characterized by (1) compulsion to seek and take the drug, (2) loss of control in limiting intake, and (3) emergence of a negative emotional state (e.g., dysphoria, anxiety, irritability) when access to the drug is prevented (defined here as *dependence*) (Koob and Le Moal, 1997). Addiction and substance dependence (as currently defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition; American Psychiatric Association, 1994) will be used interchangeably throughout this text and refer to a final stage of a usage process that moves from drug use to addiction. Clinically, the occasional but limited use of a drug with the *potential* for abuse or dependence is distinct from escalated drug use and the emergence of a chronic drug-dependent

state (Table 43.1). An important goal of current neurobiological research is to understand the neuropharmacological and neuroadaptive mechanisms within specific neurocircuits that mediate the transition from occasional, controlled drug use and the loss of behavioral control over drug-seeking and drug-taking that defines chronic addiction.

Addiction has been conceptualized as a chronic relapsing disorder with roots both in impulsivity and compulsivity and neurobiological mechanisms that change as an individual moves from one domain to the other. Subjects with impulse control disorders experience an increasing sense of tension or arousal before committing an impulsive act; pleasure, gratification, or

TABLE 43.1 DSM-IV and ICD-10 Diagnostic Criteria for *Alcohol and Drug Dependence*

	DSM-IV	ICD-10
Clustering criterion	A. A maladaptive pattern of substance use, leading to clinically significant impairment or distress as manifested by three or more of the following occurring at any time in the same 12-month period:	A. Three or more of the following have been experienced or exhibited at some time during the previous year:
Tolerance	1. Need for markedly increased amounts of a substance to achieve intoxication or desired effect; or markedly diminished effect with continued use of the same amount of the substance.	1. Evidence of tolerance, such that increased doses are required in order to achieve effects originally produced by lower doses.
Withdrawal	2. The characteristic withdrawal syndrome for a substance or use of a substance (or a closely related substance) to relieve or avoid withdrawal symptoms.	2. A physiological withdrawal state when substance use has ceased or been reduced as evidenced by: the characteristic substance withdrawal syndrome, or use of substance (or a closely related substance) to relieve or avoid withdrawal symptoms.
Impaired control	3. Persistent desire or one or more unsuccessful efforts to cut down or control substance use.	3. Difficulties in controlling substance use in terms of onset, termination, or levels of use.
Neglect of activities	4. Substance used in larger amounts or over a longer period than the person intended.	4. Progressive neglect of alternative pleasures or interests in favor of substance use; or
Time spent	5. Important social, occupational, or recreational activities given up or reduced because of substance use.	A great deal of time spent in activities necessary to obtain, to use, or to recover from the effects of substance use.
Inability to fulfill roles	6. A great deal of time spent in activities necessary to obtain, to use, or to recover from the effects of substance used.	None
Hazardous use	None	None
Continued use despite problems	7. Continued substance use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to be caused or exacerbated by use.	5. Continued substance use despite clear evidence of overtly harmful physical or psychological consequences.
Compulsive use	None	6. A strong desire or sense of compulsion to use substance.
Duration criterion	B. No duration criterion separately specified. However, several dependence criteria must occur repeatedly as specified by duration qualifiers associated with criteria (e.g., "often," "persistent," "continued").	B. No duration criterion separately specified.
Criterion for subtyping dependence	<i>With physiological dependence:</i> Evidence of tolerance or withdrawal (i.e., any of items A-1 or A-2 above are present). <i>Without physiological dependence:</i> No evidence of tolerance or withdrawal (i.e., none of items A-1 or A-2 above are present).	None

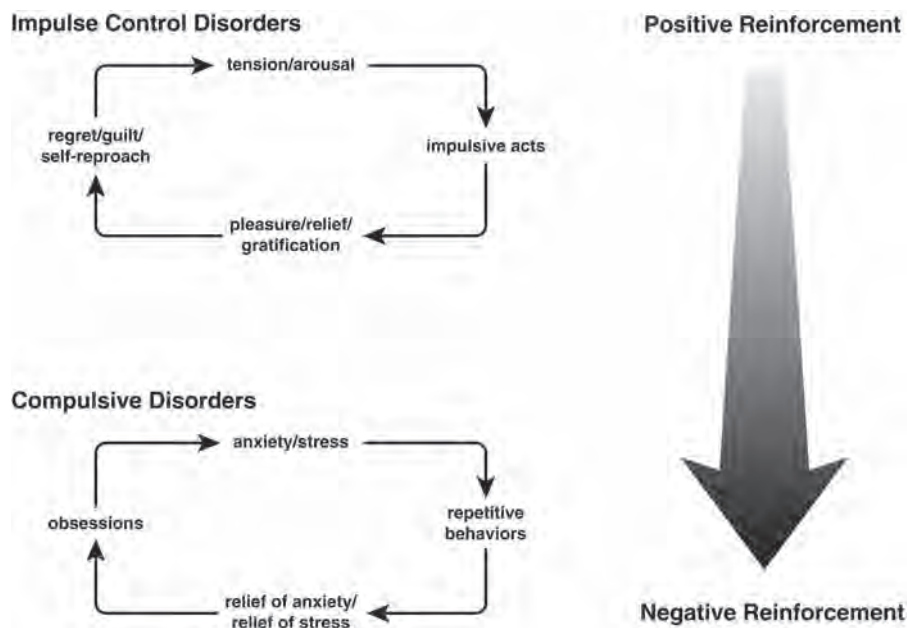

relief at the time of committing the act; and finally regret, self-reproach, or guilt following the act. In contrast, individuals with compulsive disorders experience anxiety and stress before committing a compulsive repetitive behavior, and then relief from the stress by performing the compulsive behavior. In addiction, drug-taking behavior progresses from impulsivity to compulsivity in a three-stage cycle: *binge/intoxication*, *withdrawal/negative affect*, and *preoccupation/anticipation*. As individuals move from an impulsive to a compulsive disorder, the drive for the drug-taking behavior shifts from positive to negative reinforcement (Figs. 43.8, 43.9).

Much of the recent progress in understanding the neurobiology of addiction has derived from the study of animal models of addiction on specific drugs such as opiates, stimulants, and alcohol (Shippenberg and Koob, 2002). Although no animal model of addiction fully emulates the human condition, animal models do permit investigation of specific elements of the process of drug addiction. Such elements can be defined by psychological constructs such as positive and negative reinforcement and different stages of the addiction cycle.

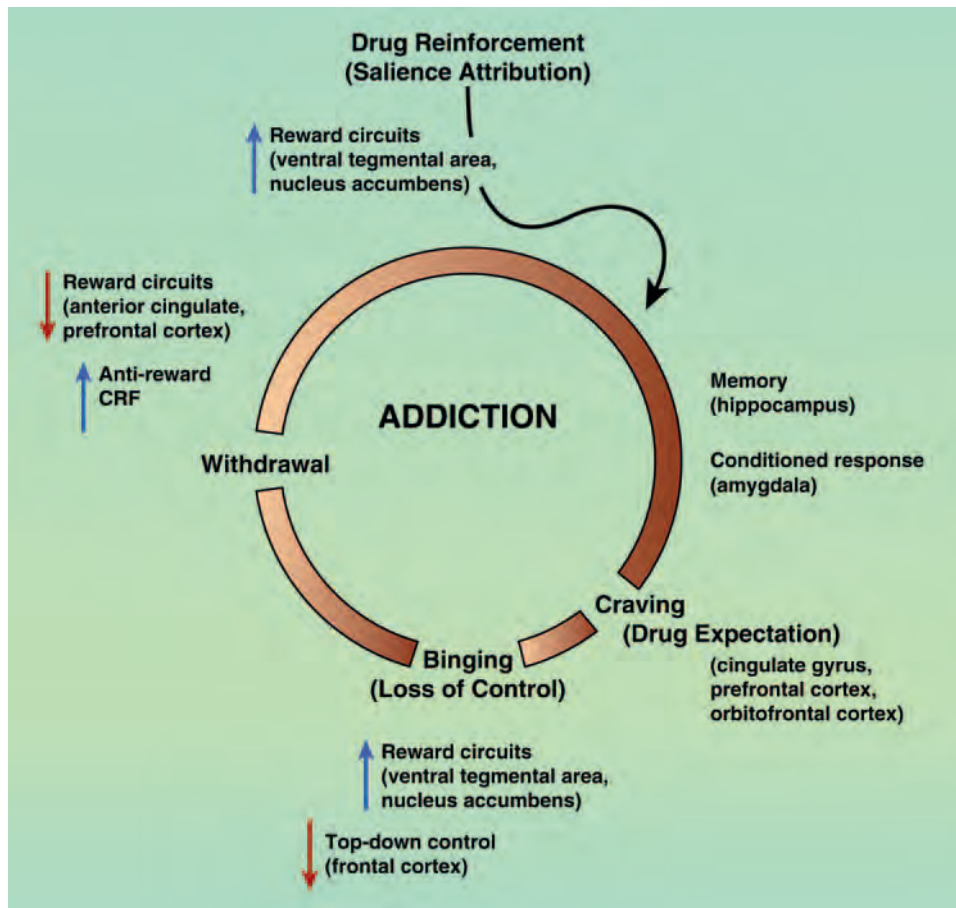

## Neurobiological Substrates of Drug Reward

### *Positive Reinforcing Effects of Drugs Are Mediated by Multiple Systems Converging on Common Targets in the Basal Forebrain*

The midbrain and forebrain appear to be involved in motivated behavior through connections of the medial forebrain bundle, composed of ascending and descending pathways, including most of the brain monoamine systems (Koob, 1992). The medial forebrain bundle is involved in brain stimulation reward and natural rewards, and work in the neurobiology of addiction has led to an understanding of the neurochemical and neuroanatomical components of this system. The principal components of this system include the ventral tegmental area, the basal forebrain (nucleus accumbens, olfactory tubercle, frontal cortex, and amygdala), and the dopamine connection between the ventral tegmental area and the basal forebrain, called the mesolimbic dopamine system. Additional components are the opioid peptide, GABA, serotonin (5-hydroxytryptamine; 5-HT), and endocannabinoid systems that interact with the ventral tegmental area and the basal forebrain (Koob, 1992)

**FIGURE 43.8** Diagram showing the stages of impulse control disorder and compulsive disorder cycles related to the sources of reinforcement. In impulse control disorders, an increasing tension and arousal occurs before the impulsive act, with pleasure, gratification, or relief during the act. Following the act there may or may not be regret or guilt. In compulsive disorders, there are recurrent and persistent thoughts (obsessions) that cause marked anxiety and stress followed by repetitive behaviors (compulsions) that are aimed at preventing or reducing distress (American Psychiatric Association, 1994). Positive reinforcement (pleasure/gratification) is more closely associated with impulse control disorders. Negative reinforcement (relief of anxiety or relief of stress) is more closely associated with compulsive disorders. Taken with permission from Koob (2004).

**FIGURE 43.9** Integrative model of brain and behavior describing the Impaired Response Inhibition and Salience Attribution (I-RISA) syndrome of drug addiction (Goldstein and Volkow, 2002). The mesolimbic dopamine circuit, which includes the nucleus accumbens, amygdala, and hippocampus, has been traditionally associated with the acute reinforcing effects of a drug and with the memory and conditioned responses that have been linked to craving. It also is likely to be involved in the emotional and motivational changes seen in drug abusers during withdrawal. The mesocortical dopamine circuit, which includes the prefrontal cortex, orbitofrontal cortex, and anterior cingulate, is likely to be involved in the conscious experience of drug intoxication, drug incentive salience, drug expectation/craving, and compulsive drug administration. Note the circular nature of this interaction: the attribution of salience to a given stimulus, which is a function of the orbitofrontal cortex, depends on the relative value of a reinforcer compared to simultaneously available reinforcers, which requires knowledge of the strength of the stimulus as a reinforcer, a function of the hippocampus and amygdala. Consumption of the drug in turn will further activate cortical circuits (orbitofrontal cortex and anterior cingulate) in proportion to the dopamine stimulation by favoring the target response and decreasing nontarget-related background activity. The activation of these interacting circuits may be indispensable for maintaining the compulsive drug administration observed during bingeing and to the vicious circle of addiction. Modified from Goldstein and Volkow (2002), with permission.

(Fig. 43.10). The functional role of each component of the basal forebrain reward system is discussed in the following sections, and the relationship between drug reward and natural reward systems is explored. The actions of several groups of drugs with respect to this system, including indirect sympathomimetics (cocaine and amphetamine), opiates (heroin), nicotine, sedative hypnotics (alcohol, barbiturates, and benzodiazepines), and  $\Delta^9$ -tetrahydrocannabinol (THC) also will be explored.

### *The Positive Reinforcing Effects of Cocaine and Other Indirect Sympathomimetics Depend Critically on the Mesolimbic Dopamine System*

Amphetamine and cocaine are psychomotor stimulants that, in humans, have behavioral effects such as suppressing hunger and fatigue and inducing euphoria. In animals, these drugs increase locomotor activity, decrease food intake, stimulate operant behavior, enhance conditioned responding, and produce place

## Neurochemical Neurocircuits in Drug Reward

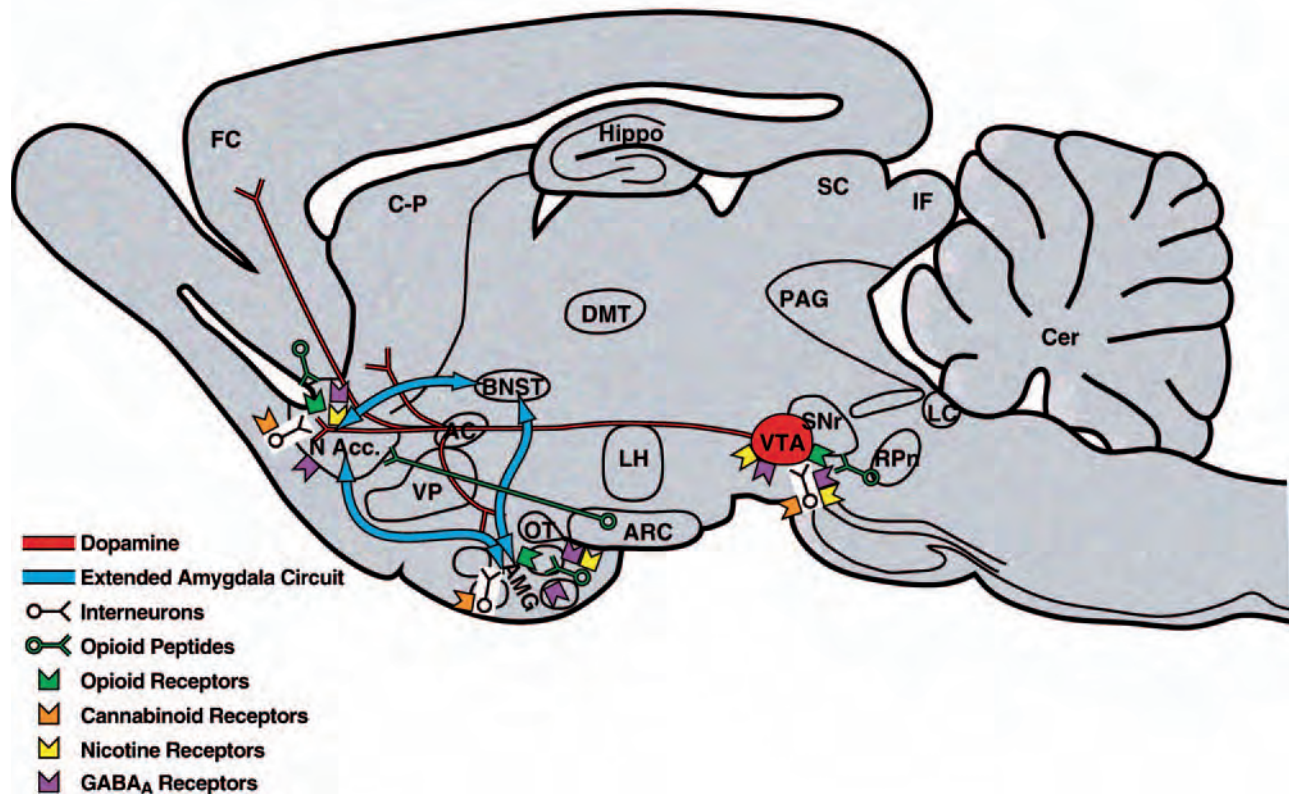

FIGURE 43.10 Sagittal section through a representative rodent brain illustrating the pathways and receptor systems implicated in the acute reinforcing actions of drugs of abuse. Cocaine and amphetamines activate the release of dopamine in the nucleus accumbens and amygdala via direct actions on dopamine terminals. Opioids activate opioid receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Opioids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens (but also are hypothesized to activate elements independent of the dopamine system). Alcohol activates  $\gamma$ -aminobutyric acid-A (GABA<sub>A</sub>) receptors in the ventral tegmental area, nucleus accumbens, and amygdala via either direct actions at the GABA<sub>A</sub> receptor or through indirect release of GABA. Alcohol is hypothesized to facilitate the release of opioid peptides in the ventral tegmental area, nucleus accumbens, and central nucleus of the amygdala. Alcohol facilitates the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens. Nicotine activates nicotinic acetylcholine receptors in the ventral tegmental area, nucleus accumbens, and amygdala, either directly or indirectly, via actions on interneurons. Nicotine also may activate opioid peptide release in the nucleus accumbens or amygdala independent of the dopamine system. Cannabinoids activate CB<sub>1</sub> receptors in the ventral tegmental area, nucleus accumbens, and amygdala via direct actions on interneurons. Cannabinoids facilitate the release of dopamine in the nucleus accumbens via an action either in the ventral tegmental area or the nucleus accumbens, but also are hypothesized to activate elements independent of the dopamine system. Endogenous cannabinoids may interact with postsynaptic elements in the nucleus accumbens involving dopamine and/or opioid peptide systems. The blue arrows represent the interactions within the extended amygdala system hypothesized to have a key role in psychostimulant reinforcement. AC, anterior commissure; AMG, amygdala; ARC, arcuate nucleus; BNST, bed nucleus of the stria terminalis; Cer, cerebellum; C-P, caudate-putamen; DMT, dorsomedial thalamus; FC, frontal cortex; Hippo, hippocampus; IF, inferior colliculus; LC, locus coeruleus; LH, lateral hypothalamus; N Acc., nucleus accumbens; OT, olfactory tract; PAG, periaqueductal gray; RPr, reticular pontine nucleus; SC, superior colliculus; SNr, substantia nigra pars reticulata; VP, ventral pallidum; VTA, ventral tegmental area. Taken with permission from Koob (2005).

preferences (Koob, 1992). Psychomotor stimulants also decrease thresholds for reinforcing brain stimulation and act as reinforcers for drug self-administration (Koob, 1992) (Fig. 43.10).

Psychomotor stimulants with a high potential for abuse have effects that lead to increases in the avail-

ability of monoamine neurotransmitters at synapses. By blocking reuptake or enhancing release, cocaine and amphetamine increase the synaptic availability of dopamine, norepinephrine, and serotonin. However, the acute reinforcing effects of these drugs depend critically on dopamine (Koob, 1992). Studies

of intravenous self-administration have provided the most direct evidence implicating dopamine, and more specifically the mesolimbic dopamine system, in the reinforcing actions of cocaine and amphetamines. Low doses of dopamine receptor antagonists injected either systemically or centrally into the nucleus accumbens, amygdala, or bed nucleus of the stria terminalis block cocaine and amphetamine self-administration in rats (Koob, 1992). A specific role for the mesolimbic dopamine system in the reinforcing properties of cocaine and amphetamine was deduced from the observation that neurotoxin-induced lesions of the terminal regions of the mesolimbic dopamine system in the nucleus accumbens produce a significant and long-lasting decrease in self-administration of cocaine and amphetamine over days (Koob, 1992). The neurotoxin 6-OHDA is an analog of dopamine that, when injected into the brain, is taken up by presynaptic dopamine nerve terminals, converted to reactive oxygen species, and destroys the terminals. 6-OHDA-induced lesions of the dopamine terminals in the nucleus accumbens even decrease the amount of work an animal will perform for cocaine without affecting many other reinforcers, such as food.

#### *Neural Substrates of Sensitization Involve Changes in the Mesolimbic Dopamine System*

Under certain circumstances, repeated administration of stimulants and opiates results in increasingly larger motor-activating effects, and these effects have been hypothesized to contribute to the development of the neuroadaptations associated with addiction, particularly those involving initial use and/or reinstatement of drug-taking following abstinence. This sensitization to the activating effects of stimulants involves activation of the mesolimbic dopamine system (Robinson and Berridge, 1993). Repeated microinjections of amphetamine into the somatodendritic region of the ventral tegmental dopamine cells, at doses that do not cause behavioral activation, are sufficient to sensitize the dopamine cells to later systemic injections of amphetamine. Thus, changes in the activity of these dopamine cells are sufficient to produce sensitization.

Multiple mechanisms for sensitization have been proposed, and a common theme is a time-dependent chain of adaptations that ultimately leads to long-lasting changes in the function of the mesolimbic dopamine system (Robinson and Berridge, 1993). For example, repeated administration of cocaine produces a decrease in the sensitivity of impulse-regulating somatodendritic dopamine  $D_2$  receptors on dopamine neurons (termed *autoreceptors* because the neuron is itself responding to the transmitter it releases). Because

these autoreceptors normally exert an inhibitory influence on the activity of dopaminergic neurons, this change in sensitivity could translate into enhanced dopamine availability with subsequent injections of cocaine (Robinson and Berridge, 1993). However, the decrease in  $D_2$  receptor sensitivity lasts only four to eight days, and behavioral sensitization can last for weeks; thus, other mechanisms also must be involved. *N*-methyl-D-aspartate (NMDA) glutamate receptor antagonists selectively block the development of sensitization to psychomotor stimulants, suggesting a role for brain glutamate systems and specific glutamate receptors in sensitization (Koob and Le Moal, 2001).

The hypothalamic–pituitary–adrenal stress axis also may play an important role in sensitization. Stressors can cause sensitization to stimulant drugs, and both the stress axis and the extrahypothalamic corticotropin-releasing factor (CRF) system appear to be important in stress-induced sensitization. Sensitization may be hypothesized to play a key role in initial sensitivity to drugs and contribute to the high incentive salience attributed to drugs during the course of addiction.

#### *Neurobiological Substrates for the Acute Reinforcing Effects of Opiates Involve Opioid Peptide Systems*

Much like psychostimulants, opiate drugs such as heroin are readily self-administered intravenously by animals, and with limited access opiates do not produce dependence (Schuster and Thompson, 1969). Advances in opiate pharmacology, such as identification of high specific binding for opiates in the brain and discovery of endogenous opioid peptides, provided insight into the brain systems responsible for the reinforcing effects of these drugs (Koob, 1992) (Box 43.4; Figs. 43.7, 43.10). Both systemic administration and central administration of competitive opiate antagonists into the nucleus accumbens and ventral tegmental area decrease intravenous opiate self-administration. The reinforcing actions of heroin and morphine appear to be mediated largely by the  $\mu$  opioid receptor subtype.  $\mu$  receptor antagonists produce dose-dependent decreases in heroin reinforcement, and  $\mu$  receptor knockout mice show loss of morphine-induced reward and loss of morphine-induced analgesia. Intracerebral opioid receptor antagonists block heroin self-administration in nondependent rats when these drugs are injected into the ventral tegmental area or the region of the nucleus accumbens. Microinjections of opioids into the ventral tegmental area also lower thresholds for ICSS and produce robust place preferences, and these effects appear to be dependent on mesolimbic dopamine function (Di Chiara and North, 1992). Rats will self-administer opioid peptides in the region of the ventral

## BOX 43.4

## OPIATE RECEPTORS

In 1978, Professors Solomon H. Snyder, John Hughes, and Hans W. Kosterlitz were awarded the Lasker award for their combined discovery of opiate receptors in the brain and for the even more amazing discovery of the existence of endogenous ligands for opiate receptors. The endogenous brain compounds were peptides, called enkephalins and endorphins, which shared all the physiologic properties of opiates. These observations opened a rich field of inquiry into the mechanism of action of opiate

drugs, and these findings began a new outlook on neuropeptide neurotransmitters, an area of intense research. First, many new neuropeptides have been discovered with brain receptors potentially amenable to nonpeptidergic agonists and antagonists. Second, because neuropeptides are contained within neurons that also utilize more conventional amino acid or amine transmitters, the possibility of multiple mediators for any specific synapse had to be considered.

tegmental area and nucleus accumbens. However, heroin self-administration is not blocked by dopamine receptor antagonists administered at doses that block cocaine self-administration nor by large neurotoxin-induced lesions of the mesolimbic dopamine system. These results demonstrate that neural elements in the regions of the ventral tegmental area and nucleus accumbens are responsible for the reinforcing properties of opiates, suggesting both dopamine-dependent and dopamine-independent opiate actions (Di Chiara and North, 1992; Koob, 1992).

#### *Nicotine Activates Mesolimbic Dopamine*

Nicotine has anti-fatigue, stimulant-like, and anti-anxiety effects and appears to improve cognitive performance in animals and humans. It has direct reinforcing actions, as measured by intravenous self-administration in animals and humans. Nicotine is a direct agonist at nicotinic acetylcholine receptors and appears to activate nicotinic acetylcholine receptors in the mesolimbic dopamine system both at the level of the ventral tegmental area and nucleus accumbens (Figs. 43.7, 43.10). Knockout of the  $\beta 2$  nicotinic acetylcholine receptor subunit blocks nicotine self-administration (Picciotto *et al.*, 1998). Blockade of dopaminergic systems with antagonists or lesions to the mesolimbic dopamine system can block nicotine self-administration, suggesting a key role for dopamine in the acute reinforcing actions of nicotine.

#### *Alcohol Has Multiple Neurochemical Substrates within Brain Reinforcement Systems*

Alcohol (i.e., ethanol), barbiturates, and benzodiazepines all have measurable sedative-hypnotic actions, including euphoria, disinhibition, anxiety reduction, sedation, and hypnosis. All of these drugs also have anxiolytic (or antianxiety) effects, reflected

in conflict situations as a reduction of behavior suppressed by punishment. The neurobiological basis of the anxiolytic properties of these sedative-hypnotic drugs has provided clues to their reinforcing properties and their abuse potential. For example, GABAergic receptor antagonists reverse many of the behavioral effects of alcohol, an observation that has led to the hypothesis that GABA has a role in its intoxicating effects. Further support for a role of brain GABA in alcohol reinforcement is the observation that potent antagonists of GABA receptor function decrease alcohol reinforcement, and one particularly affected brain site is the central nucleus of the amygdala. Activation of opioid peptide systems has been implicated in alcohol reinforcement by numerous reports that the opiate antagonists naloxone and naltrexone reduce alcohol self-administration in several animal models (Tabakoff and Hoffman, 1992). The brain site most sensitive to opioid receptor antagonists also is the central nucleus of the amygdala (Koob and Le Moal, 2001) (see Figs. 43.7, 43.10).

Dopamine receptor antagonists also reduce lever pressing for alcohol in nondeprived rats (Koob, 1992), and extracellular dopamine levels increase in nondependent rats orally self-administering low doses of alcohol (Koob and Le Moal, 2001). However, virtually complete destruction of dopamine terminals in the nucleus accumbens by 6-OHDA failed to alter voluntary responding for alcohol. Combined with the pharmacologic data discussed earlier, these results suggest that although mesolimbic dopamine transmission may be associated with important aspects of alcohol reinforcement, it is not critical for the reinforcing properties of alcohol (Koob and Le Moal, 2001). Alcohol in a physiologic dose range may antagonize the actions of glutamate (Tabakoff and Hoffman, 1992). Also, increases and decreases in synaptic availability of

serotonin (e.g., via blockade of serotonin reuptake or via administration of selective serotonin receptor antagonists) reduce the voluntary intake of alcohol. Thus, multiple neurotransmitters combine to orchestrate the reward profile of this drug (Engel et al., 1987).

#### *$\Delta^9$ -Tetrahydrocannabinol Has Effects Similar to Other Drugs of Abuse*

THC shares effects in animal models of drug reinforcement similar to those of other drugs of abuse. Upon acute administration, THC decreases ICSS reward thresholds and produces a place preference in rats. It maintains self-administration behavior in squirrel monkeys, and a synthetic THC analog is self-administered intravenously in mice. THC binds to the cannabinoid CB<sub>1</sub> receptor that is distributed widely throughout the brain, particularly in the striatum, and is thought to mediate some of the actions of the endogenous endocannabinoids. THC self-administration is blocked by both CB<sub>1</sub> and opioid receptor antagonists (Justinova et al., 2004, 2005) (Figs. 43.7, 43.10).

#### **Neurobiological Substrates for the Withdrawal/Negative Affect State of Drug Dependence**

Substance dependence is defined as compulsive, uncontrollable drug use (see above); however, the etiology of that compulsive use is controversial. One position is that the positive reinforcing effects of a drug are critical for addiction. Partially as a result of this concept, another position—substance dependence as the alleviation of withdrawal symptoms—fell out of favor as an explanation for compulsive drug use. However, although simple positive reinforcement clearly is necessary for the development of drug use, it falls short in explaining the development of compulsive use. For example, tolerance or apparent tolerance develops to drug reward during chronic use, with positive reinforcement either being absent or subsumed by negative reinforcement. Indeed, this issue raises the question of what factors distinguish drug *use* from *abuse* and *dependence* or addiction. Sensitization theory addresses this issue by invoking a shift to a state of *incentive salience*, defined as a hypersensitive neural state that produces the experience of craving. It has been hypothesized that this state of incentive salience is produced by drug-induced sensitization of the mesolimbic dopamine system (Robinson and Berridge, 1993). According to this model, the pathologically strong craving or yearning encountered during protracted abstinence would be due in large part to an overactive mesolimbic dopamine system (see earlier). Yet other theorists have invoked compensatory changes in the reward system.

#### *Negative Affect Is a Common Result of Withdrawal from Chronic Administration of Drugs of Abuse*

Withdrawal signs associated with cessation of chronic drug administration usually are characterized by responses that are opposite to the initial effects of the drug. Thus, all drugs of abuse produce rewarding effects and a withdrawal syndrome associated with subjective symptoms of dysphoria, negative affect, and anxiety (Koob and Le Moal, 2001). However, the overt symptoms of the withdrawal experience can vary depending on the nature of the effects of the drug itself. For example, whereas few physical signs of withdrawal usually are observed during cocaine withdrawal in humans, cessation of cocaine use often is characterized by severe depressive symptoms combined with irritability, anxiety, and anhedonia lasting several hours to several days (i.e., the “crash”) and may be a motivating factor in the maintenance of the cocaine dependence cycle (Koob and Le Moal, 2001). However, in the case of opiate withdrawal, subjective symptoms such as dysphoria, anxiety, craving for drugs, and malaise are accompanied by both physical symptoms of extreme discomfort, including pupillary dilation, hot and cold flashes, goose bumps, and a flu-like state. In the case of alcohol withdrawal, humans show tremor and increases in heartbeat rate, blood pressure, and body temperature, as well as subjective signs, including dysphoria, anxiety, insomnia, and malaise. Withdrawal from nicotine is characterized by anxiety, negative affect, fatigue, irritability, sleep disturbances, and an intense craving for cigarettes. Withdrawal from THC resembles a combination of sedative-hypnotic or opiate withdrawal with irritability, restlessness, hot flashes, sweating, disturbances in appetite and sleep, and low-level dysphoria. Withdrawal from benzodiazepines resembles that of alcohol withdrawal but generally is more prolonged in onset and less intense.

#### *Chronic Drug Administration Compromises the Brain Reward Systems*

In animal studies, withdrawal from chronic administration of stimulants has been studied using ICSS after repeated administration of cocaine or amphetamine over several weeks or 12–48h of cocaine self-administration. Withdrawal from prolonged self-administration of cocaine in rats increases ICSS reward thresholds. The increase in threshold dose is time-dependent and is an effect opposite to that of acute cocaine (Koob and Le Moal, 2001). Similar effects have been observed during withdrawal from chronic amphetamine administration. Opiate withdrawal induced by the administration of low doses of the

opiate receptor antagonist naloxone also elevates ICSS reward thresholds, as does spontaneous withdrawal from alcohol (Koob and Le Moal, 2001). Withdrawal from chronic nicotine and THC also produces profound increases in ICSS reward thresholds, suggesting that brain reward dysregulation is a common element of acute withdrawal from drugs of abuse (Table 43.2).

### Withdrawal/Negative Reinforcement Brain Substrate

A brain system that mediates aversion was identified early on by a combination of anatomical and behavioral experiments. For example, mapping studies identified sites eliciting escape from brain stimulation, sites at which electrical brain stimulation elicits defensive responses, and sites at which fear or pain naturally evokes aggressive responses. Many of these pathways

appear to be central reflex pathways, with both ascending and descending components modulated by influences from the central nucleus of the amygdala.

Some electrical brain stimulation sites (e.g., ventral medial hypothalamus) produced markedly ambivalent reinforcing effects, which were interpreted as an interaction between positive reinforcement and aversion systems. Electrical brain stimulation itself has been suggested to have both appetitive and aversive properties, as have drugs of abuse and, in some situations, electric shock. In fact, animal learning theory has led to the concept of opponent motivational processes (one appetitive, one aversive).

### Aversion May Be Mediated by Opponent Motivational Processes

It has been suggested that many reinforcers produce affective and hedonic effects (*a-processes*) that are opposed by *b-processes* of opposite affective sign in a simple, dynamic control system for affect (Fig. 43.11) (Solomon and Corbit, 1974). The *a-process* follows the reinforcing event with short latency and then decays. Its size decreases with repeated presentation of the reinforcer. The *b-process* has a longer latency of onset, reaches its maximum only after repeated trials, and decays very slowly. These components of emotional responses are exhibited in response to many reinforcers, including not only drugs such as heroin, but also natural rewards that also may lead to different forms

TABLE 43.2 Drug Effects on Thresholds of Rewarding Brain Stimulation

Drug class	Acute administration	Withdrawal from chronic treatment
Psychostimulants (cocaine, amphetamines)	↓	↑
Opiates (morphine, heroin)	↓	↑
Nicotine	↓	↑
Sedative-hypnotics (ethanol)	↓	↑

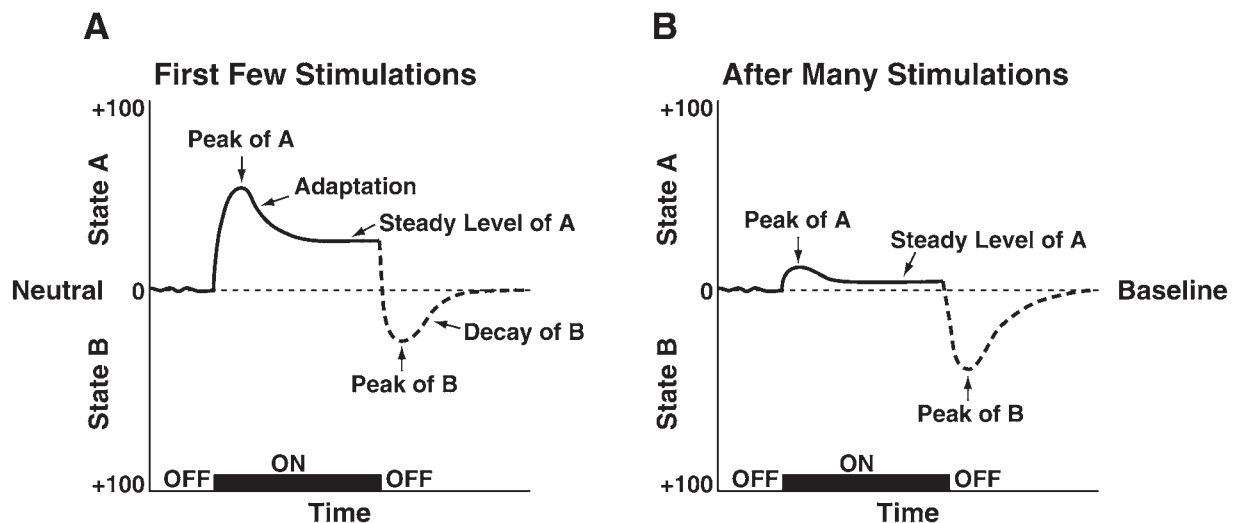

FIGURE 43.11 (A) The standard pattern of affective dynamics produced by a relatively novel unconditioned stimulus (nondependent drug intake). (B) The standard pattern of affective dynamics produced by a familiar, frequently repeated unconditioned stimulus (dependent drug intake). First, an unconditional arousing stimulus triggers a primary affective process, termed the *a-process*. An unconditional reaction that translates the intensity, quality, and duration of the stimulus (for example, the first injection of a drug). Second, as a consequence of the *a-process*, the *b-process* is evoked after a short delay, an opponent process. The two responses are consequently and temporarily linked (*a* triggers *b*) but are hypothesized to depend on different neurobiological mechanisms. The *b-process* has a longer latency, but has more inertia, a slower recruitment, and a more sluggish decay. At a given moment, the pattern of affect will be the algebraic sum of these opposite influences and the dynamics reveal, with the passage of time, the net product of the opponent process. Taken with permission from Solomon (1980).

of “dependence,” such as attachment of offspring to a mother. So, for example, either heroin or the mother elicits a hedonic *a-process*, which is followed by a rebound negative or aversive *b-process* when the heroin wears off (or the mother leaves). These effects may get stronger with repeated experiences of heroin (or the mother at a critical period of development), leading to a form of dependence in each case. The opponent process also can work in reverse. For example, if tolerance develops for an initially aversive experience, a rebound hedonic response can occur when this experience stops. Indeed, this has been suggested partly to explain the “pleasure” of jogging.

How might these opponent processes be represented in the brain? The neurobiological basis for neuroadaptive mechanisms that reflect changes in reward function have been hypothesized to be alterations of the same neurotransmitters implicated in the acute reinforcing effects of drugs (Koob and Bloom, 1988). Examples of such homeostatic, “within-system” adaptive neurobiological changes include decreases in dopaminergic and serotonergic transmission in the nucleus accumbens during drug withdrawal as measured by *in vivo* microdialysis (Weiss *et al.*, 1992; Parsons *et al.*, 1995), increased sensitivity of opioid receptor transduction mechanisms in the nucleus accumbens during opiate withdrawal (Shaw-Lutchman *et al.*, 2002), decreased GABAergic and increased NMDA glutamatergic transmission during ethanol withdrawal (Roberts *et al.*, 1996; Weiss *et al.*, 1996; Fitzgerald and Nestler, 1995). However, recruitment of other neurotransmitter systems in the adaptive responses to drugs of abuse may involve neurotransmitter systems not linked to the acute reinforcing effects of the drug, or a “between-system” neuroadaptation (Koob and Bloom, 1988). An example of a between-system neuroadaptation is the activation of brain stress systems such as CRF and dysregulation of other stress-mediating neurotransmitter systems during withdrawal (Koob and Le Moal, 2005) (see below).

## Neurochemical Adaptation in Reward Neurotransmitters

### *Dopamine and Serotonin Systems Show Neuroadaptive Changes with Substance Dependence*

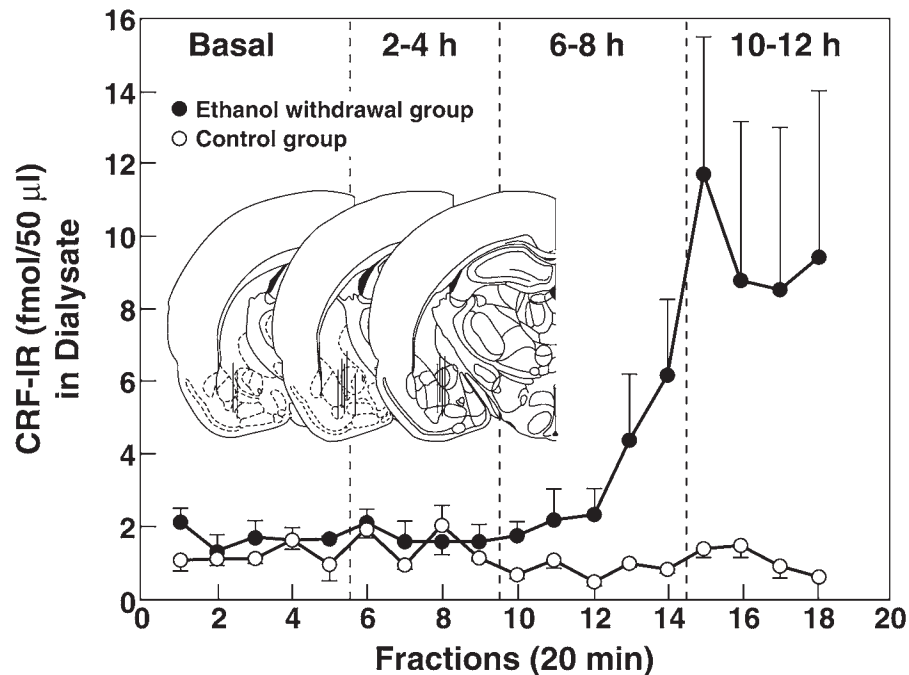

Monoamines, including the dopamine and serotonin systems, have been implicated in the reinforcing actions of each of the drugs discussed: psychostimulants, opiates, nicotine, alcohol, and THC. One way of assessing the prolonged effects of drug self-administration is to measure extracellular levels of a neurotransmitter during ongoing behaviors, such as intravenous self-administration of a drug or withdrawal from the drug

after a period of chronic self-administration. Such measurements can be made by using the technique of *in vivo* microdialysis, which involves implanting into a specific site in the brain a guide cannula through which a probe with a semipermeable membrane at the tip perfuses and collects the neurotransmitter in extracellular fluid. Several studies using this technique have shown that extracellular dopamine and serotonin levels in the nucleus accumbens decrease during acute withdrawal from cocaine, opiates, and alcohol, an effect opposite to that of acute drug administration.

### *Brain Corticotropin-Releasing Factor and Noradrenergic Systems Show Neuroadaptive Changes with Substance Dependence*

Anxiety and stress are common elements of substance dependence and acute withdrawal from drugs of abuse in humans and produce stress-like behavior in animals (Sarnyai *et al.*, 2001). Stress can be defined simply as *any challenge to or alteration in psychological homeostatic processes*. Animal studies exploring the role of CRF in the actions of alcohol, opiates, nicotine, THC, and cocaine have provided evidence of a neurochemical basis for the stress associated with abstinence following chronic drug administration. Not only is CRF a major hypothalamic releasing factor controlling the classic stress response, but it also appears to have a neurotropic role in the central nervous system, modulating behavioral responses to stress. CRF itself produces stress-related behaviors, and CRF antagonists reverse a number of behavioral responses to stress. Rats treated repeatedly with drugs such as alcohol, opiates, and cocaine show significant stress-like responses in behavioral tests that follow cessation of drug administration, and these responses are reversed by administration of a CRF antagonist directly into the brain. For example, injection of a CRF antagonist into the central nucleus of the amygdala reverses the stress-like effects of withdrawal from alcohol, cocaine, nicotine, opioid, and THC in rats. Withdrawal from alcohol, cocaine, nicotine, opioids, and THC is associated with an increase in the release of CRF into the amygdala, suggesting that alcohol withdrawal can activate CRF systems previously implicated in behavioral responses to stress (Fig. 43.12). Also, stress-induced reinstatement of drug self-administration following extinction can be reversed by CRF antagonists (Sarnyai *et al.*, 2001).

Norepinephrine in the limbic forebrain also has been associated with the physical and motivational signs of opiate withdrawal. More recent evidence suggests that projections to the bed nucleus of the stria terminalis—a critical part of the extended amygdala—may have a role in the motivational effects of opiate withdrawal (Delfs *et al.*, 2000). In addition, the

**FIGURE 43.12** Extracellular levels of corticotropin-releasing factor immunoreactivity (CRF-IR) in the central nucleus of the amygdala during withdrawal from chronic alcohol administration. Dialysate was collected over four 2-h periods, which alternated with nonsampling 2-h periods. The four sampling periods correspond to the basal collection (before removal of alcohol) and 1–4 h, 6–8 h, and 10–12 h after withdrawal of alcohol. Fractions were collected every 20 min. Data are represented as means  $\pm$  SEM ( $n = 5$  per group). ANOVA confirmed significant differences between the two groups over time ( $p < 0.05$ ). (Inset) An anatomical analysis identifying these locations (vertical lines in inset) as sites where changes in CRF concentration were detected in the alcohol experiment ( $n = 10$ ) and as being within the amygdaloid complex. Reprinted with permission from Merlo Pich *et al.* (1995).

bed nucleus of the stria terminalis is rich in CRF neurons and has been implicated in a feed-forward norepinephrine-CRF-norepinephrine system that may be involved in stress and drug dependence. In this hypothesized feed-forward system, CRF activates brain stem noradrenergic activity, which in turn activates forebrain CRF activity, effectively closing the loop. This mechanism could explain the potentiation of stress responses with repeated exposure that could lead to psychopathology. However, note that behavioral and autonomic responses may be activated in both the brain stem and the forebrain as partial exits from the loop (Koob, 1999).

In contrast to the sensitization theory, neuroadaptation theories such as the opponent process theory postulate that the processes of tolerance to the positive emotional state (hedonic tolerance) and subsequent development of a negative emotional state play important roles in the transition from drug use to drug dependence (Solomon, 1977). Whereas initial drug use may be motivated by the positive emotional state produced by a drug and potentiated by sensitization, continued drug use leads to neuroadaptation to the presence of the drug, to development of a negative emotional state, and ultimately to self-medication of

that negative emotional state. Some theorists have gone so far as to argue that the presence of a negative emotional state is the defining feature of addiction and that dysregulation of the residual reward system represents a state of allostasis, the process of obtaining stability through change (Box 43.5). The *allostasis* hypothesis suggests that *both* sensitization and opponent process mechanisms may contribute to changes in incentive motivation (or incentive salience) that convey the vulnerability to relapse for drug addiction.

### Neuroadaptation, Prolonged Abstinence, and Relapse

An explanation for the chronic relapsing nature of drug addiction is that reinforcement can be derived from secondary sources that motivate continued drug use. Both positive and negative emotional states can become associated with stimuli in the drug-taking environment through classical conditioning processes. When the drug taker is reexposed to these conditioned stimuli, compulsive drug use is reestablished (Box 43.6).

Conditioning to the positive emotional states induced by drugs has been demonstrated in animals.

## BOX 43.5

## ALLOSTASIS

Counteradaptive processes, such as opponent process, that are part of normal homeostatic limitations of reward function can fail to return within the normal range and are hypothesized to contribute to the allostatic state of addiction. Allostasis from the addiction perspective is defined as the process of maintaining apparent reward function stability by changes in brain reward mechanisms. The allostatic state is fueled not only by dysregulation of reward circuits *per se*, but also by the activation of

brain and hormonal stress systems (Koob and Le Moal, 2001). The following definitions apply: (1) *allostasis*, the process of achieving stability through change; (2) *allostatic state*, a state of chronic deviation of the regulatory system from its normal, or homeostatic, operating level; and (3) *allostatic load*, the cost to the brain and body of the deviation, accumulating over time, and reflecting in many cases pathological states and accumulation of damage.

## BOX 43.6

## CRAVING

Craving is a hypothetical construct that can be defined as the memory of the rewarding effects of a drug, superimposed upon a negative motivational state (Markou *et al.*, 1998). Human studies of craving have been fraught with difficulty in linking it to relapse *per se* in humans with drug addiction, but it is a ubiquitous construct that pervades the fabric of the clinical setting (Tiffany *et al.*, 2000). Two types of craving can be conceptualized and linked to animal models.

*Craving Type 1*: Craving is induced by stimuli that have been paired with drug self-administration such as environmental cues. Termed conditioned positive reinforcement in experimental psychology, an animal model of Craving Type 1 is cue-induced reinstatement where a cue previously paired with access to drug reinstates

responding for a lever that has been extinguished. Another example is drug-induced reinstatement where a small dose of the drug elicits responding for a lever that has been extinguished.

*Craving Type-2*: Craving is conceptualized as a state change characterized by anxiety and dysphoria or a residual negative emotional state that combines with Craving Type 1 situations to produce relapse to drug seeking. Animal models of Craving Type 2 include stress-induced reinstatement of drug seeking after extinction, or increased drug taking in animals during or after a prolonged deprivation. Craving Type 2 can be conceptualized as a residual negative emotional state or an acute stress-like state, both of which can elicit drug-seeking behavior.

Stimuli associated with drugs of abuse can maintain responding in rats and monkeys when presented without the drug. It is also possible to demonstrate conditioned withdrawal. For example, when previously neutral stimuli are paired with naloxone-induced withdrawal, the neutral stimuli themselves elicit signs of opiate withdrawal. Conditioned withdrawal has been observed in opiate-dependent animals and humans.

Neurobiological substrates for conditioned drug effects have been investigated in some detail (Everitt *et al.*, 2000; Cardinal *et al.*, 2002). The enhancement of conditioned reinforcement produced by psychomotor stimulants appears to involve the basolateral amygdala and its glutamatergic projection to the nucleus accumbens with dopaminergic modulation. The neu-

robiological substrates for conditioned withdrawal also may depend on the basolateral amygdala. In contrast, drug-induced reinstatement of drug-seeking appears to be mediated via a prefrontal cortex glutamatergic projection to the nucleus accumbens with dopaminergic modulation (Kalivas and McFarland, 2003). Another powerful source of relapse in human subjects is exposure to a stressor or the state of stress. Both of these constructs involve activation of the brain CRF systems in the basal forebrain structures that include the central nucleus of the amygdala and the bed nucleus of the stria terminalis.

Neuroanatomic and functional data have provided the basis for the hypothesis that the central nucleus of the amygdala and the bed nucleus of the stria termi-

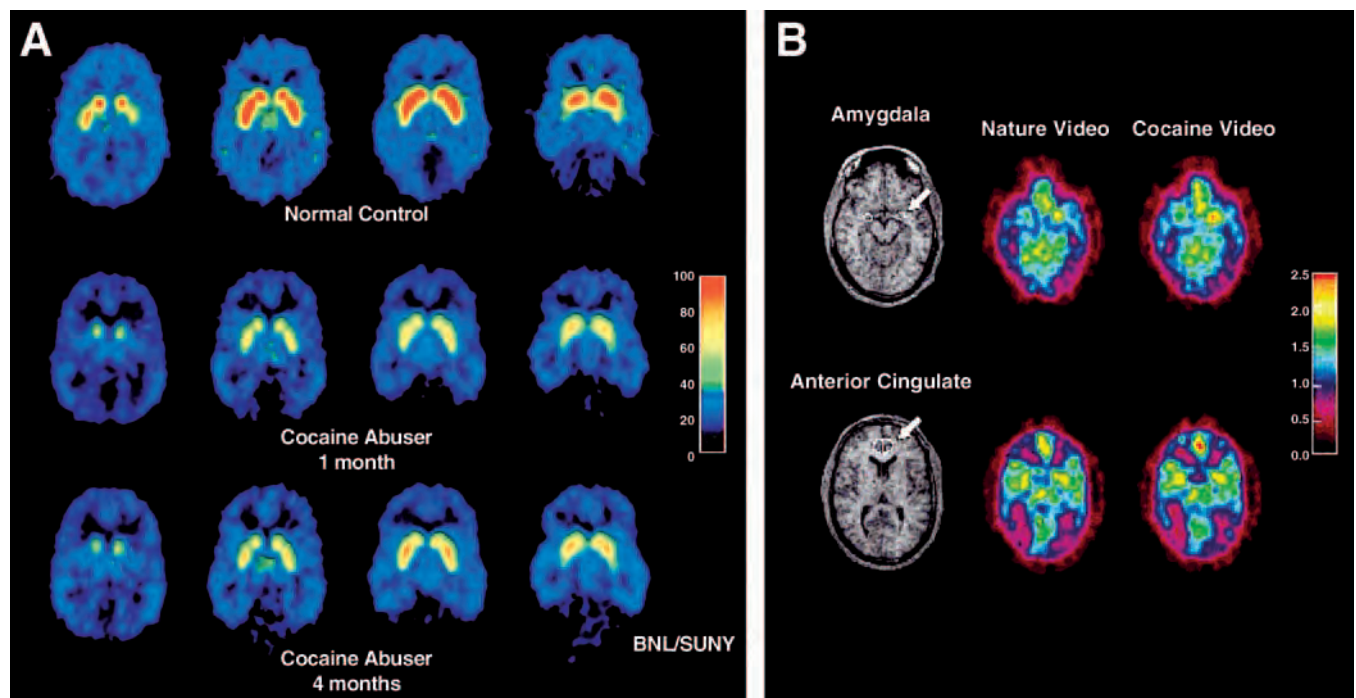

nalis form a separate entity within the basal forebrain termed the *extended amygdala* (Heimer and Alheid, 1991) that may mediate some of the emotional dysregulation associated with the stress component of addiction (Fig. 43.7). CRF and norepinephrine systems within the extended amygdala appear to be a critical substrate for not only stress-induced reinstatement (Shaham *et al.*, 2003) but also for the dysregulated hypersensitivity to stress observed in protracted abstinence (Valdez *et al.*, 2004) (see above).

### Brain Imaging Circuits Involved in Addiction

Brain imaging studies using positron emission tomography with ligands for measuring oxygen utilization or glucose metabolism or using functional magnetic resonance imaging techniques have provided important insights into the neurocircuitry changes in the human brain associated with the development, maintenance, and even vulnerability to addiction.

These imaging results, overall, have a striking resemblance to the neurocircuitry identified by animal studies. During acute intoxication with drugs such as cocaine, methamphetamine, nicotine, alcohol, and THC there are changes in the orbitofrontal cortex, prefrontal cortex, anterior cingulate cortex, amygdala, and ventral striatum. These changes are reflected in activation as measured by functional magnetic resonance imaging, and changes in oxygen utilization as measured by positron emission tomography. The changes during acute intoxication often are accompanied by an increase in the availability of dopamine, particularly in striatal regions.

In contrast, during acute and chronic withdrawal there is a reversal of these changes, with decreases in metabolic activity in the orbitofrontal cortex, prefrontal cortex, and anterior cingulate cortex, and decreases in basal dopamine activity in the striatum and prefrontal cortex as reflected in decreases in D<sub>2</sub> receptor binding (Fig. 43.13). Cue-induced reinstatement for

**FIGURE 43.13** (A) [<sup>18</sup>F]N-methylspiroperidol images in a normal control and in a cocaine abuser tested 1 month and 4 months after the last cocaine use. The images correspond to the four sequential planes where the basal ganglia are located. The color scale has been normalized to the injected dose. Notice the lower uptake of the tracer in the cocaine abuser compared to the normal control. Notice also the persistence of the decreased uptake even after 4 months of cocaine discontinuation. BNL, Brookhaven National Laboratory; SUNY, State University of New York. Taken with permission from Volkow *et al.* (1993b). (B) Transaxial images illustrating the differential increase in relative regional cerebral blood flow (CBF) in the amygdala and anterior cingulate of a detoxified cocaine patient during a nondrug-related (nature) video and a cocaine-related video. Anatomical regions of interest first were localized on the patient's magnetic resonance image (the first image in each row). Region templates subsequently were superimposed on [<sup>15</sup>O] positron emission tomography (PET) images, yielding radioactive count files for conversion to normalized (relative) regional CBF. The middle and final images in each row show relative regional CBF as measured by PET. The range on the arbitrary color scale is from 0.0 to 2.5 times background activity. Whole brain average regional CBF is 1.0 on the scale. Areas with greatest relative regional CBF are shown in red. Activity in the amygdala and in the anterior cingulate differentially increased during the cocaine video. Taken with permission from Childress *et al.* (1999).

cocaine, alcohol, nicotine, and THC appears to involve a reactivation of these same circuits, much like acute intoxication, but with the reactivation of the prefrontal cortex, orbitofrontal cortex, and anterior cingulate cortex and the additional recruitment of activation in the amygdala (Childress *et al.*, 1999) (Fig. 43.13).

### Signal Transduction Mechanisms Show Neuroadaptive Changes with Substance Dependence

Not only can the functional activity of neurotransmitters change due to the increased presynaptic activity of chronic drug use, but these changes also can be translated to postsynaptic signal transduction, where changes can be long-lasting and may result in long-term adaptations in receptor function. These changes

take place at the level of receptor binding or in the impact that the association of a drug with its receptor has on a postsynaptic cell. For example, whereas chronic opiate use has minimal effects on the binding of opiate receptors by opioid peptides, it dramatically changes signal transduction in the terminal regions of the mesolimbic dopamine system, such as the nucleus accumbens (Nestler, 2001). This occurs at least in part by increasing adenylate cyclase activity and immediate-early gene expression. Many of these effects presumably occur postsynaptic to dopamine release, but some of the same effects may be observed on dopamine neurons themselves. These changes can result in the expression of novel proteins and, consequently, changes in neuronal function (see above) that could explain clinical phenomena, such as protracted absti-

**FIGURE 43.14** Molecular mechanisms of neuroadaptation. *Cocaine and amphetamines*, as indirect sympathomimetics, stimulate the release of dopamine, which acts at G protein-coupled receptors, specifically D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub>, and D<sub>5</sub>. These receptors modulate the levels of second-messengers like cyclic adenosine monophosphate (cAMP) and Ca<sup>2+</sup>, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and voltage-gated Ca<sup>2+</sup> channels (VGCC). G<sub>i</sub> and G<sub>o</sub> proteins also can regulate K<sup>+</sup> and Ca<sup>2+</sup> channels directly through their  $\beta\gamma$  subunits. Protein kinase transduction pathways also affect the activities of transcription factors. Some of these factors, like cAMP element binding protein (CREB), are regulated posttranslationally by phosphorylation; others, like Fos, are regulated transcriptionally; still others, like Jun, are regulated both posttranslationally and/or transcriptionally. Whereas membrane and cytoplasmic changes may be only local (e.g., dendritic domains or synaptic boutons), changes in the activity of transcription factors may result in long-term functional changes. These may include changes in gene expression of proteins involved in signal transduction and/or neurotransmission, resulting in altered neuronal responses. For example, chronic exposure to psychostimulants has been reported to increase levels of protein kinase A (PKA) and adenylate cyclase in the nucleus accumbens and to decrease levels of G<sub>iw</sub>. Chronic exposure to psychostimulants also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens by chronic cocaine treatment. Chronic cocaine induces a transition from Fos induction to the induction of the much longer-lasting Fos-related antigens such as  $\Delta$ FosB. *Opioids*, by acting on neurotransmitter systems, affect the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Shown are examples of ligand-gated ion channels such as the  $\gamma$ -aminobutyric acid-A (GABA<sub>A</sub>) and glutamate N-methyl-D-aspartate (NMDA) receptor (NMR) and G protein-coupled receptors such as opioid, dopamine (DA), or cannabinoid CB<sub>1</sub> receptors, among others. These receptors modulate the levels of second messengers like cAMP and Ca<sup>2+</sup>, which in turn regulate the activity of protein kinase transducers. Chronic exposure to opioids has been reported to increase levels of PKA and adenylate cyclase in the nucleus accumbens and to decrease levels of G<sub>iw</sub>. Chronic exposure to opioids also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the nucleus accumbens and increased in the locus coeruleus by chronic morphine treatment, whereas chronic opioid exposure activates Fos-related antigens such as  $\Delta$ FosB. *Alcohol*, by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Shown are examples of ligand-gated ion channels such as the GABA<sub>A</sub> and the NMDA receptor and G protein-coupled receptors such as opioid, dopamine, or cannabinoid CB<sub>1</sub> receptors, among others. The latter also are activated by endogenous cannabinoids such as anandamide. These receptors modulate the levels of second messengers such as cAMP and Ca<sup>2+</sup>, which in turn regulate the activity of protein kinase transducers. Such protein kinases affect the functions of proteins located in the cytoplasm, plasma membrane, and nucleus. Among membrane proteins affected are ligand-gated and VGCCs. Alcohol, for instance, has been proposed to affect the GABA<sub>A</sub> response via protein kinase C (PKC) phosphorylation. G<sub>i</sub> and G<sub>o</sub> proteins also can regulate K<sup>+</sup> and Ca<sup>2+</sup> channels directly through their  $\beta\gamma$  subunits. Chronic exposure to alcohol has been reported to increase levels of PKA and adenylate cyclase in the nucleus accumbens and to decrease levels of G<sub>iw</sub>. Moreover, chronic ethanol induces differential changes in subunit composition in the GABA<sub>A</sub> and glutamate ionotropic receptors and increases expression of VGCCs. Chronic exposure to alcohol also alters the expression of transcription factors themselves. CREB expression, for instance, is increased in the nucleus accumbens and decreased in the amygdala by chronic alcohol treatment. Chronic alcohol induces a transition from Fos induction to the induction of the longer-lasting Fos-related antigens. *Nicotine* acts directly on ligand-gated ion channels. These receptors modulate the levels of Ca<sup>2+</sup>, which in turn regulate the activity of protein kinase transducers. Chronic exposure to nicotine has been reported to increase levels of PKA in the nucleus accumbens. Chronic exposure to nicotine also alters the expression of transcription factors themselves. CREB expression, for instance, is depressed in the amygdala and prefrontal cortex and increased in the nucleus accumbens and ventral tegmental area.  $\Delta^9$ -Tetrahydrocannabinol (THC), by acting on neurotransmitter systems, affects the phenotypic and functional properties of neurons through the general mechanisms outlined in the diagram. Cannabinoids act on the cannabinoid CB<sub>1</sub> G protein-coupled receptor. The CB<sub>1</sub> receptor also is activated by endogenous cannabinoids such as anandamide. This receptor modulates (inhibits) the levels of second messengers like cAMP and Ca<sup>2+</sup>, which in turn regulate the activity of protein kinase transducers. Chronic exposure to THC also alters the expression of transcription factors themselves. CaMK, Ca<sup>2+</sup>/calmodulin-dependent protein kinase; ELK-1, E-26-like protein 1; PLC $\beta$ , phospholipase C  $\beta$ ; IP3, inositol triphosphate; MAPK, mitogen-activated protein kinase; PI3K, phosphoinositide 3-kinase; R, receptor; Modified with permission from Koob *et al.* (1998).

nence and vulnerability to relapse, in people formerly addicted to drugs (Fig. 43.14).

The persistence of changes in drug reinforcement mechanisms that characterize drug addiction suggests that the underlying molecular mechanisms are long-lasting, and considerable attention has been given to the drug regulation of gene expression. Current research focuses on several types of transcription factors, including cyclic adenosine monophosphate response element binding protein and novel Fos-like proteins termed chronic Fos-related antigens. More recently, FosB, a member of the Fos family of transcription factors that dimerizes with a member of the Jun family to form activator protein-1 transcription factor complexes, has been implicated in the adaptation to chronic exposure to drugs of abuse. Activator protein-

1 transcription factor complexes bind to sites in the regulatory regions of many genes. Acute administration of several drugs of abuse activates *c-fos* and Fos-related antigens, but chronic administration of drugs of abuse eliminates these activations and produces a gradual accumulation of FosB. This highly stable protein is hypothesized to function as a sustained molecular switch contributing to vulnerability to relapse after prolonged periods of abstinence (Nestler, 2001). Thus, these transcription factors may be possible mediators of chronic drug action. However, it has not been possible yet to relate regulation of a specific transcription factor to specific features of drug reinforcement or addiction.

Genetic and molecular genetic animal models have provided a convergence of data to provide hypotheses

regarding vulnerability to addiction in some of the neuropharmacological substrates identified in neurocircuitry studies. High alcohol-preferring rats have been bred that show high voluntary consumption of alcohol, increased anxiety-like responses, and numerous neuropharmacological phenotypes such as decreased dopaminergic activity and decreased neuropeptide Y activity, both of which have support from genetic studies of chromosomal linkage (McBride *et al.*, 1990; Murphy *et al.*, 2002; Carr *et al.*, 1998).

Advances in molecular biology have led to the ability to systematically inactivate the genes that control the expression of proteins that make up receptors or neurotransmitter/neuromodulators in the central nervous system using the gene knockout approach. Knockout mice have a gene inactivated by homologous recombination. A knockout mouse deficient in both alleles of a gene is homozygous for the deletion and is termed a null mutation (–/–). Although such an approach does not guarantee that these genes are the ones that are vulnerable in the human population, they provide viable candidates for exploring the genetic basis of endophenotypes associated with addiction (Koob *et al.*, 2001).

Notable positive results with gene knockout studies in mice have focused on knockout of the  $\mu$  opioid receptor, which eliminates opioid, nicotine, alcohol and cannabinoid reward in mice (Contet *et al.*, 2004). Selective deletion of the genes for expression of the dopamine D<sub>1</sub> and D<sub>2</sub> receptor subtypes and the dopamine transporter has revealed significant decreases in activation and reward produced by psychomotor stimulants. Although developmental factors must be taken into account for the compensatory effect of deleting any one or a combination of genes, it is clear that D<sub>1</sub> and D<sub>2</sub> receptors and the dopamine transporter play important roles in the actions of psychomotor stimulants (Caine *et al.*, 2002, 2007).

BEHAVIORAL AND  
COGNITIVE NEUROSCIENCE

This page intentionally left blank

## Human Brain Evolution

Much of the allure of the neurosciences stems from the common conviction that there is something unusual about the human brain and its behavioral capacities. Nevertheless, modern neuroscientists have paid rather little attention to the study of brain evolution, and so our understanding of how the human brain differs from that of other animals is very rudimentary. In part, this neglect is due to a widely held belief that mammalian brains are all essentially similar in their internal structure and that species differ mainly in the size of the brain. This chapter reviews the modern evidence concerning brain evolution and shows that brain structure, far from being uniform across species, exhibits some remarkable variations. Because the subject is vast, the discussion is necessarily selective. Thus, after a brief review of evolutionary principles, this chapter describes the evolutionary history of three groups of vertebrates that are of special interest to people: mammals, primates, and humans themselves. The major steps are outlined in the evolution of our large, complex, and extremely useful brains from the smaller, simpler brains of the first mammals, focusing on the neocortex, as this part of the brain has been studied most extensively. The neocortex is disproportionately large in humans and is critically involved in mental activities and processes that are considered to be distinctly human.

### EVOLUTIONARY AND COMPARATIVE PRINCIPLES

#### How Do We Learn about Brain Evolution?

There are three main ways to learn about how different brains have evolved. First, the fossil record can

be studied. Much of what we have learned about the evolution of vertebrates in general has come from studying fossils. However, because bones readily fossilize, whereas soft tissues seldom do, we know a lot about the bones of our ancestors, but much less about everything else. Of course, one can infer much about some soft tissues, such as muscles, from their effects on bones, and this is true for brains as well. The brains of mammals fill the skull tightly, and thus the skull cavity of fossils rather closely reflects the size and shape of the brain, and even the locations of major fissures. Much has been learned and written about the changes in brain size from the fossil record (Jerison, 2007), and we could learn more by considering changes in the proportions of brain parts and even the proportions of parts of neocortex. For example, early primates already differed from most early mammals by having more neocortex in proportion to the rest of the brain, and more neocortex devoted to the temporal lobe where visual processing occurs. This implies a greater emphasis on functions mediated by neocortex and a greater emphasis especially on the processing of visual information.

We can even learn something about the functional organization of the neocortex from fossils. For instance, subdivisions of the body representation in the primary somatosensory cortex often are marked by fissures in the brain, and fissure patterns revealed by endocasts (internal casts of the brain case) from fossil skulls have been used to suggest specializations of the somatosensory cortex in extinct mammals. Recently, David Van Essen (1997, 2007) has proposed that an important factor in the development of brain fissures is the pattern of connections within the developing brain. According to this theory, densely interconnected regions tend to resist separation during brain growth and form bulges

(gyri) that limit the separation distance, whereas poorly interconnected regions are free to fold and form fissures (sulci) that would increase the separation distance. Thus, it is because the hand and face regions of the somatosensory cortex are poorly interconnected that a fissure may develop between the two. If this explanation of fissures is correct, then the locations of brain fissures seen in fossil endocasts can potentially tell us something about anatomical connections in the brains of extinct mammals.

Unfortunately, little of the brain's great internal complexity is revealed by its size, shape, and fissures. Thus, to learn more about brain evolution, it is necessary to study the brains of extant (present-day) species and use comparative methods to deduce the organization of ancestral brains. There has been great progress since the early 1980s in understanding how to use comparative approaches to study evolution. In the final analysis, even studies of the fossil record involve a comparative approach. It is seldom known, for example, whether any given fossil was an actual ancestor of another fossil, but only that the comparative evidence, together with suitable times of existence, suggests that they could be.

As Darwin (1859) recognized, each living species represents the living tip of a largely dead branch of an extremely bushy tree of life. By examining other living tips of the tree, we can infer much about the organizations of the brains (and other body parts) of ancestors that occupied the branching points of this tree. Theories of brain evolution, including those of the evolution of the human brain, depend on reconstructing the probable features of the brains of ever more distant relatives.

The comparative method depends on (1) examining the brains of suitable ranges of extant species and (2) determining what features they share and whether these features are shared because they were inherited from a common ancestor or because they evolved separately. The 50-year-old field of cladistics provides guidelines for making such judgments. The choice of species for comparison depends on the question being asked. For example, to deduce what the brains of early mammals were like, one should examine brains from each of the major branches of the mammalian evolutionary tree (Fig. 44.1), and thus consider members of the monotreme, marsupial, and placental mammal branches. To know about early primates, members of the major branches of primate evolution should be considered, along with mammals thought to be closely related to primates, such as tree shrews. In principle, the more branches considered, the better, because a broad comparative approach is required to accurately reconstruct ancestral brain organization.

As brain studies can be difficult, time-consuming, and labor intensive, it is not always possible to study a large number of species, and one must concentrate on the most informative species. The brains of all living mammals contain mixtures of ancestral and derived features, and comparative studies are needed to distinguish the two, however one might first consider the brains of those mammals that are likely to have changed the least since the time of their divergence. Because we know from the fossil record that early mammals had small brains with little neocortex, mammals with large brains and much neocortex obviously have changed quite a bit, and it is likely to be more useful to concentrate on present-day mammals with brain proportions similar to those of early mammals. Whereas the very large brains of humans and whales undoubtedly share features inherited from a small-brained common ancestor, it may be difficult to detect the common features among the multitude of changes. As early primates more closely resembled many of the living prosimian primates in brain size and proportions than monkeys, apes, and humans, studies of the brains of prosimians are likely to be especially relevant for theories of early primate brain organization. Also, it is useful to consider the probable impact of obvious specializations on the brain organizations of living mammals. Although monotremes represent a very early major branch of the mammalian tree, the living monotremes, consisting of the duck-billed platypus with a "bill" and a capacity for electroreception and the spiny echidna with spines and a long sticky tongue for eating ants, are quite specialized, as are their somatosensory systems.

Although the brains of some mammals may have retained more primitive characteristics than others, it is dangerous to assume that the brain of any living mammal fully represents an ancestral condition. Brain features need to be evaluated trait by trait in a comparative context, as any particular feature could be primitive (i.e., ancestral) or derived. To reconstruct the course of brain evolution, we need to distinguish ancestral and derived characters rather than ancestral and derived species. The existence of a mixture of ancestral and derived features in a single species is referred to as *mosaic evolution*.

A third source of information about brain evolution is based on understandings of the mechanisms and modes of brain development and the constraints they impose on evolution. For example, Finlay and Darlington (1995) have presented evidence that brains change in orderly ways as they get bigger. In general, larger brains have proportionately more neocortex and less brain stem. Finlay and Darlington suggest this is the case because the late-maturing neocortex of large

**FIGURE 44.1** The probable course of the major branches of mammalian evolution (e.g., mammalian orders). Proposed clades of placental mammals are numbered, whereas monotremes (A) and marsupials (B) are lettered. Each branch of the tree also has branched many times given the great numbers of present-day species. Note how this branching pattern differs from long-standing notions of a scale of nature from simple to complex. Based on Springer and deJong (2001).

brains grows proportionately longer and larger. Another difference between large and small brains is that large brains have more neurons and longer connections. The increase in neurons makes it difficult for each neuron in a large brain to maintain the same proportion of connections with other neurons, as do neurons in a small brain, and to maintain the same transmission times over longer axons. Thus, as larger brains evolve, changes in organization are needed to reduce the commitment to connections, especially connections requiring long, thick axons. A deeper understanding of the genetic, developmental, and structural constraints on brain design could allow us to better postulate how brains are likely to change in organization with changes in brain size.

## Cladistics and Phylogenetic Trees

To understand brain evolution, we need to understand the evolutionary relationships among mammals, which are summarized in biological classifications (taxonomies). The science of classification (known as “systematics”) has a long history, but an early classification that divided the world into “things that belong to the Emperor and things that don’t” is clearly outmoded. Our modern understanding of plant and animal relationships emerged from the efforts of the Swedish naturalist Linnaeus (1707–1778), who grouped species into ever-larger categories (species, genus, family, order, class, phylum) according to degrees of resemblance and dissimilarity. We now understand

why life forms exhibit the particular pattern of similarities and differences they do, and we have a logic for extending and refining the Linnaean system. In brief, complex life on Earth appears to have evolved only once. It is based on a molecular template that is passed on from generation to generation and yet is modifiable. Because this molecular material usually is not exchanged between individuals from different species, a phylogenetic classification can be derived that reflects times of divergence from common ancestors. Similarities retained over time reflect the preservation of parts of the code, whereas differences reflect alterations in the code. The many different modifications of the genome in the many diverging lines of descent over billions of years have led to the great diversity of life that we see today. Our current classification scheme is based on our understanding of phylogenetic (ancestor-descendant) relationships. Because this understanding continues to grow, parts of the classification scheme continue to be modified.

Phylogenetic relationships are deduced from comparative evidence. The entomologist Willi Hennig (1966) helped reinvigorate this field of study when he formulated a rigorous comparative method of reconstructing phylogenetic relationships, sometimes known as “cladistics.” The term reflects Hennig’s emphasis on the correct identification of “clades,” groups of organisms that share a common ancestor. A clade is simply a branch of the evolutionary tree, which is connected through a set of ancestors (which are the branching points of the tree) to all the other branches in the tree. In Hennig’s method, evolutionary relationships are reconstructed by a process of “character analysis.” A character is any observable feature or attribute of an organism. A character could be a feature of the brain, such as the corpus callosum between the two cerebral hemispheres, or a feature of any other part of the body, or (as is often the case today) a molecule or a DNA sequence. By considering the states of as many characters as possible—for example, whether a corpus callosum is present (as it is in placental mammals) or absent (as in other vertebrates)—and by adopting the assumption that closely related species will share more character states than distantly related species, one can arrive at a hypothesis about the relationships of the groups being examined. Because a given character state can evolve independently in different lineages (e.g., forelimbs that function as wings evolved independently in birds and bats), not every character will yield an accurate picture of evolutionary relationships. It is therefore important to base reconstructions of evolutionary relationships on as many characters as possible. Typically, a very large number of possible trees can be generated from a given character analysis; the

tree that requires the smallest number of changes to account for the observed pattern of character states (the maximum-parsimony solution) usually is considered to be the best estimate of the correct tree. The growth of molecular biology has provided a new source of comparative information to supplement character analyses based on anatomical characteristics, helping to improve the resolution of modern mammalian trees (Fig. 44.1). These trees guide our interpretation of the evolutionary history of brain organization.

To communicate precisely, comparative biologists have developed a specialized nomenclature. The concepts of *homology* and *analogy* are central to comparative biology (Box 44.1). A group of species that all share a common evolutionary history is a *natural taxon* or a *monophyletic group*, which is the same thing as a *clade*. “Unnatural” taxa are groups that either exclude one or more of an ancestor’s descendants (*paraphyletic groups*) or that combine descendants of multiple ancestors (*polyphyletic groups*). The traditional classification of the great apes (orangutans, gorillas, chimpanzees) in the family Pongidae now is known to be paraphyletic because it excludes humans, which share a recent common ancestor with chimpanzees and gorillas. If a character state is found throughout a monophyletic group, it likely was present in the common ancestor of the group or even earlier. Thus, comparisons are necessary with members of a *sister group*, which is the monophyletic taxon thought to be related most closely to the group under study.

To determine whether a character is derived (new) or ancestral, one examines members of one or more *outgroup*, the more distant relatives of the group under examination. The direction of change is called its *polarity*. For example, mammals include forms that lay eggs, the monotremes, whereas the sister group of monotremes, the marsupial-placental group, gives birth to live offspring. We can determine the polarity of these character states (egg laying, live birth) by examining out groups; that is, by examining other vertebrates like reptiles and amphibians. Because most nonmammalian vertebrates lay eggs, we conclude that egg laying is ancestral for mammals, and live birth derived.

## Misconceptions about Brain Evolution

Probably the most serious misconception about brain evolution is that theories of evolutionary change are necessarily highly speculative (Striedter, 1998). As in other historical sciences, direct observation of the process of brain evolution is usually not possible, but objective criteria for evaluating theories and reconstructions of ancestral brains do exist (e.g., character

## BOX 44.1

## HOMOLOGY AND ANALOGY

Homology and analogy are two of the most important concepts in evolutionary biology. Both terms refer to similarity, but to similarity arising from different sources. The terms can be applied to any biological characteristic or feature, including brain structures and even behavior. In our efforts to understand brain evolution, features of brains are compared across species, and it is important to deduce if these features have been inherited from a common ancestor or emerged independently. The two terms reflect conclusions based on the available evidence, and uncertainty is common.

### Homology

When different species possess similar characteristics because they inherited them from a common ancestor, the characteristics are said to be homologous. This does not mean they are identical in structure or function. For example, all mammals appear to have a primary somatosensory area, S1, as a subdivision of neocortex. This structure appears to be involved in electroreception in the duck-billed platypus, a monotreme, but not in other mammals. Humans and monotremes have inherited an S1 from a distant ancestor (at least 150 million years ago), but subsequently, ancestors have specialized S1 in quite different ways.

### Analogy and Homoplasy

Characteristics that have evolved independently are referred to as analogous or homoplasious. Some authors prefer to refer to similarities in function as analogous and similarities in appearance as homoplasious, whereas others use the terms interchangeably or prefer analogous as the more common term. As an example, most primates and some carnivores such as cats divide the primary visual cortex, V1, into alternating bands of tissue activated mostly by one eye or the other, the so-called ocular dominance columns or bands. Because carnivores and primates almost certainly diverged from a common ancestor that did not have ocular dominance columns, we conclude that this way of subdividing visual cortex evolved independently at least two times. When analogous similarities evolve, the process is called *convergent* or *parallel* evolution (parallel if the sequences of changes were similar).

Both homology and analogy can be applied to structures or to specific features of structures. The forelimbs of bats and birds are homologous as forelimbs because both bats and birds inherited forelimbs from their common ancestors. The common ancestor of bats and birds did not fly, however, and the modifications that have transformed the forelimbs of bats and birds into wings evolved independently; these wing-like characteristics are therefore analogous. Correctly identifying homologies is a very important step in deducing the course of evolution of the human brain. Features such as S1, which are homologous in most or nearly all mammals, must have evolved early with the first mammals or before, whereas features common to only primates, such as the middle temporal visual area (MT), would have emerged much later in only the line leading to the first primates. Some brain features related to language production may have arisen quite recently with the emergence of archaic or modern humans. Identifying homologies and their distributions across groups of related mammals (clades) allows us to reconstruct the details of brain evolution in the different lines of descent, including the one leading to modern humans.

The problem of distinguishing homologies from analogies is that both are identified by similarities. However, analogous structures have similarities based on common adaptations for functional roles, and thus they should also vary greatly in details unrelated to function. In contrast, homologous structures likely have retained many details from a common ancestor that may not be functionally necessary. Thus, aspects of structures that appear to be unessential may count more in judging homologies. Much can also be deduced from studying brain development and the development of similarities. Of course, knowledge about the phyletic (cladistic) distribution of similarities is critical, as is accounting for differences in structures by finding species with intermediate types. Ultimately, one hopes to have evidence for so many similarities that the independent evolution of them all seems extremely improbable, or sufficient evidence from differences to indicate that the similarities in structures were acquired independently. Often the evidence is far from compelling, and opinions may change with new evidence.

*Jon H. Kaas and Todd M. Preuss*

analysis). It is not the case that one opinion is as good as the next, although such a view has allowed poorly founded theories to persist.

Another serious misconception is that evolution has a single goal or direction. This stems from the persistent belief in a “phylogenetic scale” that starts with lowly forms such as sponges; proceeds with insects, fish, amphibians, reptiles, and various mammals at successively higher levels; and reaches its pinnacle with humans. This view that the history of life is like a scale or ladder reflects the popular idea that evolution is primarily a process of progressive improvement, a philosophical and religious viewpoint that reassuringly identifies us as the most perfect species. However, evolutionary biologists have long recognized the great diversity of life and have adopted from Darwin the branching tree as a metaphor for the process whereby parent species divide to form daughter species, with each branch becoming adapted to its particular environment through natural selection. This perspective still leaves a place for progress in evolution, if progress means to become better adapted, but there are so many different ways organisms can become better adapted—most of which do not involve becoming bigger brained or smarter—that there can be no single dimension of progress, as the phylogenetic scale implies. Progress, for example, might mean reducing the size of the visual system to reduce metabolic costs in mammals living underground. Thus, there is also no universal trend toward increased complexity, as evolving brains sometimes simplify by reducing or losing parts.

Overall, the brains of many mammalian groups evolved to get bigger, but this change partly reflects the fact that they started off small, and it was more often adaptive to get bigger than smaller. However, mammals with very small brains, near the theoretical limit of smallness in mammalian brain size, persist today and there are reasons to think that small brain size is not the primitive condition in all these groups, but sometimes resulted from relatively recent reductions in brain size. Interestingly, domestic mammals, with our efforts to improve a wild stock, generally have reduced brain size. Evolutionary biologists make a distinction between traits that are ancestral (also termed primitive or *plesiomorphic*) from those that are recently acquired (also known as derived or *apomorphic*), but this distinction does not imply that primitive is simple and that derived is complex.

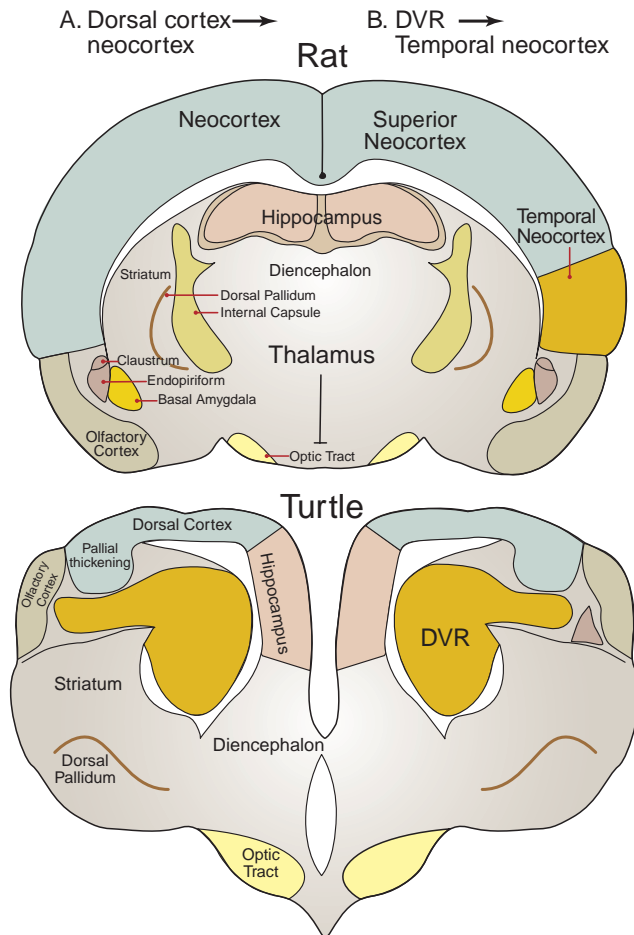

A third misconception is that ontogeny recapitulates phylogeny. At one time, evolution was thought to proceed by sequentially adding new parts (*terminal addition*), and that in the development of complex forms, the newest parts were those added last. Thus,

the evolutionary history of any organism would be revealed in its sequence of development. Though this is not the case in general, the study of brain development remains relevant to the study of brain evolution because evolution occurs through alterations in the course of development. It is also the case that many changes in the course of development that have led to new adaptations have occurred in the later stages of development, primarily because alterations in early stages often are lethal or produce profoundly different and maladaptive adult forms. Nevertheless, it is important to recognize that the course of development can be altered in many ways and at many stages. Studies of brain development are useful because they can indicate how homologous structures that appear dissimilar in adults arose from forms that were more similar early in development.

The concepts of progress and terminal addition have led some investigators to consider certain features of the brains of such mammals as humans, monkeys, and cats as either relatively old or new on the basis of their histological appearance. Poorly differentiated areas of neocortex—areas with indistinct lamination—were considered to be ancient, and well-differentiated areas were thought to be new. For example, because the primary visual cortex (V1) has very highly differentiated layers in many primates, including humans, V1 has been considered by some to be a recently acquired area of the cortex. However, a comparative analysis indicates that the primary visual cortex (V1) is as old as the first mammals, perhaps much older. The cellular layers of V1 were poorly differentiated in early mammals, and they remain poorly differentiated in many living species. Yet, humans do not have the most highly laminated V1: this distinction belongs to the tarsier, a tiny, nocturnal primate with enormous eyes. As another example, the superior colliculus or optic tectum, an ancient visual structure, has well-differentiated layers in many birds and reptiles, but they are poorly or moderately differentiated in many mammals (including humans), yet well differentiated in other mammals, such as squirrels and tree shrews.

### Origin of the Neocortex

The hallmark of the evolution of mammalian brains was the emergence of the neocortex. The cerebral cortex (or pallium) covers the deeper parts of the forebrain (telencephalon). In mammals, the cortex generally is divided into three parts: the lateral *paleocortex* or olfactory piriform cortex, the medial *archicortex* or hippocampus and subiculum, and the *neocortex* or *isocortex* lying in between (Fig. 44.2). The archicortex

**FIGURE 44.2** Theories of the origin of neocortex. One view is that (A) only the dorsal cortex of stem amniotes gave rise to the neocortex. A less supported view is that (B) the dorsal cortex gave rise only to the superior part of the neocortex, whereas the dorsal ventricular ridge (DVR) gave rise to the temporal neocortex of extant mammals such as rats (top). See below for the location of dorsal cortex and the DVR in extant reptiles such as turtles. The neocortex and dorsal cortex are much different in size, as well as in cellular organization (see text).

and paleocortex can be recognized in reptiles, and their names reflect the early conclusion that they are phylogenetically old parts of the forebrain. All extant mammals have an obvious neocortex, and the presence of a neocortex is clearly indicated in the endocasts of the skulls of early mammals, but nothing quite like the neocortex exists in sauropsids, reptiles, and birds, which represent the nonmammalian branches of amniote evolution. Hence, the term *neocortex* was applied to this seemingly new part of the brain. Nevertheless, the neocortex as a structure is not really new, as current evidence indicates that it is homologous to a structure in reptiles called the dorsal cortex. In contrast to the neocortex of mammals, however, which has multiple layers with different cell types and

packing densities, the dorsal cortex of reptiles is a rather small and thin sheet of tissue. Whereas dorsal cortex has little more than a single row of neurons, an imaginary line drawn through the thickness of the neocortex would likely encounter over 100 neurons. Thus, the neocortex is much different in structure than the dorsal cortex. Unfortunately, no species exist today to show us what intermediate states were like in the evolution of the mammalian neocortex. Because the neocortex as a structure did not really originate with mammals and because it is not “new,” some investigators refer to the neocortex as the *isocortex*, using a term that refers to the relatively uniform appearance of the neocortex throughout all regions. However, the changes in the dorsal cortex that produced the neocortex are impressive, and no other vertebrates have a structure that clearly resembles the neocortex. Thus, mammals are characterized as much by their neocortex as a modified structure as they are by their mammary glands.

Although the neocortex has a nearly uniform histological appearance, its considerable variability in size and organization is what allows mammals to differ so much in behavior and abilities. To understand how variations in the neocortex make this possible, it is necessary to identify ancestral features of the neocortex, that is, features that were present in the last common ancestor of living mammals, and then determine how this organization was modified in different lineages of living mammals, such as primates.

The laminar organization of the neocortex appears to be similar in most mammals, suggesting that the ancestral design was so useful that many features have been retained in modern groups. For example, in most mammals and over most of the neocortex, six layers can be recognized (Brodmann, 1909). Of the six layers of neurons, layer 4 receives activating inputs from the thalamus or from other parts of the cortex. Layer 3 communicates with other regions of the cortex, layer 5 projects to subcortical structures, and layer 6 sends feedback to the thalamic nuclei or cortical area providing activating inputs. This ancestral framework for cortical neural circuits has been modified and elaborated in various lines of descent to give us the great variability in brain function we see today. The neocortex has changed by diversifying its neuron types, differentiating (and in some cases simplifying) its laminar structure in various ways, altering connections, changing its overall size and the sizes of individual cortical areas, adding cortical areas, and dividing areas into specialized modular processing units or cortical “columns.” What was achieved through these changes ranges from echolocation to language. Of course, changes in the neocortex have been accompanied by

modifications occurring in other parts of the brain because cortical and subcortical structures often have integrated functions. For example, the superior colliculus of the midbrain has been variously modified in function, largely by changing and expanding the direct inputs from neocortex, but also through other alterations. To begin to understand how cortical organization has changed to produce the remarkable human brain, we first focus on the neocortex of early mammals.

## Brains of Early Mammals

Early mammals had small brains with little neocortex. By comparing the histological appearance of the neocortex in extant mammals of differing lines of descent, we can conclude that the neocortex of early mammals was not as highly differentiated in terms of distinct layers and neuron types as is the cortex of many modern mammals. However, the cortex likely was not homogeneous in appearance either. In present-day mammals, the primary sensory areas typically have a noticeably different layer 4 (the receiving layer) with somewhat smaller and more densely packed neurons than in other areas. From such slight regional differences in appearance, early investigators such as Brodmann (1909) surmised that all mammals have functionally significant subdivisions of the cortex, called *areas*, that some areas are shared by many species (homologous areas), and that mammals differ in numbers of areas. What was difficult for Brodmann and other early investigators was to reliably identify areas by their histological appearance, especially in the poorly differentiated cortex of many small-brained mammals, but sometimes even in the large expanses of the rather homogeneous cortex in large-brained mammals. As a result, areas were often incorrectly delimited, and the sometimes radical changes in the appearance of certain areas that took place across species resulted in mistaken interpretations of homology. To Brodmann's credit, he correctly identified the primary visual cortex in species as different from each other as humans, where the task is easy because of the area's histological distinctiveness, and hedgehogs, which are insectivores with poor cortical differentiation.

Although Brodmann's subdivisions of human and other brains are commonly portrayed in textbooks today, many of his proposed areas and proposed homologies have little validity. Fortunately, modern methods allow us to compare many features of cortical biology in great detail, including connection patterns, neuron-response properties, and cortical histochemistry, which allows us to identify cortical areas and

evaluate homologies with a high degree of assurance. From these methods, we can conclude that the neocortex of early mammals was subdivided into a small number of functionally distinct areas, on the order of 10–20, and these areas have been retained in most lines of descent.

The neocortex of North American opossums (Fig. 44.3), which are small-brained marsupials, reflects many of the features of other small-brained mammals. Much of the limited expanse of the neocortex is dominated by sensory inputs relayed from the thalamus. Caudally, the neocortex includes a large primary visual area, V1, bordered laterally by a strip-like second visual area, V2. More laterally, an additional strip of cortex responds to visual stimuli, but the organization of this cortex is not known. Nearly all existing mammals have a V1, V2, and a more lateral zone of visual cortex. This pattern likely emerged with (or before) the first mammals. More rostrally, opossums have a primary somatosensory area, S1, bordered laterally by two additional representations of tactile receptors, the second somatosensory areas, S2, and the parietal ventral area, PV. Connection patterns indicate that narrow bands of the cortex rostral and caudal to S1 are also involved in processing somatosensory inputs. This collection of five somatosensory fields is seen repeatedly in small-brained mammals, although S2 and PV are not always distinct from each other. A region of cortex caudal to S2 and PV responds to auditory stimuli, and much of this region is occupied by the primary auditory area, A1, which is present in all or nearly all living mammals. However, the auditory cortex contains a number of additional areas in most mammals, including many of the studied small-brained mammals, although homologies are often uncertain. Thus, early mammals probably had several auditory fields.

More rostrally, the frontal cortex of opossums is very small and does not contain any obvious motor areas. Instead, motor-related information from the cerebellum is relayed to S1. However, opossums are marsupials (Fig. 44.1), and most or all placental mammals have a primary motor area, M1, just rostral to S1 (and the narrow somatosensory band bordering S1), and possibly a second motor area, M2, also known as the supplementary motor area, SMA. The frontal cortex also includes an orbitofrontal region, which mediates autonomic responses to exteroceptive stimuli. On the medial wall of the cerebral hemisphere, opossums and other mammals share several divisions of the limbic cortex with inputs from the anterior and lateral dorsal nuclei of the thalamus. In addition, narrow strips of the entorhinal cortex are present that connect the neocortex with the hippocampus.

**FIGURE 44.3** Some of the proposed neocortical areas in North American opossums. Somatosensory areas include the primary area (S1), a secondary area (S2), a parietal ventral area (PV), and caudal (SC) and rostral (SR) somatosensory belts. The auditory cortex (AUD) is limited and likely contains a primary field (A1) and possibly another area or two. The visual cortex includes primary (V1) and secondary (V2) areas and a visual (Vis) belt. The caudotemporal (ct) field is probably visual. In V1, the upper visual field (uf) is represented caudal to the lower visual field (lf). Modified from Beck *et al.* (1996).

From this ancestral pattern, a great variety of brain organizations have evolved through alterations in size and the number of parts and the connections within and between parts (Kaas, 2007a). Consider, for example, the variations of the primary somatosensory cortex. The duck-billed platypus devotes most of S1 to representing tactile receptors of its highly sensitive bill, and it has added inputs from electroreceptors. The star-nosed mole devotes most of S1 to its long, fleshy nose appendages, rats mostly activate S1 with their facial whiskers, and human S1 has a large representation of the hand, lips, and mouth. In addition, the amount of neocortex varies greatly across species of mammals (Jerison, 2007), and some of this variation is due to differences in numbers of cortical areas present in different groups of mammals (Finlay and Brodsky, 2007; Kaas, 2007a).

The number of sensory areas increased independently in several lines of evolution. For example, both cats and monkeys have a large number of visual areas, but the carnivore and primate lines appear to have acquired most of these areas independently rather than from a common ancestor. Thus, many of the visual areas in cats have no homologies in monkeys or humans. A similar situation holds for other regions of the brain. New areas were added, most commonly to sensory and motor regions of cortex rather than to multisensory “association” cortex as once thought. With new cortical areas, new connections between areas and subcortical structures emerged. Thus,

mammals in various lines of descent evolved new cortical areas and connections, as well as other many specializations of previously existing ones. As a long-recognized example of the emergence of a new brain feature, the corpus callosum, the major pathway interconnecting the neocortex of the two cerebral hemispheres, is a derived character of placental mammals, having emerged in the ancestors of placentals after they diverged from marsupials. Whereas connections between the two hemispheres are mediated by the anterior commissure in marsupials and monotremes, most of these connections are carried in the shorter, more direct callosal pathway in placental mammals.

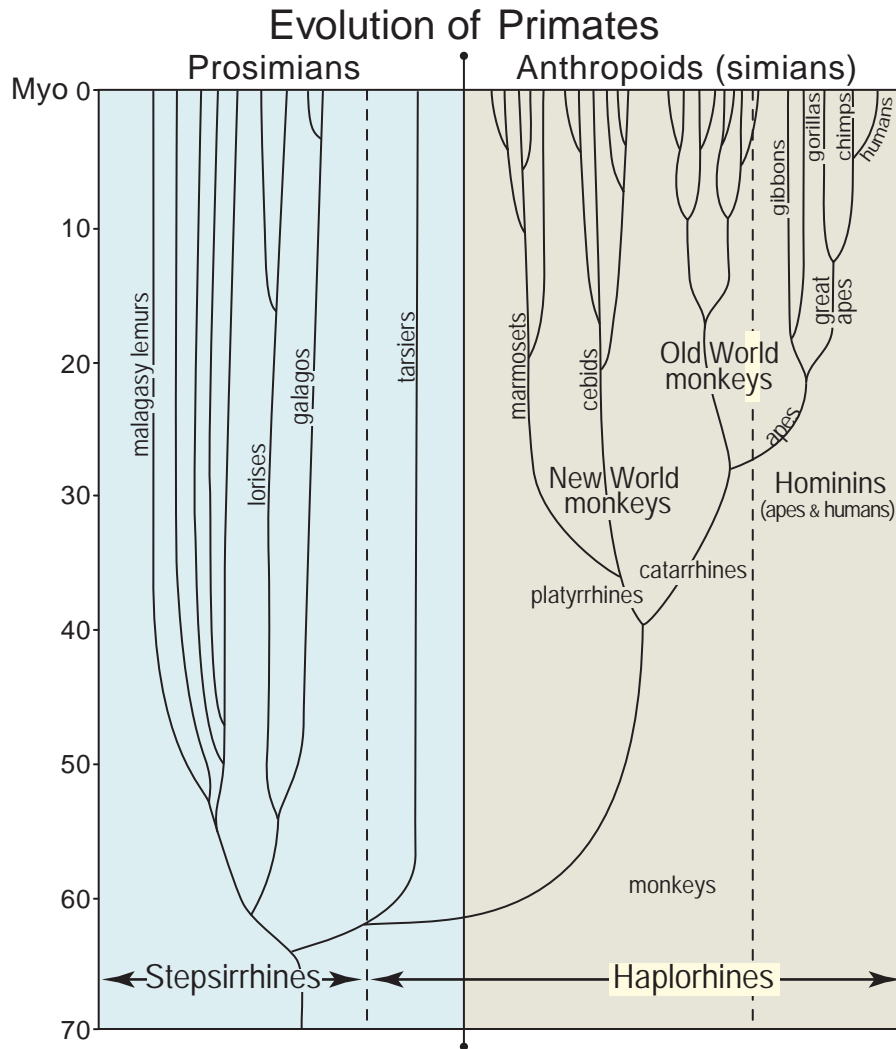

## EVOLUTION OF PRIMATE BRAINS

### Evolution of Primates

Early primates emerged from small-brained, nocturnal, insect-eating mammals some 60 to 70 million years ago and soon branched into three main lines leading to present-day prosimians, tarsiers, and anthropoids (Fig. 44.4). The prosimian suborder of primates includes lorises, lemurs, and galagos; the anthropoid suborder consists of New World monkeys, Old World monkeys, and the ape–human group. Tarsiers are small, prosimian-like animals. Two main schemes of classification of primates have been in use, mainly because it has not been obvious where to place tarsiers. Many authors use a traditional classification and distinguish prosimian from anthropoid primates and include tarsiers with prosimians. However, this is now thought to be an unnatural paraphyletic grouping because tarsiers, despite their generally prosimian-like appearance, generally are considered to be more closely related to anthropoids than to lemurs, lorises, and galagos. This conclusion is reflected in the cladistic classification preferred by other authors, in which lemurs, lorises, and galagos are placed in the suborder, Strepsirhini, a group that has retained ancestral features, including a naked, moist rhinarum (wet nose). Tarsiers and anthropoids, which have a reduced olfactory system (and thus a dry nose), are placed in the suborder Haplorhini. The anthropoid primates are divided into the infraorders Platyrrhini (New World monkeys) and Catarrhini (Old World monkeys, apes, and humans).

The earliest primates are thought to have been small-bodied, nocturnal visual predators living on insects and small vertebrates, as well as fruit. They adapted to the tropical rainforests by emphasizing vision and visually guided reaching and grasping.

**FIGURE 44.4** The evolution and classification of primates. Tarsiers are generally considered to be prosimians, but they are related more closely to anthropoids, so they are recognized as haplorhine primates. Despite the ancient split of prosimian and anthropoid primates, they share many brain features that are unique to primates. Tree shrews and flying lemurs are thought to be close relatives of primates, and together with them constitute the superorder Archonta. See Preuss (2007) for discussion.

This involved having larger, forward-facing eyes, opposable big toes and thumbs, and digits tipped with nails. These primates produced the largely nocturnal strepsirhine radiation with its varied forms, including some species now living in Madagascar that have become diurnal. The haplorhine primates emerged about 60 million years ago in association with a shift from nocturnal to diurnal life, together with an increased emphasis on fruit eating (Ross, 1996).

With the shift to diurnality came reduced dependence on olfaction, enhancement of the visual system, enlarged body size, and sometimes a more gregarious mode of life. Specifically, the olfactory apparatus was reduced in size, and the eyes enlarged and brought close together. Early haplorhines evolved a fovea, a

specialized region of the retina filled with small photoreceptors and devoid of blood vessels, that enhances central visual acuity. The reflecting surface at the back of the eye (tapetum lucidum), an adaptation to nocturnal vision present in prosimians and many other nocturnal mammals, was lost. Anthropoids underwent further specializations, modifying cone morphology, increasing the proportion cones to rods, and filling the fovea with cones to the near-exclusion of rods. These adaptations enabled anthropoids to achieve a high degree of color discrimination. Nevertheless, whereas humans and other Old World anthropoid primates have three types of retinal cones, ancestral anthropoids probably possess the two types of cones, similar to most modern prosimians and New World monkeys. A

third cone type, enabling full trichromatic vision, appears to have evolved independently in the ancestors of Old World anthropoids and in several New World monkey groups. The enhancements of color vision in the anthropoids are plausibly regarded as adaptations for distinguishing ripe, edible fruits. The shift to diurnality was also marked by larger social groupings, which may offer enhanced protection from predation. These changes were accompanied by increased brain size, including increases in the temporal lobe visual region, and in regions of the parietal and frontal cortex mediating motor control and social interactions.

The ancestors of present-day tarsiers evidently abandoned the diurnal niche to become nocturnal visual predators again. Tarsiers retain a fovea, but they have a rod-dominated retina and their enormous eyes are sensitive at low light levels without the aid of a reflecting tapetum. The primary visual cortex became very large relative to the rest of the brain and is extremely well differentiated, with a multiplicity of layers and sublayers (Collins *et al.*, 2005). Tarsiers became such extremely specialized visual predators that they eat no plant food. Other haplorhines (anthropoids) remained diurnal and spread to many niches, including those outside the rainforest and niches based more on eating leaves as well as fruits. Some increased considerably in body size. Later anthropoids were able to process hard, husked fruits with their hands and teeth. Some early anthropoids managed to reach South America from Africa, apparently by rafting, to form the New World monkey radiation. All modern anthropoids are diurnal with the exception of owl monkeys, a New World monkey group, that has (like tarsiers) become secondarily nocturnal.

In Africa, early anthropoids diverged some 25 to 30 million years ago into lines leading to modern Old World monkeys and to apes. At first, apes were the most successful radiation, coming to occupy a range of rainforest and open woodland environments, whereas monkeys were quite rare. Perhaps as many as 30 different types of apes existed at one time. This condition changed radically some 10 million years ago when monkeys became abundant and apes rare. This change may have resulted from the advent of a more seasonably variable and drier climate. Ancestral Old World monkeys acquired specialized teeth suited to a leaf and fruit diet in drier climates. Also, the more rapid reproduction of monkeys may have made them more resistant to extinction than apes.

Some 5 or 6 million years ago, a line of apes diverged into two branches: one that gave rise to modern common chimpanzees and bonobos (pygmy chimpanzees), and a second branch that led to the group of

bipedal apes, the “hominins,” that includes modern humans (Fig. 44.5). Traditionally members of the human branch were referred to as “hominids,” that is, as members of the Family Hominidae. Today, taking into account the close relationship of humans to the great apes, it is customary to extend the term “hominid” to the entire great ape clade, to use the term “hominines” (Subfamily Homininae) to refer to the African ape clade (chimpanzees, bonobos, humans, and gorillas), and to apply the term “hominins” (Tribe Hominini) to members of the human branch of the African ape clade. (A tribe is, taxonomically speaking, a sub-subfamily.)

The oldest known hominins, the so-called australopithecines, date back at least 4 million years. These early hominins were bipedal, but skeletal traits suggest they retained considerable ability for climbing trees. Body size was rather small and males were much bigger than females. The brain was only slightly larger than for apes of similar body size. Hominin traits may have emerged as adaptations to a drier environment with grassland and savanna.

Early australopithecines soon gave rise to a number of species differing in body size and limb proportions, as well as in characteristics of the jaws and teeth and brain size. Primitive members of our own genus began to emerge some 2 million years ago with *Homo habilis* (or “handy man,” due to its use of stone tools). *Homo habilis* had a slightly increased cranial capacity compared to australopithecines, reduced face and teeth, and pelvic modifications for improved bipedal locomotion and the birth of neonates with larger heads. About 1.7 million years ago, *H. habilis* appears to have been replaced by *H. erectus*, a larger hominin with a further reduction in face and teeth and a larger brain. Shortly thereafter, *Homo erectus* spread out of Africa to central Asia. *Homo sapiens* emerged from an African population of *H. erectus* some 250,000 to 300,000 years ago. Other members of the genus *Homo* coexisted with *Homo sapiens* until as recently as 35,000 years ago, notably the Neanderthals, who adapted to a colder Europe and southwest Asia over 130,000 years ago. They disappeared and were replaced by modern *H. sapiens* some 35,000 years ago. Neanderthals were shorter and more heavily built than modern humans, but had a comparable or slightly larger cranial capacity. Over the last 15,000 years, some populations of humans have become smaller and have reduced their brain size, possibly as a result of a poorer diet as agriculture replaced hunting and gathering.

Chimpanzees and bonobos (also misleadingly known as “pygmy chimpanzees”) appear to be our closest surviving relatives. Humans and chimpanzees are 98 to 99% similar in the coding sequences of genes,

# Evolution of Hominins

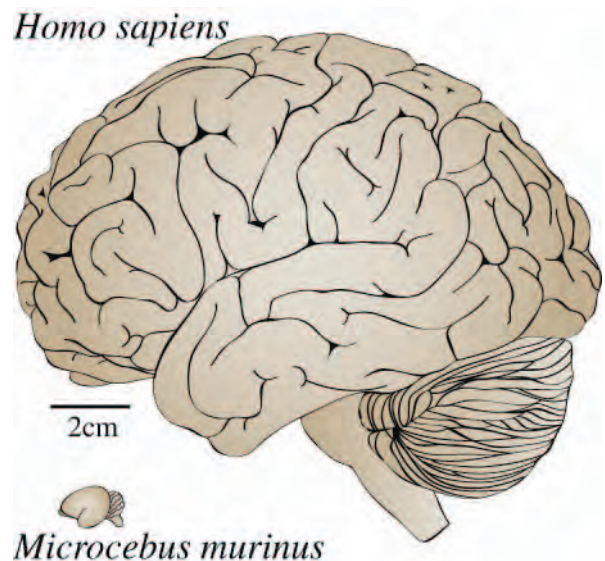

**FIGURE 44.5** The evolution of apes and humans. Apes include living apes and a late fossil judged to not be bipedal (*Ardipithecus ramidus*). *Australopithecus* and *Paranthropus* appear to have been bipedal. The age of the famous fossil, Lucy, is indicated. Relationships are somewhat uncertain, and more branches on the tree exist (de Sousa and Wood, 2007).

which is more similar than found among morphologically indistinguishable sister species of some genera. The bases for the great phenotypic differences between humans and chimpanzees, including those in brain size and presumably brain organization, are not well understood, but changes in patterns of gene expression are likely to be important.

### Brains of Early Primates

The brains of primates vary greatly in size and fissure patterns. Humans have the largest of primate brains, whereas mouse lemurs have the smallest (Fig. 44.6). Judging from fossil endocasts and other parts of the skeleton, early primates were lemur-like in body form, and their brains were shaped like those of present-day lemurs, although smaller. The modern mouse lemur has moderately expanded temporal and occipital lobes, indicating an emphasis on vision, a calcarine fissure or fold within the primary visual cortex, and a lateral (Sylvian) fissure separating

**FIGURE 44.6** Lateral views of the brains of a human and a small prosimian primate, the mouse lemur, to illustrate the great range of sizes for present-day primates.

somatosensory areas of the parietal lobe from auditory areas of the temporal lobe. Most modern primates share these two fissures. Many early as well as present-day primates also have an additional prominent fissure in the temporal lobe (the superior temporal sulcus). Other fissures are more variable.

Among living prosimians, evidence about brain organization comes mostly from studies of galagos, nocturnal animals from Africa that are cat-sized or smaller and eat mainly fruit, tree gums, and insects. Their brains have only a few fissures (Fig. 44.7). Their visual system contains several features that are common to all primates that have been examined, including a distinctive type of lamination in the lateral geniculate nucleus of the visual thalamus (with magnocellular and parvocellular layers) and a pulvinar complex with the distinct inferior and lateral pulvinar divisions. As in other primates, the superior colliculus of the midbrain represents only the contralateral half of the visual field, whereas other mammals have a more extensive representation that includes the complete visual field of the contralateral eye. The visual

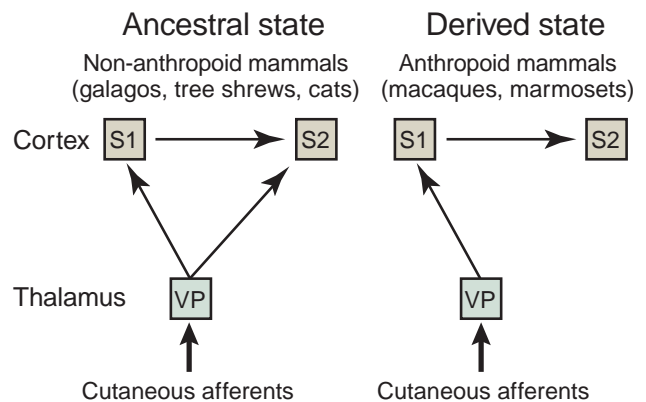

**FIGURE 44.7** A lateral view of the brain of a prosimian primate, *Galago garnetti*, showing some of the proposed visual, somatosensory, auditory, and motor areas. Visual areas include the primary (V1) and secondary (V2) areas, common to most mammals, but with the modular subdivisions (blobs in V1; bands in V2) characteristic of primates. As in other primates, galagos have a third visual area (V3), a dorsomedial area (DM), a middle temporal area (MT), a dorsolateral area (DL), a fundal-sulcal-temporal area (FST), an inferior temporal visual region (IT) with subdivisions. Posterior parietal cortex (PP) contains a caudal division with visual inputs and a rostral division with sensorimotor functions. The auditory cortex includes a primary field (A1), a rostral area (R), and an auditory belt (AB), which includes several areas and regions of the parabelt auditory cortex. The somatosensory cortex includes a primary area (S1 or 3b), a parietal ventral area (PV), a secondary area (S2), a somatosensory rostral belt (SR or 3a), and a somatosensory caudal belt (SC or possibly area 1 or areas 1 plus 2). Motor areas include a primary area (M1), ventral (PMV) and dorsal (PMD) premotor areas, a supplementary motor area (SMA), a frontal eye field (FEF), and other motor areas on the medial wall of the cerebral hemisphere. Modified from Kaas (2007b).

cortex includes areas V1 and V2, both retained from nonprimate ancestors but with primate modifications including “blobs,” which are cytochrome oxidase-rich modules in V1, and band-like modules that span the width of V2.

Other visual areas apparently shared with all other primates include V3, a dorsomedial area (DM), and a middle temporal visual area (MT), all of which receive direct inputs from V1. Other areas, such as the dorsolateral area (DL or V4), also are shared widely among primates, but not enough is known about visual cortex organization in the various primate species to be certain of how many of the more than 30 proposed visual areas are common among primates. Some or most of these areas, such as MT, are not found in nonprimates, or at least not in a primate-like form, and these areas are distinctive features of primate brains (Kaas, 2007b; Preuss, 2007).

Organization of the auditory system of galagos and other prosimians is not well understood, but they appear to share two primary or primary-like areas, A1 and R (“rostral”), with other primates, and they likely share several nonprimary areas as well. A1 and possibly R are likely to have been retained from nonprimate ancestors. The somatosensory cortex appears to be relatively unchanged from nonprimate ancestors, as an S1, S2, and PV have been identified in galagos, and there are additional, narrow belts of somatosensory cortex along the rostral and caudal borders of S1. S2 and PV retain the primitive feature of being activated directly by inputs from the ventroposterior nucleus of the thalamus (Fig. 44.8). Motor cortex organization is surprisingly advanced, with the five or more premotor areas that are also found in anthropoid primates.

**FIGURE 44.8** Somatosensory processing in prosimian primates and anthropoid primates. The processing in anthropoids is serial, rather than parallel and serial. Because the prosimian type also is found in a number of nonprimate mammals, we infer that this is the ancestral state. The ventroposterior nucleus (VP) of the somatosensory thalamus and the first (S1) and second (S2) somatosensory areas of the cortex are shown.

Although the brains of prosimians are not especially large, they share a number of primate-specific areas with anthropoids over and above the complement inherited from their mammalian ancestors. Overall, prosimians and other primates share a large number of brain specializations that likely evolved in early primates or their immediate ancestors (Preuss, 2007). The study of prosimians is critical for understanding that features of brain organization are distinctive of primates.

### Brains of Early Anthropoids

The anatomy of early anthropoids suggests that an emphasis on high-acuity, diurnal vision and reduced emphasis on smell were important in their evolution. The endocasts of the skulls of early anthropoids indicate that the visual cortex of the temporal lobe was more expansive than in prosimians.

Collectively, present-day New World and Old World monkeys cover a wide range of body and brain sizes. The extent to which fissures develop on the brain surface of these primates depends largely on brain size. All primates, no matter how small, have a deep calcarine fissure in the occipital lobe. Most also have a deep lateral sulcus (Sylvian fissure). These are the only well-developed sulci in marmosets, the smallest of the New World monkeys. Slightly larger New World monkeys, such as owl monkeys and squirrel monkeys, also have a shallow central sulcus and a shallow superior temporal sulcus. The largest New World monkeys, such as spider monkeys and cebus monkeys (capuchins), have even more sulci and resemble (at least superficially) the well-fissured brains of Old World monkeys, such as macaques and baboons.

Both Old World and New World monkeys have all the areas of the neocortex described for prosimians, as well as some additional areas. Most notably, the somatosensory cortex has been altered so that areas 3a, 3b, 1, and 2 are well differentiated from each other, with each area corresponding to a separate representation of receptors of the contralateral body surface (Kaas, 2007b). Within S1 (area 3b), the proportional representation of body parts varies somewhat across species, so that in some monkeys as much as half of the area is devoted to the face and oral cavity. The hand is also prominently represented, especially in monkeys such as macaques. Some New World monkeys, such as spider monkeys, have a large representation of their highly tactile, prehensile tail. Marmosets appear to have a relatively poorly differentiated somatosensory region, which lacks a definite area 2, a field that is responsive to tactile stimuli and muscle movements in other monkeys. This may be a consequence of brain

size reduction in marmosets, which have evolved smaller brains and bodies from larger ancestors.

In all anthropoids, S2 and PV appear to have lost activating inputs from the ventroposterior nucleus of the somatosensory thalamus, and they depend on inputs from areas 3a, 3b, 1, and 2 (Fig. 44.8). S2 and PV receive modulatory inputs from the ventroposterior inferior nucleus. Thus, processing in the somatosensory system became more serial than parallel with the advent of monkeys. Other differences likely exist between anthropoids and prosimians in the somatosensory portions of the lateral sulcus and posterior parietal cortex, but more research is needed. Both of these regions of somatosensory processing have expanded greatly in anthropoids compared to prosimians, and several areas involved in visually guided reaching have been described in macaque monkeys.

Currently, there is much interest in how the visual system of monkeys is subdivided into cortical areas and how these visual areas function in behavior. Elaborate proposals have been presented, but considerable uncertainty remains. In Old World monkeys, over 30 visual areas have been proposed, and it seems likely that anthropoids in general have more visual areas than prosimians, although the full extent of this difference is not yet clear. In the auditory cortex, a core of three primary-like areas, a belt of seven to eight additional fields, and a "parabelt" of several additional areas have been proposed, but not enough is known about auditory cortex of prosimians to know what differences exist. The proposed subdivisions of the motor cortex in prosimians and simians are quite similar, although some of the premotor areas of prosimians have been subdivided into two or three areas in Old World monkeys. Finally, comparisons of cortical connections and architectonics in galagos and macaque monkeys have led to the conclusion that macaques have several areas of dorsolateral prefrontal cortex in addition to those found in galagos.

### Evolution of Hominin Brains

In trying to determine the recent course of the evolution of the human brain, we depend more on the fossil record than on a comparative approach, as we are the only surviving hominin species. Human brains are much bigger than those of our closest living relatives, the African apes. From the fossil record (Fig. 44.9), we can see that early australopithecines had brains that were only 10–25% larger than the brains of present day African apes when body size is taken into account. However, brains increased rapidly in size as the various species of *Homo* evolved over the last 2 million years. Early hominins had brains in the 600- to

### Brain size (in cm<sup>3</sup>) plotted against time (Myr) for specimens attributed to Hominidae

**FIGURE 44.9** Evidence for the rapid growth of brains of hominins over the last 2 million years. The brain sizes of modern chimpanzees and gorillas have been added for comparison. Modified from McHenry (1994).

800-cc range; *H. erectus*, about 500,000 years ago, had brain volumes close to 1000cc; and soon thereafter brains reached the volumes within the range of modern *H. sapiens*, which averages about 1400cc.

In deducing the changes in internal organization that likely occurred over this remarkable increase in brain size, it would be useful to know more about the organization of the brains of the living apes. However, only limited information is available from early motor and somatosensory mapping experiments on apes, and further noninvasive studies, as in humans, are needed. Much can be learned by studying the histology of tissue from brains of apes that have died natural deaths using modern histochemical techniques (Preuss, 2001), but at the present time, we have only a limited understanding of how the brains of apes differ from those of monkeys. Traditionally, it was postulated that the higher-order “association” regions of the frontal, parietal, and temporal lobes underwent great expansion in human evolution. This view recently has been called into question by the finding that the relative proportions of the frontal, parietal, and temporal lobes are similar in great apes and humans, notwithstanding the much larger absolute size of the human brain. The fact remains, however, that the primary sensory cortical and thalamic structures are of roughly the same absolute size in humans and great apes, whereas the association regions of humans are much larger in absolute terms. This is consistent with classical accounts of human brain evolution that emphasize the expansion of higher-order regions. Changes in human evolution did not only involve an increase in brain size. Recent

comparative studies have documented human specializations at the level of cellular and modular organization as well. At the present time, however, we do not know enough about the specializations of human brain organization to understand how brain changes are related to human specializations of cognitive organization, such as the capacity for conceptualizing the mental states of other individuals (“theory of mind”; Povinelli and Preuss, 1995).

One of the signature specializations of *Homo sapiens* is of course language, and it often has been assumed that the evolution of language involved the evolution of specialized language areas in the brain, such as Wernicke’s area in the temporoparietal cortex and Broca’s area in the frontal lobe. Human brains are not symmetrical in shape, so that the planum temporale, the sheet of cortex on the lower surface of the lateral sulcus (the upper face of the temporal lobe), is usually larger in the left cerebral hemisphere than on the right. As the left hemisphere usually becomes dominant for language, the larger size of the left planum temporale has long been assumed to be related to language. Interestingly, however, great apes exhibit the same asymmetry of the temporal lobe as humans, despite their lack of language. When and how language emerged in hominins remain issues of much speculation, as does the nature of the changes in brain organization that support language (Deacon, 2007). What seems likely is that previously existing brain regions used for other, nonlinguistic functions in nonhuman primates, such as the ventral premotor area and dorsal-stream auditory areas, became specialized for language in the ancestors

of humans, ultimately acquiring the functions of Broca's and Wernicke's areas. Presumably, the evolution of language involved changes in the internal organizations of these areas (see, for example, Buxhoeveden *et al.*, 2001).

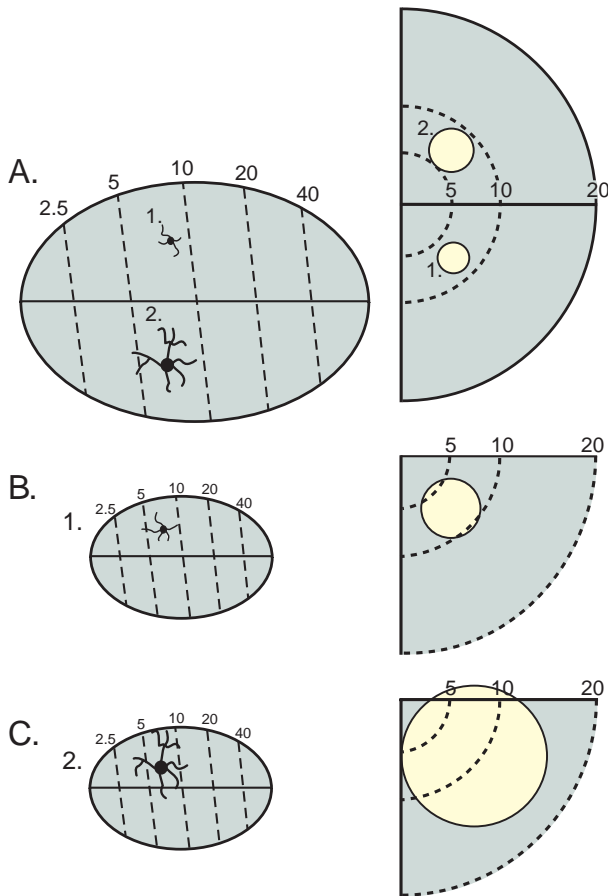

## WHY BRAIN SIZE IS IMPORTANT

A general assumption is that larger brains are better because they can do more. This does not imply that brains of the same size (or same size in proportion to the body) do the same things, because brain organization is modified for different functions. Nevertheless, larger brains do have obvious design problems that are likely to have been solved in similar ways in the different lines of evolution. To some extent, neurons usually enlarge as brains get bigger, but dendrites and axons cannot enlarge much without compromising their functions. To maintain passive cable conduction in dendrites, Bekkers and Stevens (1970) calculated that dendrites would need to increase four times in diameter when they double in length. Similarly, when axons double in length, axon diameter must also double, to maintain conduction times. As brain size increases, some dendrites and axons do become longer and enlarge disproportionately. Given the problems associated with increasing neuron size, the major way of increasing brain size is to increase the number of neurons. This introduces a related problem as the number of neurons increases: it becomes more and more difficult to maintain each neuron's connections with the same percentage of other neurons, since the required number of connections grows much faster than the number of neurons. Cell body densities typically decrease and cortical thickness increases, but the increase in connections is not nearly enough to maintain ratios of connectivity or to fully compensate for longer connection distances. As a result, larger brains generally devote much more of their mass to connections.

There are two major ways in which larger brains can be modified to reduce the design problems produced by larger distances and more neurons. First, the brain can become more modular, so that most connections of individual neurons are with neighboring, rather than more distant, neurons. This can be done, for example, by increasing the number of processing areas so that areas are usually smaller. In addition, areas can be subdivided into smaller functional divisions (columns or modules), which likewise reduce the need for long connections. Thus, larger brains are likely to have larger numbers of cortical areas, and larger areas

are likely to contain several types of modules. Second, connections that require long, thick axons should be reduced as much as possible. This can be done by grouping functionally related areas together so that necessary connections between areas are shorter. An effective way of reducing the need for long connections, as brains get bigger, is to increase the degree of specialization of each cerebral hemisphere. As regions and areas of each hemisphere become differently specialized, the major cortical connections become more focused within the same hemisphere, rather than between hemispheres. As a result, the size of the corpus callosum does not increase proportionately with the size of the brain. In addition, proportionately fewer of the callosal axons are of the larger diameters that would be needed to preserve fast conduction times. Therefore, large brains should be less symmetrical than small brains. The large human brain appears to be extreme in this respect.

Another issue is that large cortical areas are unlikely to function in the same manner as small cortical areas. Unless neurons compensate with larger dendrites and intrinsic connections as areas get larger, the computational window or scope of neurons will decrease. For example, as a visual area gets bigger, individual neurons would evaluate information from less and less of the total visual field (Fig. 44.10). This implies that as areas get bigger, their neurons become less capable of global center-surround comparisons and more devoted to local center-surround comparisons. Thus, some of the integrative functions of large areas must be displaced to smaller areas. It is also apparent that changes in the sizes of dendritic arbors and the lengths of intrinsic axons in smaller areas would have more impact on the sizes of computational windows of neurons. Comparable changes in dendrites and axons would enlarge or reduce receptive field sizes more in a small than a large visual area (Fig. 44.10). Because their functions are more modifiable by small structural modifications, smaller areas may be specialized more easily for different functions. Recent measurements suggest that neurons in large areas typically do not have longer dendritic arbors and larger intrinsic connections, and indeed, they may have smaller dendritic arbors. In addition, although primary sensory areas are often larger in larger brains, they are not enlarged in proportion to the rest of cortex (Fig. 44.11). Thus, the primary visual cortex is less than three times larger in human brains than in the brains of macaque monkeys, whereas the neocortex as a whole is over 10 times larger (Fig. 44.10). In humans, primary visual cortex is about the same size as in the much smaller chimpanzee brain. The general lack of proportional growth of cortical areas with brain size reduces the

**FIGURE 44.10** The effects of varying the horizontal spread of dendritic arbors of neurons in large (A) and small (B and C) visual areas. An increase in arbor size (1 to 2) in a large area (A) produces little change in receptive field size (circles 1 to 2 in the central 20° of the visual hemifield on the right), whereas such a change (B to C) in a small area changes the scope of the receptive field greatly. Thus, the functions of small areas are changed more dramatically by small morphological adjustments. Surface view schematics of retinotopically organized visual areas are on the left, whereas schematics of receptive fields in the visual hemifield and the lower visual quadrant are on the right. From Kaas (2000).

impact of the changing of functions of areas with size, and reflects the addition of other smaller cortical areas.

Other size-related constraints relate to mechanisms of development. We often assume that natural selection can act independently on each brain trait, but this is unlikely to be the case. Instead, selection may operate on a few developmental mechanisms, such as those that control the number of neurons or the extent to which correlated activity levels maintain functional connections. Along this line of reasoning, Finlay and Darlington (1995) have provided evidence that late-developing brain structures such as neocortex have enlarged disproportionately in mammals with larger brains (“late makes large”). As we learn more about

**FIGURE 44.11** Species differences in (B) the surface area of the neocortex and (A) of the primary visual cortex in one cerebral hemisphere. The neocortex of humans is over 500 times larger in surface area and over twice as thick as the neocortex in the smallest mammals that resembled those leading to the first primates and over three times the surface area of our closest living relatives, the chimpanzees. Some of the areas of the brain are also larger in humans, but not to the extent expected from the great enlargement of the neocortex. From Kaas (2000).

the genetics and mechanisms of development and how development is modified in evolution, we should be able to form more accurate models of brain evolution, and understand more fully how the human brain emerged from those of our ancestors. We might also benefit from considerations of other possible constraints on brain size. A larger brain creates more heat, and thus needs a better cooling system (Falk, 1990), and the higher metabolic costs of a larger brain may require a better diet or the reduction in size of other metabolically expensive tissues, such as the gut.

### **Beyond Brain Size: Variations in Neuron Densities, Neuron Types, and Local Connections**

Although brain size has important implications for brain function, distantly related species of about the same brain size sometimes appear to have quite different behavioral capacities. One reason, of course, is that the brains may be organized differently; sharing for example, some cortical areas but not others, or specializing shared cortical areas in different ways. Although more comparative studies are needed, it seems unlikely that large rodents with brains as large as those of some monkeys have as many cortical areas as the monkeys. Specializations of shared (homologous) areas are probably quite common. Primates, for example, exhibit a number of variations in the organization of primary visual cortex, including specializations found in apes and humans, but not monkeys, as well as specializations that are restricted to humans (Preuss *et al.*, 1999; Preuss and Coleman, 2002). At the cellular level, humans and apes are the only primates that have a type of neuron, the spindle cell, in the anterior cingulate and frontoinsular cortex (Watson and Allman, 2007). The functional significance of such variations in brain structure and organization is largely unknown, but these variations indicate that there is much to consider besides brain size.

Another important factor is that recent studies indicate that primate brains simply have many more neurons than rodent brains (and probably the brains of other taxonomic groups) of the same size (Herculano-Houzel *et al.*, 2007). This is because as the brains of rodents increase in size from small to large species, the density of neurons in the brain decreases, and so, the gain in neuronal numbers is not as great as one might expect. However, in primates, the neuronal density does not change very much with brain size so that more neurons are gained with each increase in brain size. If the same scaling rules relating numbers of neurons to brain size in rodents applied to primates, a human brain with about 100 billion neurons would

have to weigh over 45 kg., and be supported by a body the size of a blue whale. The greater neuronal densities in the brains of larger primates would seem to present an advantage in processing capacity that gives primates with larger brains a considerable advantage over rodents with large brains.

---

## CONCLUSIONS

---

Based on comparative studies and the fossil record, we conclude that early mammals had small brains with little neocortex and few functional subdivisions (areas or fields) of cortex. Vision was emphasized in the early primates, and the visual cortex in the temporal and occipital lobes enlarged. These primates also had several unique features of the visual system, including new visual areas such as MT, distinctive kinds of modules in V1 (blobs) and V2 (bands), separate magnocellular and parvocellular layers in the lateral geniculate nucleus, and a representation in the superior colliculus restricted to the contralateral visual hemifield. Several premotor areas were present, whereas the somatosensory system was relatively primitive. Later anthropoid primates had larger brains, more neocortex, and more areas of neocortex. The somatosensory cortex had expanded and included the four strip-like areas on the anterior parietal lobe, areas 3a, 3b, 1, and 2. We know little about possible specializations of the brains of apes. However, over the last 6 million years of evolution in the human lineage, brains increased three to four times in size, due mainly to the enlargement of the cortex. Although the relative proportions of the different cortical lobes remain similar in humans and apes, the available evidence suggests that the cortex did not expand uniformly in human evolution: the association regions of frontal, temporal, and parietal lobes are much larger in absolute terms in humans than in apes, whereas human primary sensory areas are about the same absolute size as those of apes. The expansion of nonprimary cortex was probably accompanied by a further increase in the number of cortical areas, modifications leading to functional and anatomical asymmetries in the two cerebral hemispheres, specializations for language and cognition, and larger expanses of prefrontal, parietal, and temporal cortex. The larger brains had many more neurons with a greater proportion of tissue devoted to connections relative to cell bodies, and presumably had a higher ratio of local connections to long-distance connections.

Further progress in understanding the course of the evolution of the human brain can be achieved with

current methods of investigation. We have the opportunity to learn much about the similarities and differences among the brains of various primates. Neuroscientists have generally concentrated on studies of brain features that are widely shared, but we need to know more about the differences in brain structure and function that make us distinctively human.

# Cognitive Development and Aging

The human brain has evolved over a very extensive period (Chapter 44), but an individual human brain develops rapidly over the first few years of life, allowing the nearly helpless human infant to gain control of locomotion, language, and thought. The story of brain development in the early years of infancy through adolescence occupies the first part of this chapter. This is followed by consideration of the cognitive changes that occur during this period of the life span and how these capacities are altered over the course of normal aging. The final parts of the chapter discuss pathological processes that (1) affect cognitive development in childhood and adolescence and (2) can cause devastating cognitive impairment in the elderly.

## BRAIN DEVELOPMENT

### Basic Concepts of Brain Development

#### *Brain Maturation Progresses Well into Adolescence*

Brain development is an organized, predetermined, and highly dynamic multistep process that continues beyond birth into the postnatal period, well into adolescence in humans. Most of our knowledge about human brain development has been obtained through analyses of postmortem specimens and, more recently, powerful neuroimaging techniques. These approaches have provided extensive information on how the size and shape of different brain regions change from conception through adulthood (Fig. 45.1). The brain grows rapidly in the first two years of life, by which time it has achieved 80% of its adult weight. Thereafter, brain growth is slower, reaching over 90% of average adult weight by the sixth year. The development of the ce-

rebral cortical surface proceeds gradually from the flat (lissencephalic) brain of the fetus to the adult gyral pattern at birth. Primary sulci (Sylvian fissure, and rolandic, parietal, and superior temporal sulci) and gyri (pre- and postcentral gyri, superior temporal and middle temporal gyri, superior and middle frontal gyri, and superior and inferior occipital gyri) become well defined between 26 and 28 weeks of gestation. Development of secondary and tertiary gyri occurs later in gestation, and in the last trimester the sulci become deeply enfolded.

Cortical development in most mammals is broadly divided into two phases. The first is a genetically determined sequence of events occurring *in utero* that can be modified by both the local environment within the fetal nervous system and the maternal environment. The second phase is one that occurs in the perinatal period when the connectivity of the cortex becomes sensitive to patterns of neural activity. Glial processes also critically participate in normal development, supporting cell proliferation, differentiation and guidance, and the formation of myelin sheets around axons. Brain structure size and developmental trajectories are highly variable and sexually dimorphic.

#### *The Cortex Thickens during Development*

Development of the cortical mantle in the human brain was documented extensively in the classic studies of Conel (1939–1963). Longitudinal neuroimaging studies in large samples of children (Lenroot and Giedd, 2006) have shown changes in volume of cortical gray matter that are nonlinear and regionally specific. Volume of gray matter increases during preadolescence with a maximum occurring around 10 to 12 years of age in the parietal lobe, 11 to 12 years of age in the frontal lobe, and 16 to 17 years of age in

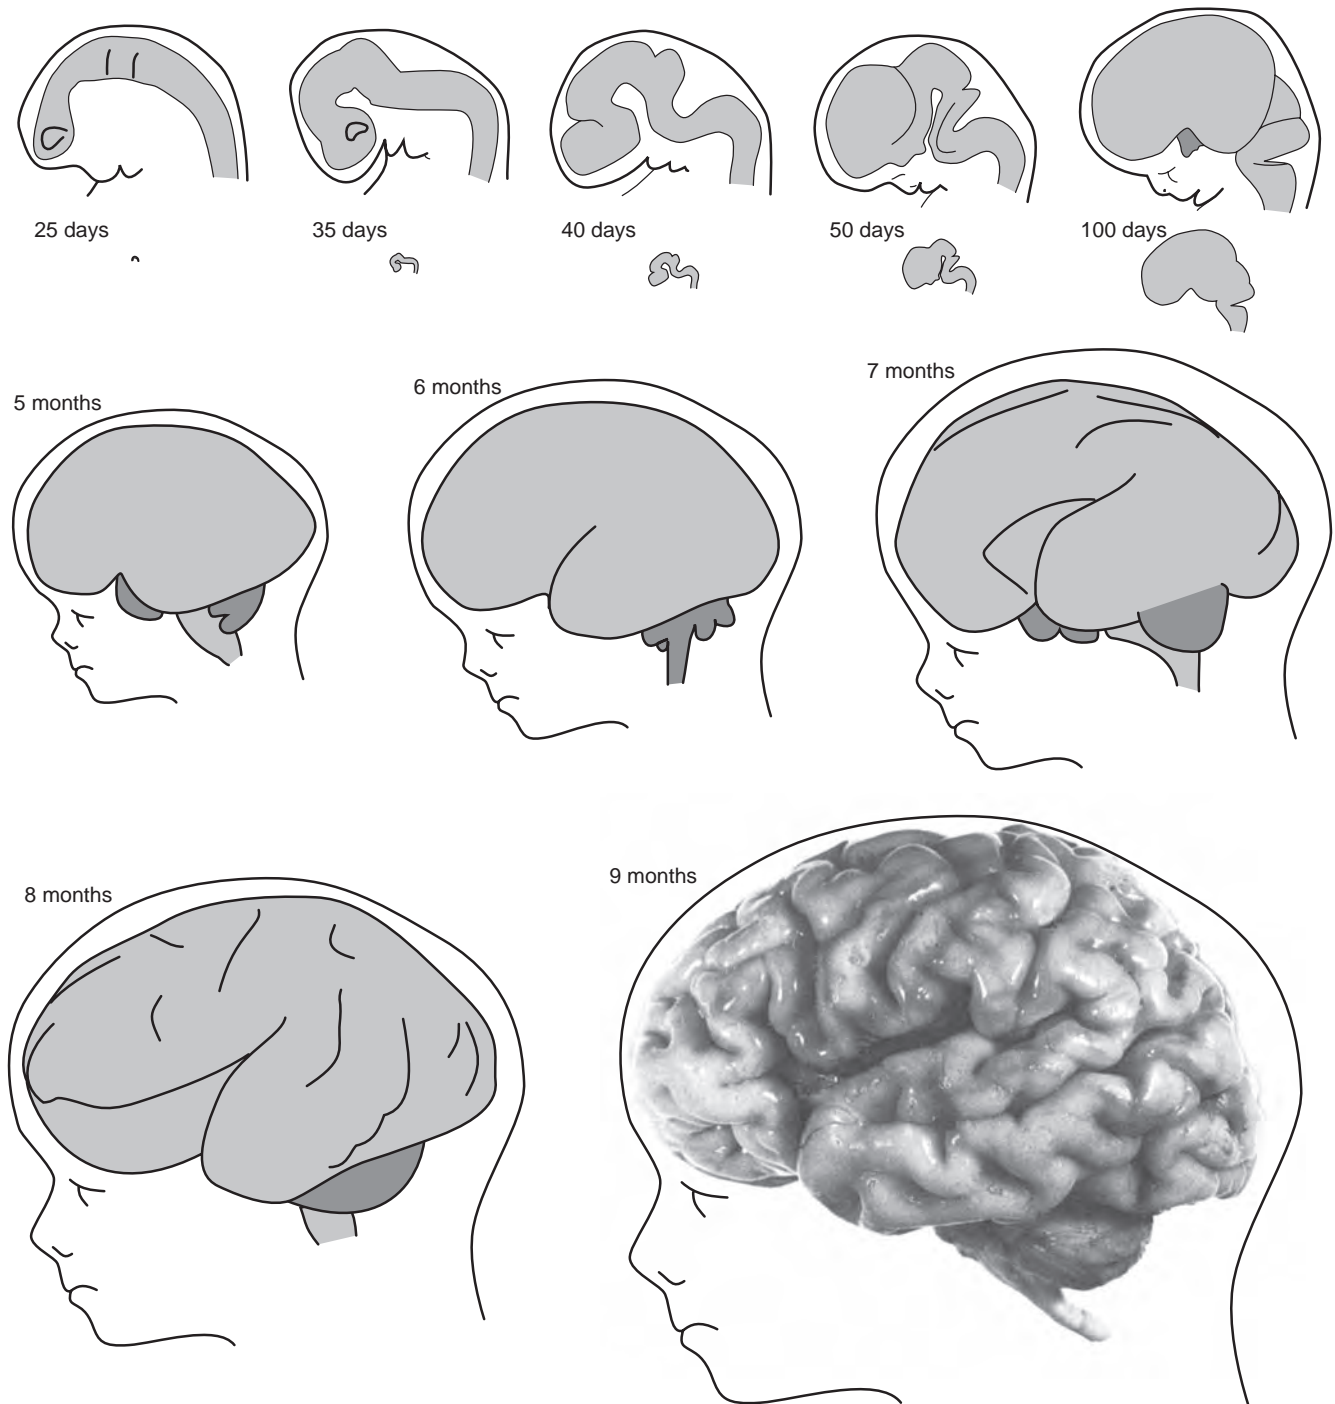

FIGURE 45.1 The size and form of the human brain as it develops through gestation and early infancy.

the temporal lobe, followed by a decline in post-adolescence. Although neuroimaging techniques lack the resolution to identify the specific structural modifications that underlie changes in cortical volume during development (i.e., cell number, synapse density, myelination), they do indicate that development of the human cerebral cortex differs in males and females, is

highly dynamic over time, and varies across different cortical areas.

#### ***Dendritic Spine Number Increases during Development***

The formation of dendritic spines and the time course of changes in the length and branching patterns

of dendrites have been described for visual and frontal cortical areas in humans. Within the visual cortex, peak spine density is achieved around 5 months of age; this number then decreases until adult values are obtained around 21 months of age. Progressive elongation of dendrites occurs up to 24 months. Thus, during the period from 5 to 24 months, the major event may be a decrease in spine density rather than an actual decline in total spine number. Dendritic development in the visual system reaches mature levels in deep cortical layers earlier than in superficial layers, displaying the “inside-out” pattern of development that is characteristic of neurogenesis and migration (Chapters 15 and 16).

Development and maturation of the frontal cortex proceed more slowly. Whereas neuronal density in the primary visual cortex (V1) reaches adult levels by 4 to 5 months, neuronal density in the frontal cortex fails to reach adult levels even at 7 years of age. Additionally, by 2 years of age, dendritic length in frontal cortex (which is mature by 18–24 months in V1) is only half that found in adults. Left–right asymmetries exist in the dendritic branching patterns of pyramidal neurons within layer V of the inferior frontal and anterior precentral cortex. During the first year, growth is more advanced on the right side, but by 6 to 8 years of age, the maturation of distal dendrites on the left exceeds that of the right.

### *Synapses First Increase and Then Decrease in Number*

As in the brains of other animals (Chapter 20), the immature human brain contains many more synapses than the mature brain (Huttenlocher, 1990). Within the primary visual cortex, synaptic density increases gradually during late gestation and early postnatal life, and then doubles from 2 to 4 months of age. After 1 year of age, however, there is a decline in synaptic density until adult values (50–60% of the maximum) are attained at about 11 years. The time course of the decrease in synaptic density varies across different cortical layers (Fig. 45.2). The decrease does not display the “inside-out” pattern of development; rather, there is a considerable decrease, over time, in the number of synapses in every layer. A postnatal increase and subsequent decline in synaptic density also occurs in the middle frontal gyrus (layer III), but these frontal cortex changes take place over a longer time course than in the primary visual cortex (Fig. 45.3). The maximum density of synapses occurs around 1 year of age (compared to 4 months in the visual cortex), and adult values are not reached until roughly 16 years of age (compared to 7–11 years for the visual cortex).

In summary, these quantitative anatomical results suggest that, in contrast to other animals (Chapter 19), programmed cell death plays only a limited role in

**FIGURE 45.2** Variations in the density of synapses of different cortical layers of the human primary visual cortex during development. Arrows point to the emergence of various visual functions in relation to the increase in synapses in the visual cortex. NB, newborn. Adapted with permission from Huttenlocher and De Courten (1987).

**FIGURE 45.3** Variations in the human prefrontal cortex during development: Density of synapses in layer III of the medial frontal gyrus (black circles) and resting glucose uptake (LCMRglc) in the frontal cortex (blue circles). Arrows point to the approximate periods of emergence of various prefrontal cortex functions. NB, newborn. Adapted with permission from Huttenlocker (1990) and Chugani *et al.* (1993).

human brain development. Synapse elimination in humans and other primates exceeds that observed in many species, however, suggesting that modifications in synaptic connectivity may be particularly important for the development of complex nervous systems. Current findings are consistent with a role for incoming afferent input in selectively stabilizing functional synapses and in eliminating or suppressing inactive contacts. The exuberant connectivity observed during development may also support compensatory processes in cases of early brain trauma, allowing surviving synapses to assume functions normally subserved by damaged inputs.

#### *Postnatal Refinement of Synaptic Contacts Occurs in the Neostriatum and Hippocampus as Well*

Although the morphological development of certain subcortical structures, such as the thalamus and cerebellum, is nearly complete at birth, other structures continue to mature into early postnatal life. In the neostriatum, synaptic density continues to increase until the end of the first postnatal month, and changes in neuronal and neuropil morphology are observed until 2 to 4 months postnatally. Refinement of synaptic contacts proceeds until the end of the first postnatal year when the striatal neurochemical mosaic attains adult characteristics. In the hippocampus, neurons have reached their destination at birth in all CA fields, but immature cells continue to accrue within the

dentate gyrus throughout the first year of life (Seress, 2001). In addition, continued dendritic remodeling in the hippocampus has been observed as late as the fifth postnatal year in humans (Seress, 2001). Myelination in the subicular and presubicular regions, a key relay zone between the hippocampus and many cortical areas, continues through adolescence and adulthood (Benes *et al.*, 1994) with female subjects showing a greater extent of myelination between the ages of 6 and 29 than males. These changes are accompanied by corresponding changes in the volume of the hippocampus during early development (Giedd *et al.*, 1996).

#### *White Matter Increases throughout Childhood and Adolescence*

In contrast to the inverted U shape of gray matter development, white matter maturation in the brain continues long after the gray matter has reached its definitive volume (Yakovlev and Lecours, 1967; Lenroot and Giedd, 2006). In general, myelination progresses from caudal to cephalic. Thus, the brain stem myelinates prior to the cerebellum and basal ganglia. Similarly, the cerebellum and basal ganglia myelinate prior to the cerebral hemispheres. Sensory and motor systems display mature myelination within the first two years of life. However, nonspecific thalamic radiations do not reach mature levels until 5 to 7 years of age, and intracortical fibers continue their myelination processes well into the third decade of

life. Numerous morphological studies demonstrate that the corpus callosum is uniformly thin in the first month postnatally. The genu and then the splenium undergo rapid growth spurts during the next five months, resulting in their characteristic “bulbous” appearance.

#### *Cerebral Metabolic Rate Increases and Then Decreases after Birth*

Increases in neuronal activity have been linked to increases in cerebral metabolism, as measured by neuroimaging techniques. Data show substantial subcortical activation in newborns, notably in the thalamus and phylogenetically old portions of the cerebellum, but little activation of the cerebral cortex. However, over the first 3 to 4 years of life, cortical metabolic rate increases until it reaches levels twice those observed in adults. After 4 years of age, metabolic activity declines gradually to adult levels at around age 15. The time course of the rise and decline of activity, as revealed by positron emission tomography (PET), varies across cortical regions but parallels the rise and decline in the number of synapses in these areas, suggesting that the exuberant cortical synapses observed during development are metabolically active. As these synapses are eliminated, metabolic activity decreases.

#### *Dorsolateral Prefrontal Cortex Is One of the Last Brain Regions to Develop*

Refinement in the circuit organization of the dorsolateral prefrontal cortex, like that of the hippocampal formation (see earlier discussion), continues until quite late in development. In the case of the dorsolateral prefrontal cortex, a gradual decline in synaptic density continues well into late adolescence and suggests that connectivity in this cortical region undergoes substantial change until 15 to 20 years of age. These changes are accompanied by a decrease in metabolic rate during the same period (Fig. 45.3). It is believed that changes in the neuromodulatory effects of dopamine may influence the adolescent refinement of excitatory and inhibitory inputs to layer III pyramidal neurons and that dopamine may have a particularly strong influence on cortical information processing around the time of puberty (for the relevance of this late prefrontal cortex development in the emergence of psychopathologic states, such as schizophrenia, see the section on pathological processes).

#### **Summary**

Structural, metabolic, and physiological indices of human brain development all point to a long postnatal time course that displays considerable variability from

region to region and from system to system. Thus, whereas postnatal development in the hippocampus proceeds until approximately 4 to 5 years of age, it continues until 7 to 11 years for the visual cortex and until around 16 years of age for the frontal cortical areas. The dorsolateral portion of the prefrontal cortex appears to be one of the last regions of the brain to develop. Interestingly, the development of myelin has been observed as late as the third to fourth decade of life for fibers within the association areas of the neocortex. Finally, brain structure size and developmental trajectories are sexually dimorphic.

## **COGNITIVE DEVELOPMENT AND AGING: A LIFE SPAN PERSPECTIVE**

Investigators are now attempting to link the types of neural changes described in the preceding section to the maturation of sensory, behavioral, and cognitive capacities in infants and children. Such studies are limited in number. Until recently, the predominant view was that postnatal development of the cortex is largely intrinsically determined. However, new studies of both animals and humans have revealed a central role for extrinsic factors in shaping the organization of neural systems and in permitting recovery from brain damage. Indeed, calculations showing that information in the genome is not sufficient to specify the connectivity of the brain, together with evidence for the long-lasting existence of transient, redundant connections in primates, suggest that neural changes under the influence of environmental input play a significant and persistent role in the development of functional specificity in the human brain.

### **Cognitive Development in the First Years of Life**

#### *Early Subcortical Behavioral Responses Are Inhibited by Cortical Development*

The increasing metabolic rate observed in basal ganglia and many cortical regions during the second and third postnatal months is correlated with several organizational changes that occur in the infant brain during this period. Thus, the frequency of several subcortical reflexes (e.g., the tonic neck reflex, the grasp reflex, as well as the frequency of endogenous smiles and spontaneous crying) decreases, presumably as a consequence of increased cortical drive on the brain stem centers that control these reflexes. A similar mechanism may underlie the observation that the risk of sudden infant death syndrome peaks during

this postnatal interval. Specifically, this syndrome is thought to be associated with a developmentally regulated increase in cortical inhibition of the brain stem centers that control normal respiration.

### *Anatomical Development of the Visual System in Infants Is Linked to Functional Development*

Several parallels have been noted between anatomical changes and the emergence of visual system function in humans. The visual abilities of the newborn have been linked to subcortical structures that show mature anatomy and high metabolic rates during this period. The limited visual abilities of the newborn are augmented by the appearance of smooth pursuit tracking around 6 to 8 weeks. The emergence of this capacity may be related to the maturation of cortical layers IV, V, and VI in V1 (Fig. 45.2). These layers connect magnocellular afferents from the lateral geniculate nucleus and the middle temporal (MT) region, a pathway important for the detection of visual movement. Visual acuity and visual alertness increase dramatically around 4 months of age, when the volume of visual cortex reaches adult levels and the highest density of synapses is present. Shortly thereafter, cortically mediated binocular interactions become apparent. These interactions, which include stereoacuity, binocular summation of the light reflex, and stereopsis (binocular depth perception), appear in the same time frame as maturation of the middle cortical layers and rapid synaptogenesis in V1. This period of rapid growth appears to be a time of increased vulnerability to altered afferent input. Strabismic amblyopia and amblyopia due to the absence of patterned input (i.e., centrally mediated visual impairments) are reported to occur at this age unless corrected early.

The time period during which visual impairments can be corrected is different for different visual functions. For example, correction for an absent lens (aphakia) due to cataracts may be completely effective only when performed prior to 2 months of age (i.e., just prior to the onset of exuberant synaptogenesis in V1). However, very high synaptic density persists to at least the age of 4 years in V1. The presence of this extensive connectivity may account for the ability to recover from amblyopia (with forced use of the strabismic eye) during this time. If the disruption of binocular convergence by strabismus is not corrected within the first year of life, the ability to see stereoscopically may not develop even though the development of acuity and contrast sensitivity is normal. Thus, there may be separate critical periods (Chapter 22) for the development of resolution acuity and stereopsis. Because the parvocellular system is thought to under-

lie acuity, whereas disparity detection is mediated by the magnocellular system, the magnocellular system may be more modifiable by environmental input than the parvocellular system. This differential sensitivity may be due to the slower maturation of the magnocellular system and/or to differences in the number of exuberant synapses within these systems.

Studies of individuals born deaf and blind suggest that in humans, as in other animals, there is a time period when cortical areas that normally process information from the deprived modality can be reorganized to process information from intact modalities. From the alteration of visual functions seen in individuals born deaf, it appears that areas of the auditory cortex have been recruited for visual function. Deaf subjects, by comparison, show abnormally strong electrical responses to peripheral visual stimuli. These responses are not found in normally hearing individuals, even those exposed to sign language by deaf parents. The prolonged persistence of exuberant cortico-cortico connections may provide the substrate for such cortical reorganization.

### *Development of the Ventral Visual Stream and Object Representation*

A multitude of visual cortical areas located in the striate and extrastriate cortex contribute to different aspects of visual processing (Chapter 46). These visual areas have been divided into two visual processing systems, one coursing ventrally from the striate and extrastriate areas to the ventrolateral temporal cortex and the other coursing dorsally from the striate and extrastriate cortex to the parietal cortex. The dorsal stream mediates spatial processing associated with attention to movement and location, whereas the ventral stream is involved primarily in processing information about patterns and objects. Both streams project rostrally, each reaching common and adjacent areas of the prefrontal cortex.

Major functions of the ventral stream include the ability both to segment a pattern into a set of constituent parts (local level of processing) and to integrate those parts into a coherent whole (global level of processing). In adults, systematic differences exist in the distribution of global and local levels of processing within the brain, such that global levels of processing are associated with the right posterior temporal region and local levels of processing with the left posterior temporal regions. Around 4 months of age, infants show hemispheric differences for global and local processing that are similar to adults. Thus, at this age, children segment out well-formed units and use simple associations to organize these units into a configura-

tion. With further maturation, children show changes in the way they decompose objects into parts and in the relations they use to organize the parts. These changes may reflect the protracted development of the posterior temporal cortical areas, a finding consistent with ERP studies in human infants indicating functional activation within the temporal cortical areas around 6 months of age. The latter observation parallels the emergence, around the same age, of object representation and visual rule learning (Alvarado and Bachevalier, 2000).

### *Development of the Dorsal Visual Stream and Spatial Attention*

A variety of spatial processes have been associated with activation of the dorsal visual pathway, such as the processing of information about spatial attention and spatial location (Chapter 47). Considerable clinical and experimental evidence shows that the posterior parietal lobe plays a crucial role in the ability to shift attention to different spatial locations. By at least 6 months of age, infants, like adults, show facilitated stimulus detection as a function of prior cueing; that is, they take less time to detect an object if it is presented at a location that has been cued previously. They also demonstrate, as do adults, quicker target detection when the interval between the cue and target is short than when this interval is long. Even though this basic attentional response may be robust as early as 4 months of age, the timing parameters that elicit the response change with development, suggesting that further maturational processes occur in the parietal cortex.

### *Precursors of Declarative Memory Emerge Early in Development*

Looking preference has been used to study the emergence of recognition memory ability in both human infants and monkeys (Bachevalier and Vargha-Khadem, 2005). In both species, the most common procedure is to first present the infant with an attractive stimulus for a period of time (generally 20 to 30s). After an intervening delay that can vary from a few seconds to many hours, the familiar stimulus is shown together with a new item. Human infants as young as 1 day old display a strong preference for looking at the novel object after delays as long as 24h, demonstrating that they recognize the previously presented item as familiar. The early emergence of recognition memory is also observed in infant monkeys and, in this species, surgical removal of the hippocampal formation and adjacent tissue before the age of 3 weeks disrupts this ability. The capacity for recall over long periods of time, as measured by nonverbal deferred imitation

tasks, also emerges by the end of first year in humans and is impaired after early hippocampal injury (Bauer, 2002; de Haan *et al.*, 2006).

The early emergence and continued improvement of recognition and recall abilities is consistent with what is known about maturation of the hippocampal formation in both humans and monkeys (see earlier discussion). In both species, the hippocampal formation is almost adult-like at birth, although there are a number of postnatal morphological refinements that continue until the end of the first year in monkeys and until about 4 to 5 years of age in humans. These protracted modifications in hippocampal circuitry, together with the further maturation of cortical areas in the temporal and prefrontal lobes, may provide a basis for the relatively late elaboration of certain capacities, including spatial and relational memory (Chapters 50 and 52) around 1 year of age in monkeys and 4 to 5 years of age in humans.

### *Orientation to Faces, Recognition of Mother's Face, and Imitation of Facial Expressions Are Present at Birth*

The human face is a powerful visual source of social information, and the development of face-processing abilities appears to follow a delayed postnatal development. Newborns preferentially orient to faces, recognize the mother and other familiar faces, and imitate facial expressions. These precocious tendencies appear to be mediated by a subcortical retinotectal pathway. For example, newborns display preferences selectively for moving stimuli presented in the peripheral visual field (i.e., under conditions that engage the subcortical systems), but not when they are displayed in the central visual field.

The fact that newborns just hours to days after birth look longer at the mother's face than a stranger's face (even when cues from her smell and voice are eliminated) indicates that, from very early on, there is a mechanism capable of learning about individual faces based on experience. This early learning system may be mediated by the hippocampal formation, as this area is known to be involved in memory and it matures early relative to memory-related neocortical areas (see earlier discussion). Nevertheless, the face-processing abilities of the newborn are qualitatively different than the sophisticated capacities present in the adult, and none of these tendencies are necessarily the direct precursors of the cortically mediated, adult face-processing system (Chapter 46). Instead, these responses might serve the purpose of providing input to developing cortical circuits that will at some later time functionally emerge to mediate face processing.

### *At 3 Months of Age Infants Are Able to Form Categories of Visual Stimuli*

A marked change in infants' visual attention to faces occurs at approximately 8 weeks of age. At this time, infants' preferential following of peripheral moving faces declines, and a preference emerges for fixating faces compared to other patterns presented in the central visual field. This behavioral change is thought to be due to the functional development of visual cortical pathways that inhibit the preferential following response and mediate the new preferential fixation response. At 2 months of age, infants become more sensitive to the internal facial features of static faces. In addition, within the face, the eyes are a more salient feature of the face than the nose or mouth, but where the eyes are located is immaterial to the babies' preference for face-like drawings. Furthermore, at roughly the same age, infants begin to relate information between individual faces and to form categories; that is, they perceive visual stimuli with comparable features as being more similar than visual stimuli with different features. They also exhibit inversion effects (i.e., recognition of upright faces is easier than recognition of inverted faces). The change between 1 and 3 months has been associated with the functional development of temporal cortical areas and their connections with the hippocampus and adjacent structures. However, at this early age, the change may not be specific to faces, as 3-month-old infants can form perceptual categories of a variety of other complex categories, such as tables and trees.

### *Hemispheric Differences in Face Processing Emerge around 4 Months of Age*

By 4 to 9 months, hemispheric differences in face processing emerge, as babies at this age move their eyes more quickly to the mother's face than a stranger's face when the stimuli are presented in the left visual field, but not when they are presented in the right visual field. In contrast, simple geometric shapes are discriminated equally well in either visual field. These results suggest that by this age the right hemisphere may be more proficient than the left in recognizing faces. Finally, during childhood, the child's prototype of the face becomes more tuned to the types of faces that the child sees most often, and with this may emerge race effects and other species effects seen in adult face processing. Other race effects refer to the ability to distinguish among faces of one's own race more quickly than faces of other races. Other species effects refer to the ability to distinguish between human faces more quickly than faces of other species. These last changes may be based on experience due to

increased exposure to faces, the number and type of features children attend to and encode, and the maturation of a posterior temporal cortical area (the fusiform area) that is known to be involved in face processing in adults.

### *Fear of Unfamiliar Faces Emerges between 7 and 9 Months*

Although infants are able to discriminate among some facial expressions of emotion by 3 months of age, they do have difficulty discriminating between sadness and surprise. It is only by 7 months of age that infants, like adults, show categorical perception of facial expressions. For example, with pictures of faces in which emotional expressions are progressively degraded from happy to fear, human infants and adults exhibit more accurate discrimination for pictures of faces that cross emotional categories (happy versus fear) than for pictures of faces within the same emotional category, despite equal physical differences in the pictures. With this increased ability to categorize faces, and the increased exposure to familiar faces, two remarkable events occur between 7–9 months of age: the emergence of fear for unfamiliar people and anxiety during temporary separation from the caretaker. Distress under both conditions must involve more than the ability to discriminate strangers from parents because 3 month-olds can make this discrimination, but do not show fear reactions.

One speculation concerning stranger and separation fear is that improvements in working memory, and an enhanced ability to retrieve memories of a past event, are required for the appearance of these reactions. This change appears to be associated with the maturation of the orbital frontal cortex (Schoore, 1996), a region of the prefrontal cortex intimately interconnected with limbic areas in the temporal lobe (temporal pole cortex and amygdala), with subcortical drive centers in the hypothalamus, and with dopamine neurons in reward centers in the ventral tegmental area. By the end of the first year, the initial phase of orbital frontal maturation is achieved and allows for developmental advances that enable the individual to react to situations on the basis of stored representations, rather than on information immediately present in the environment. In the case of the orbital frontal cortex, this capacity applies specifically to socioemotional information. Indeed, by 10 months, infants are first able to construct and store abstract prototypes of human visual facial patterns, and can use these prototypes to evaluate novel information.

In an illuminating experiment, a preferential looking task was used to habituate 10-month-old infants to pictures of faces. One condition presented faces of

different females, and in the other condition, the same female face was presented in various poses. After infants habituated to the stimuli (i.e., decreased their looking), they were given two test trials: one with a face of a familiar female and another with a face of a novel female. When infants were previously habituated using different female faces, they spent equivalent amounts of time gazing at familiar and novel faces on the test trials. However, when infants were habituated to the same face with different poses, they generalized their looking response to the familiar face but dishabituated (or looked longer) at the novel face. This pattern of results suggests that infants can abstract relevant categorical information by 10 month of age.

### *Changes in Visual Search Are Related to Development of the Prefrontal Cortex*

Infants younger than 7 or 8 months of age will not uncover a hidden object. If a cloth is thrown over a toy while an infant of 5 or 6 months is reaching for it, the infant will withdraw his or her hand and stop reaching. By 7 or 8 months, most infants who watch an object being hidden can retrieve it. However, if the infant then watches as the object is hidden at a second location, most infants of 7 to 8 months search for the object at its first hiding location, which is now empty. Jean Piaget called this the A-not-B error because the infant is correct at the first hiding place (A) but not at the second (B). It is rare to see this error when there is no delay between when the object is hidden and when the infant is allowed to reach. However, a delay as brief as 1, 2, or 3 s is sufficient to produce the error in infants 7 to 8 months of age. As they grow older, the error is still seen, but only if the delay between hiding and retrieval is increased. The A-not-B error suggests that during the second half of the first year the brain has matured sufficiently to enable the infant to hold a representation of the object's location in mind (working memory) for a few seconds (Chapter 52) or to understand the relationship of (a) their previous action of retrieving the object, (b) the subsequent hiding of the object in a different location (even though they observed the hiding), and (c) the object's present whereabouts (Diamond, 1990). The enhanced working memory observed in the 7- to 10-month-old infant parallels the protracted maturation and refinement of dorsolateral prefrontal cortex circuitry (Fig. 45.3). After 12 months of age, it is difficult to elicit the A-not-B error.

### *Language Undergoes Rapid but Prolonged Development*

In humans, the prolonged structural, metabolic, and neurophysiological maturation of "association" cortical

areas, which continues well into adolescence, provides the substrate for the panoply of higher cognitive functions that continue to develop during this time. Attempts have been made to link the very rapid development of speech and language skills over the first three years of life to these general changes. This goal has remained elusive, probably because so many aspects of the brain and behavior are changing together. Moreover, key elements of language appear to be processed at cellular and synaptic levels of organization that are difficult to investigate in humans with even the most sophisticated techniques available.

There is wide agreement that language is strongly dependent on structures within the left perisylvian region (Chapter 51). Very early on (by 28 weeks of gestation), structural asymmetries appear between the temporal lobes; these may provide the substrate for the functional asymmetries that appear later. The rapid and early acquisition of phonological information and speech production and comprehension, and the subsequent burst in size of the vocabulary, may be linked to the rapid rise in the number of synapses and the marked increases in cortical metabolism that occur during the second year of life. Also, the persistence of large numbers of exuberant synapses through adolescence may provide the anatomical substrate for prolonged neural plasticity and recovery of language skills following cortical damage in the first decade of life. It is well established that language skills can display considerable recovery following large lesions involving the left hemisphere during the first 7 to 10 years of life. The impressive language recovery in children who have undergone left hemisphere removal is even more striking in light of the enduring impairment seen in specifically language-impaired children or the reading difficulties encountered by dyslexics, in whom macroscopic aspects of brain structure are basically normal. These findings underscore the importance of characterizing microscopic structural aspects of the brain and the functional organization of the brain in relation to processing.

The prolonged time course of development that may confer plasticity on the immature brain appears to be characterized by optimal or critical periods (Chapter 22) for language acquisition. Several studies report that both first and second language acquisitions are impaired, and cerebral organization is altered, when language is acquired after the first decade of life. Moreover, as has been observed for vision (Fig. 45.2), different aspects of language appear to display different critical periods. Vocabulary items can be acquired long past the first decade of life, but the grammatical rules of a language appear to be acquired most readily before the age of 10. Along with other evidence, this

pattern suggests that different neural systems, with differing developmental time courses, mediate these various aspects of language.

## Summary

Cognitive development parallels some of the most important changes in brain development. Thus, the visual abilities of the newborn are limited and control by subcortical systems predominates. With the maturation of visual cortical areas in the first few postnatal months, visual acuity, visual alertness, and stereopsis develop. With further development of visual cortical areas within the temporal lobe, an infant's ability to recognize faces using internal facial features, mostly the eye region, emerges around 3 months of age. However, it is only by 7 to 9 months of age that infants develop fear of unfamiliar people. It is believed that this behavior is associated with the development, around this age, of the orbital frontal cortex, a cortical area that enables the infant to react to situations on the basis of stored representations (working memory). The enhanced spatial working memory abilities observed by the middle of the first year parallel the protracted maturation and refinement of the dorsolateral prefrontal circuitry. Finally, the maturation of association areas of the cortex, which continues well into adolescence, provides the substrate for the development of higher cognitive functions, such as language. In the future, it will be possible to analyze the neural basis of cognition in increasing detail by using high-resolution methods for imaging brain structure and function in normally developing children and children with specific structural or functional deficits.

## Cognitive Aging

### *Average Human Life Expectancy Has Increased Dramatically*

The world's population is growing older. Whereas life expectancy in the United States was approximately 50 years in 1900, infant mortality rates decreased dramatically during the last century, and combined with advances in disease prevention and treatment, current life expectancy is approaching 80 years in most industrialized countries. A significant demographic trend is that the percentage of the population over 65 years of age is projected to double over the next several decades, with particularly rapid growth among those over 85. Neurodegenerative disorders such as Alzheimer's disease are among the most devastating consequences of growing older (see section on Dementia, this chapter). There is increasing recognition, however, that many otherwise healthy aged individuals experi-

ence deficits in memory and other aspects of cognitive function that, although less severe, significantly compromise the quality of life. The following sections outline key concepts that have emerged from the study of normal cognitive aging in the absence of frank disease.

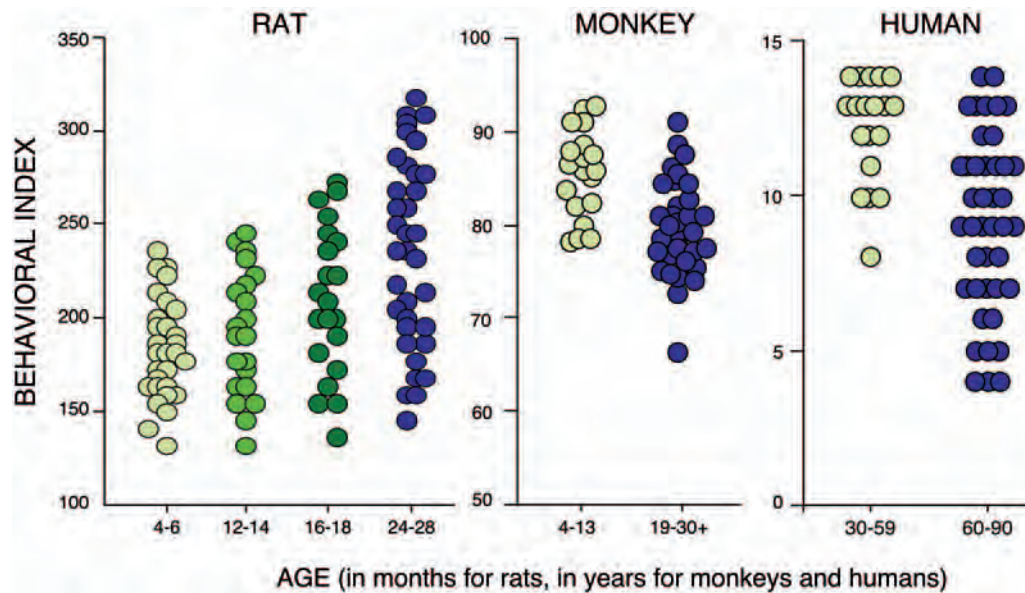

### *Effects of Normal Aging on Memory Are Variable*

Cognition encompasses a variety of dissociable capacities mediated by partially distinct neural systems, including perception, attention, executive function, and memory (Section V). This organization yields a valuable framework for the study of cognitive aging. Through careful analyses aimed at documenting the specific types and severity of cognitive deficits that accompany aging, neuropsychological research has provided important clues about the brain systems that are likely to mediate dysfunction. This strategy has been widely exploited to examine the effects of normal aging on learning and memory, where a rich background of information is available concerning the characteristics of impairment that follows damage to selective brain regions in young adults.

An important concept to emerge from neuropsychological studies is that the effect of aging on the type of memory mediated by the hippocampal formation and related medial temporal lobe structures is highly variable among older individuals (Figure 45.4). In humans and animal models, memory ability among the aged is continuously distributed across a broad range such that some individuals exhibit considerable impairment while others—at the same chronological age—perform as well as young adults. Long considered a complicating factor in gerontological research, this variability suggests the important conclusion that marked deterioration in memory is not an inescapable consequence of growing older and that in a substantial proportion of aged individuals, the functional integrity of the medial temporal lobe system is preserved. The next section considers findings from animal models that support this perspective, and that have guided efforts to identify the neurobiological alterations that account for individual differences in normal cognitive aging.

### *Animal Models of Cognitive and Neurobiological Aging*

As described in Chapter 50, normal adult rats solve the spatial, or "place," version of the Morris water maze by learning and remembering the escape location in relation to the configuration of cues surrounding the testing apparatus, and this capacity requires the functional integrity of the hippocampal formation. Guided by this background, many laboratories

**FIGURE 45.4** The status of memory varies considerably across aged individuals. The data comprise a summary measure of spatial memory in rats (courtesy of M. Gallagher, Johns Hopkins University), object recognition memory in monkeys (courtesy of P. Rapp, Mount Sinai School of Medicine), and delayed recall in humans (courtesy of M. Albert, Johns Hopkins School of Medicine). For rats, low scores represent better memory, and high values reflect better performance in monkeys and humans. Symbols signify scores for individual subjects. Note that in all species the status of memory among the aged is distributed across a broad range, from individuals that score on a par with the best young adults to other individuals that exhibit substantial impairment.

have used the Morris water maze and other tests of spatial information processing to examine the effects of aging on learning and memory that are mediated by the hippocampal system (Rosenzweig and Barnes, 2003).

Rats generally are considered “aged” at approximately 24 to 28 months of age, roughly equivalent to humans in their 70s. Relative to young adults, aged rats are significantly slower to learn the hidden platform location in the place version of the water maze. Although these findings are consistent with a possible hippocampal contribution to cognitive aging, an important alternative is that impaired visual acuity, motor function, or other factors might account for the deficits observed in older subjects. This possibility has been tested using control procedures that make many of the same sensory, motor, and motivational demands as the hidden platform task, but that lack an explicit spatial learning component. In a common variant of testing, for example, rats swim to a platform that protrudes above the surface of the water, providing a salient visual goal to guide navigation. Because the position of the cued platform is varied randomly across trials, learning and memory for spatial information are not required. Many aged rats acquire this task normally, demonstrating that they can swim as rapidly as young adults, are motivated to escape, and retain sufficient visual acuity to support cue-directed navigation

(Gallagher *et al.*, 1993). Thus, although certain aspects of motor and visual function are susceptible to age-related decline, these impairments fail to explain the deficits that aged rats exhibit in the spatial version of the water maze. Rather, the overall profile that emerges during aging—impaired learning and memory for spatial information against a background of intact goal-approach learning—is qualitatively similar to the effects of damage to the hippocampal system in young subjects. Results from other testing procedures confirm that learning and memory mediated by the hippocampus and related brain structures are susceptible to an age-related decline (Rosenzweig and Barnes, 2003).

As noted earlier, research in animal models has revealed substantial individual variability in the cognitive outcome of aging. Figure 45.4, for example, illustrates individual learning scores for large numbers of young, middle-aged, and aged rats tested in the spatial version of the water maze. The performance measure in this case reflects the average of each rat’s distance from the escape platform, assessed over the course of multiple trials. Accordingly, low scores represent better learning focused on the escape location. Similar to the distribution of performance observed in humans, spatial learning scores for aged rats are distributed continuously across a broad range such that some perform as well as even the most proficient young subjects. By comparison, approximately half the older

animals exhibit marked deficits, scoring outside the range of the young adult group.

Variability in the cognitive effects of aging has been documented in other animal models as well. The neuropsychology of aging in nonhuman primates has been examined using testing procedures adopted from studies on the effects of medial temporal lobe damage in young adult monkeys (Chapter 50). In the delayed nonmatching to sample task, subjects are tested for their ability to recognize a visual stimulus across delay intervals ranging from seconds to many minutes or more. Young adult monkeys with sufficiently extensive damage to any component of the medial temporal lobe memory system display significant deficits on this task, particularly when the memory demands are increased by lengthening the retention interval. Recognition memory also declines during aging in the monkey, and as in humans and rats, the degree of impairment varies substantially across individual subjects (Fig. 45.4). As discussed in the next section, this variability makes it possible to ask what neurobiological alterations distinguish the brains of individuals with age-related memory impairment from other, age-matched subjects with preserved function. By this approach the aim is to identify those changes in the structure and physiology of the aged brain that are specifically coupled to individual differences in the cognitive outcome of normal aging.

## Neurobiology of Age-Related Memory Decline

### *Age-Related Learning and Memory Impairment Is Associated with Compromised Hippocampal Physiology*

Behavioral studies suggest that the functional integrity of the hippocampal system declines during aging. Electrophysiological investigations extend these observations by directly assessing the computational processing functions of the aged hippocampus. Models of learning-related cellular plasticity, such as hippocampal long-term potentiation (LTP; Chapter 49), establish a useful background against which to explore the effects of aging. A prominent theme is that aging influences hippocampal physiology in a highly selective manner that spares many properties of hippocampal function (Burke and Barnes, 2006; Wilson *et al.*, 2006). Parameters that exhibit little or no change in older subjects include the resting potential, the input resistance, and the amplitude and duration of evoked action potentials of principal hippocampal neurons. By comparison, although the peak magnitude of LTP is comparable in the young adult and aged hippocampus, the intensity and frequency of stimulation necessary to achieve that response increase with advanced age.

Once established, LTP also decays to prepotentiated baseline levels more rapidly in aged subjects than in young animals. This enhanced rate of decay is correlated with the rapid forgetting aged rats exhibit on tests of spatial memory, consistent with the conclusion that a reduced capacity for synaptic enhancement in the hippocampus contributes to this behavioral deficit. Recent studies also reveal significant change in hippocampal long-term depression (i.e., an enduring decrease in synaptic efficacy; LTD), demonstrating that multiple plasticity mechanisms are affected in relation to variability in the cognitive outcome of aging.

Electrophysiological studies of ongoing neuronal activity in awake-behaving rats shed additional light on how normal aging influences hippocampal information processing. As described in Chapter 50, a particularly well-characterized phenomenon is that the firing rate of individual pyramidal neurons in the hippocampus increases dramatically as animals navigate through a restricted area within a testing environment. This “place field” activity is largely independent of specific behaviors exhibited during exploration, and instead seems to be controlled by geometric relations between the multiple sensory cues that define a particular spatial location. Recapitulating a theme from studies of LTP and LTD many aspects of place field firing remain relatively normal in the aged hippocampus, including the percentage of neurons that exhibit location-specific firing, and the spatial selectivity of place fields. The informational content encoded by the aged hippocampus, however, is reliably altered (Burke and Barnes, 2006; Wilson *et al.*, 2006). For example, hippocampal pyramidal cells in old rats are abnormally prone to confuse familiar environments that share certain stimulus elements, unpredictably engaging the wrong distribution, or “map,” of place fields during successive bouts of exploration in a given setting.

Related findings demonstrate that hippocampal encoding also becomes increasingly rigid with age such that a relatively narrow subset of available spatial cues comes to control place field activity. These changes are more prevalent in the CA3 field of the hippocampus than in CA1, and among aged individuals that demonstrate impaired spatial learning (Wilson *et al.*, 2006). Research on the structural integrity of the hippocampus, discussed in the following sections, points to a potential link between the behavioral and electrophysiological consequences of aging.

### *Early Findings Suggested Neuron Loss Is Distributed Diffusely throughout the Aged Brain*

One of the most widely held notions about brain aging is that a substantial number of neurons

inevitably die as we grow older. Early studies supported this view, suggesting that neuron death occurs throughout life, with the cumulative loss exceeding 50% in many neocortical areas by age 95 (for an historical review, see Brody, 1970). Although not all brain regions seemed affected to the same degree, significant age-related neuron loss was reported for all regions examined, including both primary sensory and association areas of the cortex. On the basis of these early observations, it seemed reasonable to suppose that widely distributed neuron death might account for many of the cognitive deficits associated with normal aging. A significant concern, however, was that the finding of widespread neuronal loss might be attributable to preclinical dementing disease in an unknown proportion of the aged individuals who were examined. This confound is overcome effectively in studies using animal models of cognitive aging because rats and monkeys do not develop dementia spontaneously. In addition, as described next, advanced quantitative tools for examining neuron loss in the aged brain are now widely available.

#### ***Memory Impairment during Normal Aging Does Not Require Substantial Hippocampal Neuron Loss***

Improved methods for quantifying cell number have led to significant revision in traditional views on age-related neuron loss (Morrison and Hof, 1997). Until recently, most investigators had focused on cell density, defined as the number of neurons present in a fixed area or volume of tissue. A significant limitation of this approach, however, is that density can vary widely in the absence of any actual difference in cell number. Assume, for example, that total neuron number is identical in two brains, but that the overall size of the brains differs due to normal biological variability among individuals, gliosis, white matter abnormalities, or other neuropil alterations. Under these conditions, neuron density will be lower in the larger brain, simply as a consequence of the cells being distributed in a larger volume. In this way, real or processing-related volumetric differences between young and aged brains could substantially influence cell density in the absence of any actual age-dependent difference in neuron number.

The field of stereology has provided standardized tools for directly estimating the total number of neurons in any defined brain region, yielding an unequivocal measure for examining potential neuron loss during normal aging (Box 45.1). In contrast to early studies measuring cell density, the conclusion from recent investigations using modern stereological methods is that the total number of principal neurons

(i.e., the granule cells of the dentate gyrus and pyramidal neurons in the CA3 and CA1 fields) generally is preserved in the aged hippocampus. Substantial preservation also has been documented in adjacent parahippocampal cortical regions that critically participate in memory. Whereas similar results have been observed in humans, data from animal models of cognitive aging are particularly compelling in demonstrating that hippocampal neuron number remains stable even among aged individuals with pronounced learning and memory deficits. As illustrated in Figure 45.5, for example, stereological analyses have revealed that the total number of neurons comprising the hippocampal region is comparable in young adult subjects and aged rats, regardless of their capacity for spatial learning and memory. Prompted by such observations, researchers have looked toward changes in synaptic connectivity and other markers of functional deterioration as a more likely basis for normal cognitive aging.

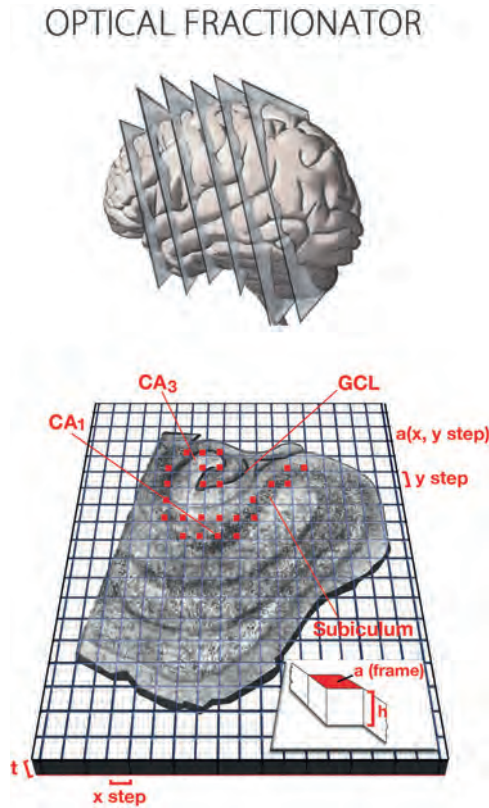

#### ***Hippocampal Connectivity Is Compromised during Normal Aging***

The entorhinal cortex originates the major source of cortical input to the hippocampus, giving rise to the so-called perforant path, which synapses on the distal dendrites of dentate gyrus granule cells in the outer portions of the molecular layer. The same entorhinal cortex neurons also innervate other fields of the hippocampus, including the most distal aspects of CA3 pyramidal cell dendrites. Multiple lines of investigation suggest that the integrity of these inputs is compromised with age. Electron microscopic quantification using modern stereology, for example, has documented that aging is associated with significant loss among a morphologically distinct subset of synapses in the outer molecular layer of the dentate gyrus (i.e., the zone innervated by the entorhinal cortex) (Geinisman *et al.*, 1992), together with alterations of synaptic structure (e.g., decreased postsynaptic density length) in other hippocampal subfields. Input originating in the entorhinal cortex conveys much of the neocortically derived information that the hippocampus processes in support of normal learning and memory, and accordingly, it is reasonable to suppose that the disruption of entorhinal–hippocampal connectivity might contribute to the cognitive outcome of aging. Consistent with this proposal, the magnitude of the morphological alterations observed in the hippocampal termination zones of the entorhinal cortex is greatest among aged animals with documented deficits on tasks that require the hippocampus and among older rats that exhibit abnormalities in various physiological measures of hippocampal plasticity.

## BOX 45.1

## THE OPTICAL FRACTIONATOR STEREOLOGICAL METHOD

The figure shows the key features of a stereological technique designed to provide accurate and efficient estimates of total neuron number in a brain region of interest. The hippocampal formation is used as an example. The method consists of counting the number of neurons in a known and representative fraction of a neuroanatomically defined structure in such a way that each cell has an equal probability of being counted. The sum of the neurons counted, multiplied by the reciprocal of the fraction of the structure that was sampled, provides an estimate of total neuron number.

Serial histological sections are prepared through the rostrocaudal extent of the hippocampus and are stained

by routine methods for visualizing neurons microscopically. An evenly spaced series of the sections is then chosen for analysis (positions represented schematically in top panel). This first level of sampling, the “section fraction,” therefore comprises the fraction of the total number of sections examined. For example, if every tenth section through the hippocampus is analyzed, the section fraction equals 1/10. The appropriate sections are then surveyed according to a systematic sampling scheme, typically carried out using a microscope with a motorized, computer-controlled stage. The lower part of the figure illustrates this design in which the microscope stage is moved in even X and Y intervals, and neurons are counted within the areas defined by the small red squares (“a (frame)” in the inset). The second level of the fractionator sampling scheme is therefore the “area fraction,” or the fraction of the XY step from which the cell counts are derived.

The last level of sampling is counting cells only within a known fraction ( $h$ ) of the total section thickness ( $t$ ), avoiding a variety of known errors introduced by including the cut surfaces of the histological preparations in the analysis. This is accomplished using a high-magnification microscope objective (usually 100X) with a shallow focal depth. In the illustration provided, the “thickness fraction” is defined as  $h/t$ . Neurons are counted as they first come into focus, according to an unbiased counting rule, called the “optical disector,” that eliminates the possibility of counting a given cell more than once.

Finally, total neuron number in the region of interest ( $N$ ) is estimated as the sum of the neurons counted (sumQ), multiplied by the reciprocal of the three sampling fractions; the “section fraction,” “area fraction,” and the “thickness fraction.” For the present example, the total estimated neuron number is given by

$$N = (\text{sumQ}) \times (10/1) \times (XY\text{step area}/a(\text{frame})) \times (t/h).$$

Original illustration design by L. E. Mekiou and P. R. Rapp.

### *Executive Function Mediated by the Prefrontal Cortex Declines during Normal Aging*

Normal aging is sometimes thought of as a generalized process of nonspecific deterioration across many neural systems, implying that age-related cognitive decline might be the cumulative effect of subtle altera-

tions distributed diffusely throughout the brain. There is actually little empirical support for this notion, however, and as we have seen in the case of hippocampal circuitry, the current perspective is that the neurobiological consequences of aging exhibit considerable selectivity. At the same time, it is important to recognize that the effects of aging on memory do not occur

**FIGURE 45.5** Estimated total neuron number (plus S.E.) in principal cell layers of the hippocampus and parahippocampal cortices (i.e., entorhinal, perirhinal, and postrhinal) for behaviorally characterized young and aged rats. All values are unilateral. Half of the aged rats exhibited substantial spatial learning deficits in the Morris water maze (aged impaired); the other half performed within the range of learning scores for the young group (aged unimpaired). Neuron number is stable with age and across a broad range of learning capacities. Adapted with permission from Rapp and Gallagher (1996) and Rapp *et al.* (2002).

in isolation and that cognitive capacities mediated by other neural systems are also susceptible to decline.

As discussed in Chapter 52, the functionally and neuroanatomically heterogeneous areas comprising the prefrontal cortex support a constellation of capacities referred to as “executive function.” Whereas damage to these regions does not produce the frank amnesia that follows medial temporal lobe lesions, significant deficits are observed in a variety of processing functions that influence memory, including the strategic use and manipulation of remembered information, the ability to identify the source from which information was acquired, and the order in which it was presented. It is therefore of interest that a qualitatively similar profile of deficits emerges during the course of normal aging (Gallagher and Rapp, 1997). Elderly humans, for example, frequently experience difficulty recalling the original source of remembered information, even under conditions in which recollection of a target item is successful. These failures in “source memory” predict performance on other tests of frontal lobe function, including memory for temporal order, suggesting that a common neurobiological basis might underlie these deficits.

Neuropsychological studies in animal models reinforce the conclusion that prefrontal cortex dysfunction contributes to certain features of cognitive aging. One of the best-documented deficits associated with aging in monkeys, for example, is poor performance under testing conditions that emphasize the spatial and temporal, or the “where and when,” components of memory (Gallagher and Rapp, 1997). In the classic delayed response task, subjects observe while a food treat is hidden in one of two locations that are then covered with identical plaques (Fig. 52.5). Because each of the reward locations are baited frequently across trials within a single test session, there is substantial opportunity for interference, and accurate performance depends on the ability to keep in mind the spatial location that was baited most recently. Damage involving the dorsolateral prefrontal cortex in young monkeys produces impairment at retention intervals of just a few seconds or more in the delayed response procedure. Impairment on this task following lesions of the hippocampal system, in contrast, is selectively observed at longer delays.

Numerous studies since the late 1970s have documented that aged monkeys exhibit a profile of delayed

response deficits qualitatively similar to the effects of prefrontal cortex lesions in young animals. Additional signs of prefrontal decline have also been documented in the aged monkey, including marked perseveration and behavioral rigidity when older subjects are confronted with shifting task contingencies. For example, whereas young adult monkeys quickly cease responding to a previously positive stimulus when it is no longer rewarded, aged subjects are slower to make this behavioral adjustment.

Are the effects of normal aging on capacities mediated by the prefrontal cortex coupled to other signatures of cognitive decline, consistent with the view of aging as a process of generalized deterioration? Available evidence suggests that this is not the case. For example, age-related deficits on tests of prefrontal cortex function tend to emerge earlier during the course of aging than alterations in declarative memory supported by the medial temporal lobe system. In addition, when impairments indicative of both frontal and medial temporal lobe dysfunction cooccur in the same subjects, these effects are statistically unrelated to each other (Gallagher and Rapp, 1997). This issue has been examined by testing healthy elderly people on a neuropsychological battery that includes assessments of both frontal lobe function and declarative memory. Results from this type of experiment indicate that whereas measures of information processing within each domain are correlated with each other (e.g., the severity of impairment on different tests of hippocampal memory are correlated), there is no apparent relationship in performance across tests of frontal and medial temporal lobe function. Thus, different aspects of cognitive function can decline independently during aging and these effects are not the consequence of a global, brain-wide degenerative process.

#### *Neurobiology of Aging in the Prefrontal Cortex*

Although the basis of age-related decline in capacities supported by the prefrontal cortex remains to be established, an outline has begun to emerge. Similar to the hippocampal system, neuron death is not a prominent feature of normal aging in frontal lobe areas that mediate information processing functions known to decline with age. Other structural alterations have been documented, however, including a substantial decline in the density of prefrontal cortex synapses, marked changes in dendritic architecture, and a variety of abnormalities in the myelination of axons (Peters *et al.*, 1998). These parameters are correlated with behavioral signatures of cognitive aging in monkeys, raising the possibility that, like the hippocampal system, changes in the organization of critical prefrontal circuitry may play a significant role. Results from

*in vivo* imaging studies in humans support this interpretation, and moreover, suggest that the functional organization of the aged brain may be more dynamic than previously presumed.

Gerontological research traditionally has focused on the nature and severity of age-related impairment with the implicit assumption that capacities found to be resistant to aging reflect a preservation of the same mechanisms that support these abilities in younger individuals. A number of investigations, however, have demonstrated that, rather than exhibiting a simple pattern of regional decline or maintenance, normal aging is associated with a reliable shift in the relative balance of activations in brain areas important for normal cognitive function, including the prefrontal cortex and medial temporal lobe. Indeed a profile of increased prefrontal and blunted medial temporal activation has been observed even under conditions where aged people score as accurately as young adults. These findings imply that the distribution of neural systems engaged during testing is altered significantly over the course of normal aging, and that successful cognitive outcomes may rely, in part, on adaptive functional reorganization (Hedden and Gabrieli, 2005). Intervention aimed at harnessing this dynamic capacity in support of optimally healthy cognitive aging is an area of active investigation.

#### *Neurochemically Specific Subcortical Systems Are Susceptible to Aging and Positioned to Broadly Influence Behavior*

Current evidence challenges the view that normal aging is associated with generalized deterioration distributed diffusely throughout the brain. It should be noted, however, that aging does affect the integrity of neurochemically specific classes of cells whose ascending projections influence widespread brain areas. Cholinergic cell groups in the basal forebrain have been studied particularly intensively because this system exhibits pronounced degeneration in Alzheimer's disease. Less severe effects are also observed during normal aging, involving acetylcholine-containing neurons that project to the hippocampus, amygdala, and neocortex. A significant implication is that cholinergic cell loss might disrupt the information processing functions of these target regions, and consistent with this possibility, reliable correlations have been reported between the magnitude of cholinergic deficits and behavioral impairment in aged individuals. Cholinergic abnormalities alone, however, fail to account for the full profile of cognitive deficits observed during aging since neurotoxin lesions that selectively destroy these neurons fail to reproduce key features of the behavioral decline observed in older individuals. One possibility is

that age-related cholinergic impairment comprises an important component of a broader constellation of alterations that leads to cognitive dysfunction. Other neurochemical systems that might contribute include dopamine-containing circuitry that originates in mid-brain cell groups and noradrenergic inputs that arise from the locus coeruleus. These systems innervate a variety of more anterior brain regions, and consistent with this broad distribution, neurochemical alterations have been linked to a diverse array of behavioral deficits ranging from age-related cognitive impairment to disturbances in motor function. These findings encourage the view that appropriately designed pharmacological interventions might have beneficial effects on a similarly broad profile of outcome measures of aging.

### Summary

This section considered the cognitive and neurobiological effects of normal aging in humans and animal models. Key themes include the observation that the impact of aging on memory varies widely from one individual to the next. Whereas neuron death was once presumed to be the proximal cause of many cognitive deficits associated with aging, including impairments in learning and memory, it is now clear that age-related cognitive decline does not require marked neuron loss in the hippocampus and related cortical areas. Instead, it now appears that subtle alterations in connectivity, and downstream changes in cellular function, are more likely the causative factors. Building on advances from *in vivo* imaging studies, a comprehensive, neural systems account of normal cognitive aging is beginning to emerge.

## PATHOLOGICAL PROCESSES IN COGNITIVE DEVELOPMENT AND AGING

---

### Developmental Psychopathologies

Research in this field focuses on elucidating the interplay among the biological, psychological, and social-contextual aspects of normal and abnormal development across the life span. Recent advances in neuroimaging and gene linkage technology have vastly expanded research possibilities for noninvasive clinical studies. Even with a new arsenal of research technologies, however, it has not been possible to isolate and define characteristics of each developmental disability. Such efforts are limited by several factors:

1. Disagreement regarding the criteria for diagnosis. Because different researchers often use differing

- behavioral criteria, cross-study comparisons frequently show inconsistencies in results.
2. Heterogeneity of disorders. Even when consistent behavioral criteria are carefully applied, different underlying etiologies can result in the same behavioral profile.
3. Difficulties inherent in the study of children. Although modern brain imaging techniques such as magnetic resonance imaging are considered noninvasive, they are stressful and time-consuming, and parents will not always allow their affected children to participate in such studies. Although studies can be conducted using adults who have been affected since childhood, data obtained from such studies may not accurately reflect anomalies that characterize the early disruption of brain development because brains change over time. Moreover, retrospective diagnoses of childhood disorders frequently rely on memory (e.g., a patient is asked "Did you have difficulty reading as a young child?") and hence can be unreliable.

Despite these challenges, ongoing research has uncovered important neurological and genetic features that seem to be associated with specific developmental disorders (see Boxes 45.2 and 45.3 for examples). The following sections outline what is known about how specific injuries or anomalies in development of the brain may result in specific patterns of cognitive and behavioral impairment. Two examples of developmental psychopathology are described: autism and schizophrenia.

### Autism

Autism is a neurodevelopmental syndrome characterized by deficits in a broad domain of social interaction, play, language, and communication, and a restrictive range of interests and activities, including repetitive and stereotypic movements and persistent preoccupation that begin in infancy and become apparent by the end of the third year of life. Although autism was once believed to be a rare disorder, recent surveys report a prevalence of 40 to 50 per 10,000 births. Parents often first become concerned because their child fails to use words to communicate, even though he or she recites passages from videotapes or says the alphabet. Like other kinds of abnormal behavior, autism is a heterogeneous condition that can range widely in severity.

### Characteristics of Autism

A multitude of symptoms occur in autism, including social isolation (the autistic child largely ignores other people, shows little attachment to parents or

## BOX 45.2

## DYSLEXIA

Reading skills occupy a uniquely important position in overall cognitive development, strongly dependent on antecedent skill acquisition and critically supportive of educational success. After accounting for the effects of inadequate instruction, the most common cause of severe reading problems in childhood is *developmental dyslexia*, a disorder typically characterized by impairment in applying the sound–correspondence rules necessary to decode print (Chapter 51). Although reading impairment is common, with an incidence of 5–10% among school-age children, our understanding of its biological roots is relatively recent.

Neurobiological studies of dyslexia are challenging, as the behavioral manifestations of this disorder are complex. Although defined by poor reading performance, dyslexia involves additional deficits, including poor phonological processing, poor verbal working memory, and slow naming ability. Dyslexics frequently show subtle deficits in motor control and early sensory processing, most notably in the visual system. Imaging studies have revealed that brain structure in dyslexics differs from that seen in individuals with normal reading skills. Micro and macroscopic structural abnormalities have been detected in perisylvian language regions (temporal and parietal banks of the sylvian fissure as well as the insula), visual system structures, the thalamus, and the corpus callosum. The planum temporale is an expanse of neocortex on the temporal bank of the sylvian fissure, its anterior border defined by Heschl's gyrus. From the time of birth the left planum temporale is larger than the homologous region in the right hemisphere in 70–80% of individuals. Reductions or reversal of this leftward asymmetry has been documented in individuals with developmental dyslexia. The functional concomitants of these anatomical variations have been explored in functional imaging studies that have revealed differences in patterns of task-related activity between dyslexics and controls during the performance of

reading and phonological decoding tasks. Interestingly, the cortical areas identified are similar in English, French, and Italian dyslexics, supporting a biological origin for this reading abnormality, independent of cultural upbringing. Similarly, candidate genes for dyslexia have been identified and replicated in different countries, suggesting the multigenetic contribution to reading disability.

Besides the problems related to reading, dyslexics also exhibit subtle abnormalities in visual processing. Evidence for selective involvement of magnocellular pathways of the visual system (Chapter 27) has accumulated, beginning with the demonstration that cell bodies in the magnocellular layers of the lateral geniculate nucleus are smaller in dyslexics compared to a control group. The fact that both contrast sensitivity and visual persistence are abnormal in reading disabled children is consistent with the notion that these children have disturbances in the magnocellular system, which is specialized for temporally demanding visual processing. These behavioral results are supported by functional imaging studies demonstrating less task-related activity in extrastriate and parietal cortex during visual motion detection by dyslexics.

Future studies will determine the nature of the neural mechanisms that link deficits in early visual processing with more cognitive skills such as phonological awareness. Also remaining to be clarified are issues concerning which of these deficits is a primary cause of dyslexia as opposed to a consequence of having partially compensated for a reading disorder. Such information will aid in identifying better avenues for reading remediation. To date, the best methods for improving the reading abilities of dyslexics focus on structured teaching of the code that allows individuals to sound out words (phonological awareness) in the context of fluency and comprehension exercises.

Guinevere F. Eden

other relatives, and retreats into a world of his or her own), stereotyped behaviors (the autistic child rocks back and forth, stares at neutral stimuli, rotates an object, or engages in other repetitive behaviors for long, uninterrupted time periods), resistance to change in routine, abnormal responses to sensory stimuli (the autistic child may ignore visual stimuli and sounds, especially speech sounds, sometimes to such an extent that it might be thought the child is deaf), inappropri-

ate emotional expressions (the autistic child has sudden bouts of fear and crying for no obvious reason; at other times the child displays utter fearlessness and unprovoked laughter), and poor use of speech. Individuals with autism can also exhibit symptoms that fall along a continuum of disorders. For example, many have mental retardation and show delays in the development of language. Others display neither language delay nor mental retardation, although they are clearly

socially inept. Finally, autism is also associated with idiosyncratic interests and restricted and repetitive behavioral repertoire. For a long time, autism was thought to be the result of poor parenting. However, a growing number of studies over the last two decades provide mounting evidence that autism results from an early onset brain dysfunction.

### *Neuropathological Alterations in Autism*

Several studies of autistic individuals provide evidence for megalencephaly (whole brain enlargement) and for increased head circumference. The nature of this enlargement has yet to be studied carefully, but it is specifically observed in the occipital, parietal, and temporal lobes. Postmortem analyses of the brains of autistic individuals have revealed increased cortical thickness and abnormalities in cortical morphology. Furthermore, abnormalities in the size and density of neurons in the medial temporal lobe and limbic system, including the amygdala, hippocampus, and entorhinal cortex, septal nuclei, and cingulate cortex, have also been documented. These neuropathological abnormalities make sense with respect to certain major symptoms of autism because the limbic system is known to play a central role in coordinating social-emotional functioning. Other evidence implicating this neural system in autism includes (1) case studies of patients with temporal lobe lesions and autistic-like behaviors, (2) a significant and specific association between temporal lobe lesions from tuberous sclerosis and autism, (3) a volumetric decrease in the amygdala in autism, (4) reduced functional activity on SPECT scans in the temporal lobe in autism, and (5) animal models of autism based on early lesions to medial temporal lobe structures.

A fMRI study of autism has documented dysfunction localized to the ventral temporal lobe using a face recognition task (Baron-Cohen *et al.*, 1999). In this study, high-functioning individuals with autism and matched controls were presented with a series of photographs of eyes while their brains were being scanned to assess brain regions activated by two different tasks. In the first task (experimental condition), each photograph was presented simultaneously with words (either unconcerned or concerned, or sympathetic or unsympathetic). Participants were asked to indicate by pressing a button which word best describes what the person in the photograph is feeling or thinking. In the second task (control condition), each photograph was presented with the words "male" or "female" and the subjects were asked to make a gender recognition by pressing a button. In both tasks, the performance of autistic individuals and controls was above chance. However, the controls were more accurate in the two

tasks than the autistic individuals. To investigate the brain regions activated by the experimental task, brain maps obtained during the control task were subtracted from brain maps obtained during the experimental task. In the control group, the experimental task activated two main regions of the brain: the frontotemporal neocortical areas, including the left dorsolateral prefrontal cortex and supplementary motor areas, bilateral temporoparietal regions, and subcortical structures, including the left amygdala and parahippocampal gyrus. The autism group activated the frontal components but did not activate the amygdala. The significance of these data is that one critical role of the amygdala is to identify the mental states or emotions of other individuals and that this structure appears to be dysfunctional in persons with autism (see Pelphrey *et al.*, 2004 for additional information on the neuroanatomical substrates of social cognition dysfunction in autism).

Significant atrophy of the vermal lobules in the cerebellum has also been reported in autistic individuals, although this effect does not appear specific to autism and is found widely in neurodevelopmental disorders. By comparison, there is now extensive evidence for the involvement of higher association areas in the pathophysiology of autism, particularly the frontal and parietal cortices.

### *Autism Is a Complex Genetic Disorder*

The most compelling evidence for a genetic contribution to autism comes from studies of monozygotic (identical) and dizygotic (fraternal) twins. When one member of a pair of monozygotic twins is autistic, the other twin has more than a 50% probability of being autistic. However, if one member of a pair of dizygotic twins is autistic, the other twin has only a 3% probability of developing autism. Using conventional nomenclature, we say that monozygotic twins have a 50% or higher concordance for autism and that dizygotic twins have a 3% concordance. The relative risk factor for siblings is one of the highest for a complex genetic disorder.

The most significant genetic finding relevant to autism is the recent identification of genes responsible for Rett's syndrome and fragile X syndrome, two conditions associated with autistic features. Rett's syndrome is caused by mutations in the methyl-CpG binding protein 2 (MECP2) gene. Decreased expression of this gene leads to a failure to suppress expression of genes regulated by methylation. Fragile X syndrome is a disorder caused by mutation of the gene FMR1 (Box 45.3). A better understanding of how reduced expression of the MECP2 and FMR1 genes leads to mental retardation as well as social and lan-

## BOX 45.3

## TRIPLET REPEAT DISORDERS

Not all neurogenetic diseases follow simple inheritance patterns; not all developmental disorders reveal themselves immediately; and diseases with similar genetic etiologies can have widely different manifestations. Trinucleotide repeat mutations, or dynamic mutations, were discovered only in the early 1990s but are responsible for a number of important neurodegenerative disorders, such as Huntington's Disease (Box 31.5), Fragile X mental retardation, and myotonic dystrophy. To date, 14 neurological disorders have been found to result from such a mutational mechanism, and the list will probably continue to grow.

**Triplet repeat mutations** are unstable and prone to expand as alleles are passed from one generation to the next, although contractions can occur. Repeats at different loci differ markedly in their rates and extents of expansion, and the instability of repeats at each locus often depends upon the sex of the transmitting parent.

**Fragile X syndrome**, an X-linked dominant mental retardation syndrome, was the first disease shown to result from a triplet repeat mutation. There is a CGG repeat expansion at a locus (Xq27.3) giving rise to a folate-sensitive fragile site (FRAXA). The CGG repeat ranges in length in the general population from 5 to 50 triplets. Affected individuals carry more than 230 repeats, up to several thousand triplets. CGG tracts between 45 and 200 repeats in length are termed "premutations"; they are not long enough to result in mental retardation, yet are prerequisite for further expansion to the full mutation. Escalating risk of affected offspring is associated with increasing size of premutations in female carriers. Curiously, offspring of male carriers of premutations are not at risk for fragile X syndrome, as these alleles have not been observed to expand to full mutations upon male transmission. The normal function of the affected protein FMR1 remains to be fully determined, but it appears to play a role in RNA metabolism, likely in the areas of transport, stability, and/or translation.

**Myotonic dystrophy (DM)** remains a particularly enigmatic triplet repeat disorder affecting multiple systems, causing myotonia, muscle weakness, cardiac conduction defects, diabetes, cataracts, premature balding, and sometimes dysmorphic features and mild mental retardation. There is a tendency for these features to appear in more severe form in subsequent generations of a family. In DM there is a CTG repeat in the 3' untranslated region of the myotonin protein kinase gene (DMPK).

This CTG tract is small in the general population (5–37 triplets) but can expand dramatically to thousands of repeats. Slightly increased lengths (70–100) can result in mild effects, such as late-onset cataracts, and the classic symptoms of early adulthood myotonia are found in individuals with hundreds of repeats. Very large expansions can cause severe disease in newborns.

The mechanism(s) by which the mutation leads to the various clinical symptoms remains uncertain. A variety of effects have been described and the repeat expansions clearly affect both the DMPK gene and nearby genes. It is also likely that the expanded CTG repeat carrying mRNAs can act to diminish the levels of nuclear proteins that bind at these sequences, resulting in misregulation of genes not linked to DMPK. Mutations in equivalent mouse genes have not provided a complete model of the human disease. The phenotype in DM results from multiple effects of the repeat expansion, rather than a simple loss or gain of function mechanism.

**Friedreich's ataxia (FA)** causes both limb and gait ataxia, loss of position and vibration sense, decreased tendon reflexes, cardiomyopathy, diabetes, and, in some patients, optic atrophy and deafness. FA is a recessive disorder and the only triplet repeat disorder known to involve a GAA sequence. Carriers of FA are rather common (1/85), and, consequently, so is the GAA expansion. Members of the general population carry between 7 and 34 repeats, and pathogenic alleles can number in the hundreds. The affected frataxin gene product appears to be involved in mitochondrial iron homeostasis, and its absence affects postmitotic cells rich in mitochondria. The mechanism by which the GAA repeat affects gene function appears to be inhibition of primary RNA transcripts.

A second class of triplet repeat disorders includes those caused by expansion of translated CAG repeats that encode a polyglutamine tract in each of the respective proteins. These "polyglutamine" disorders share many features, suggesting that a common pathogenetic mechanism is at play in spite of the fact that the mutated genes share no homology outside of the CAG repeats. They are progressive neurologic diseases with onset of symptoms in young to mid-adulthood with only a specific group of neurons vulnerable in each disease. Symptoms develop when the number of uninterrupted repeats exceed about 35 glutamines. The phenotype is caused not by loss of function of the relevant protein but rather by a gain of function conferred by the expanded polyglutamine tract.

### BOX 45.3 (cont'd)

The **spinocerebellar ataxias (SCA)** are genetically distinct but overlap a great deal in their clinical presentation—between subtypes and even within families affected by the same disease. It is nearly impossible to distinguish one subtype from another on the basis of clinical signs alone. **Spinocerebellar Ataxia Type 1 (SCA1)** was the first of the inherited ataxias to be mapped. Patients with SCA1 suffer from progressive ataxia (loss of balance and coordination), dysarthria, and eventual respiratory failure. SCA1 is characterized pathologically by cerebellar atrophy with severe loss of Purkinje cells and brain stem neurons. Patients with SCA1 have an expanded “perfect” CAG repeat tract encoding ataxin-1, the function of which is largely unknown.

Studies of human patients with deletions of, for example, the HD, or SCA1 genes (and of mice lacking these genes) confirm that disease is not due to loss of function of the respective proteins. More importantly, studies of mouse and fruit fly models that overexpress full-length or truncated forms of either ataxin-1, ataxin-3, huntingtin, AR, atrophin-1, or ataxin-7 demonstrate progressive neuronal dysfunction consistent with a gain of function mechanism. Several illuminating findings have emerged from the study of human patients, cell culture systems, and the various animal models. In transgenic mice, expression of truncated polypeptides containing expanded glutamine tracts caused widespread dysfunction

that extends beyond the specific groups of neurons affected by the full-length protein. The expanded polyglutamine tracts may cause the respective proteins to misfold or resist degradation. Aberrant protein–protein interactions or alterations in levels of proteins essential for the normal functioning of neurons (such as proteins that regulate Ca<sup>+2</sup> levels and neurotransmitters), in turn, could exacerbate neuronal dysfunction and lead to neuronal death.

The finding that chaperone overexpression mitigates the phenotype in one vertebrate and several invertebrate models of polyglutamine disorders, and the identification of several additional modifiers of the neuronal phenotype, provide a platform for identifying key pathways of pathogenesis and potential therapeutic targets.

guage disorders will likely provide a better understanding of the autistic disorder.

### Schizophrenia

Schizophrenia is a catastrophic illness with an onset typically in adolescence or early adulthood. It was identified and defined in the early twentieth century as *dementia praecox* (Latin for deterioration of the mind at an early age). In 1911, Eugen Bleuler introduced the term schizophrenia. This term can be confusing because its translation from the Greek means “split mind,” which is sometimes interpreted as multiple personality, a condition in which a person alternates between one personality and another. A schizophrenic person has only one personality and the split in the schizophrenic mind is between emotional and intellectual realms. The combination of significant incapacity, onset early in life, and chronicity of illness makes schizophrenia a particularly tragic disorder, occurring in 0.5 to 1% of the population.

### Characteristics of Schizophrenia

The clinical symptoms of schizophrenia often are divided into two broad categories: positive and negative. Positive symptoms include delusions, hallucinations, disorganized speech, and disorganized or bizarre behavior. These symptoms are referred to as positive because they represent distortions or exaggerations of normal cognitive or emotional functions. The negative symptoms of schizophrenia reflect a loss or diminution of normal function. Negative symptoms include alogia (marked poverty of speech or speech devoid of coherent content), affective flattening (diminution in the ability to express emotion), anhedonia (inability to experience pleasure), avolition (inability to initiate or persist in goal-directed behavior), and attentional impairment. Although the positive symptoms of schizophrenia are often colorful and draw attention to the patient’s illness, the negative symptoms are an important feature of the disease that impair the person’s ability to function normally in daily life.

The profound and pervasive cognitive and emotional disturbances that characterize schizophrenia suggest that it is a serious brain disease affecting multiple functions and systems. Auditory hallucinations and disruptions in linguistic expression suggest involvement of the auditory cortex and perisylvian language regions. Other positive symptoms, such as delusions or disorganized behavior, are more difficult to localize to specific regions and suggest dysfunction distributed across multiple neural systems and circuits. Negative symptoms may be related to the prefrontal cortex, which mediates goal-directed behavior and fluency of thought and speech. The affective flattening and asociality suggest involvement of the limbic areas within the temporal lobe.

### *The Dopamine Hypothesis of Schizophrenia*

A great deal of research since the 1950s has made it clear that schizophrenia is associated with abnormalities in the dopaminergic synapses of the brain. Still, the exact nature of this perturbation remains elusive. The strongest link between dopamine synapses and schizophrenia comes from studies of drugs that alleviate the symptoms of schizophrenia. A large number of antischizophrenic, or neuroleptic, drugs have been found, most of which belong to two chemical families, the phenothiazines, which include chlorpromazine, and the butyrophenones, which include haloperidol. All these drugs have two properties in common: they block postsynaptic dopamine receptors and they inhibit the release of dopamine from the presynaptic neuron. One interpretation of these results is that schizophrenia is due to excess activity at dopamine synapses. Establishing cause-and-effect relationships in human psychiatric disorders, however, is challenging. For example, although a substantial increase in the number of dopaminergic receptors is observed in the schizophrenic brain, because virtually all patients receive neuroleptic medication, it is not known if increased receptor density is a consequence of the disease itself or a response to an extended use of anti-dopaminergic drugs. An additional complication for the dopamine receptor hypothesis of schizophrenia concerns the time course for the effects of neuroleptic drugs. Although these treatments block dopamine receptors almost at once and reach their full pharmacological effectiveness within a few days, effects on behavior emerge more slowly, over two or three weeks. Clearly the symptomatic relief achieved with neuroleptic intervention involves mechanisms in addition to the blockade of dopamine receptors.

One possibility is that the prolonged use of neuroleptic drugs decreases the number of spontaneously active dopamine neurons in what is known as the mes-

olimbic system, a set of neurons that projects from the midbrain tegmentum to the limbic system. Another possibility is that the underlying problem in schizophrenia is not an excess of dopamine activity at all, but a deficit of glutamate activity. Glutamate is the predominant excitatory amino acid released by neurons in the cerebral cortex that project widely throughout the limbic system, and dopamine synapses are known to inhibit glutamate release in these target regions. If glutamate release is reduced in the schizophrenic brain, one way to correct this deficiency would be to block activity at dopaminergic receptors, relieving glutamate synapses from inhibition.

### *Neuropathological Alterations in Schizophrenia*

The most consistently described structural alterations in schizophrenia are ventricular enlargement and decreases in the volume of temporal lobe structures, including the hippocampus, amygdala, and entorhinal cortex. Cytoarchitecture and cell densities also reportedly are altered in limbic structures: reduced cell number and size have been observed in the hippocampus, parahippocampal gyrus, and entorhinal cortex, along with disturbed cytoarchitecture involving a cellular disarray in hippocampus, and the entorhinal and cingulate cortices. This distribution of structural abnormalities may help account for the symptoms of schizophrenia in that these limbic structures link neocortical association areas with the septum-hypothalamic complex and are therefore key in sensory information processing and sensory gating. Defects in this neural circuit could lead to a dissociation between neocortically mediated cognitive processing and limbic-hypothalamic emotional reactions and to a disturbed emotional experience of external sensory perceptions.

The structural alterations reported in schizophrenia are often subtle and certainly heterogeneous, contributing minimally to the elucidation of the disease if symptoms are to be attributed to defects in single brain regions. Alternatively, it is currently hypothesized that the variety and severity of symptoms observed in schizophrenia can be explained by defects in several brain regions affecting the neural circuits that mediate higher cognitive functions. Such neural circuitry would include neocortical association areas, the limbic system and midline thalamic structures, with possible involvement of the basal ganglia.

### *The Neurodevelopmental Hypothesis of Schizophrenia*

Several clinical observations point to neurodevelopmental abnormalities in schizophrenia: onset in adolescence in most patients and earlier onset among males, pronounced premorbid neurodevelopmental

abnormalities, such as asociality and “soft” neurological signs; impaired cognitive and neuromotor functioning; minor physical anomalies; presence of structural abnormalities at the onset of the illness, which may predate the illness; and the absence of neurodegenerative processes.

Postmortem morphological observations in the brains of schizophrenic patients suggest that multiple aspects of neural development may be disrupted. The spatial disorganization of neurons found in the hippocampus and the inappropriate laminar location of cells in the entorhinal cortex, for example, suggest a potential defect in neuronal migration. Other evidence indicates that the organization of synaptic connectivity is affected. The functional circuitry of the frontal cortex undergoes significant remodeling until adolescence, mediated by an NMDA receptor-dependent mechanism. The number of these receptors is reduced in the brain of schizophrenics. Still other abnormalities involve biochemical alterations of membrane phospholipids in the dorsolateral prefrontal region. These changes include a decrease in phosphomonoesters and an increase in phosphodiesteres. Such biochemical changes in membrane phospholipids are known to occur during normal synaptic pruning in adolescence, but appear to be exaggerated in the dorsolateral prefrontal cortex of schizophrenics. These enhanced biochemical changes may lead to greater synaptic pruning in schizophrenics than in normal individuals and contribute to the reduction in prefrontal neuropil volume that accompanies the disease.

The precise timing of neurodevelopmental abnormalities in schizophrenia remains controversial. Some implicate a fixed neural lesion from early life interacting with normal neurodevelopmental events that take place much later. Others posit that schizophrenia is caused by a deviation from normal brain maturational processes during late adolescence, involving large-scale synaptic elimination or pruning in brain regions critical for cognitive development. Still others propose that early brain pathology acts as a risk factor rather than a sufficient cause so that its effects can only be understood in the light of the individual's later exposure to other risk and protective factors.

### *Genetics Play a Role in Schizophrenia*

As for autism, a substantial body of evidence indicates that schizophrenia is associated with both genetic and environmental factors. Findings pointing to a significant genetic contribution come from family, twin, and adoption studies. Evidence for environmental factors derives from studies of prenatal intrauterine environment, neonatal obstetric complications, and postnatal brain insults. Currently, it remains an open

question whether these environmental factors play a necessary role in the neurodevelopmental abnormalities responsible for psychotic brain disorders or whether their role is additive or interactive with genetic contributions.

People with schizophrenia are more likely than others to have schizophrenic relatives. The most compelling evidence is the 50% concordance rate for monozygotic twins relative to 15% concordance for dizygotic twins. Neuroimaging studies of discordant monozygotic twins consistently indicate more prominent structural brain abnormalities in the ill twin. More importantly, a neuroimaging study demonstrated that schizophrenia is associated with dysfunction of a prefrontal-limbic network (Weinberger *et al.*, 1992). In this study, monozygotic twins discordant for schizophrenia underwent PET blood flow scans while they performed a task known to activate the dorsolateral prefrontal cortex in normal subjects. This task, known as the Wisconsin Card Sorting Task (WCST), measures abstract problem solving requiring attention and working memory. The participant sees four cards bearing designs that differ in color, form, and number of elements. The subject's task is to sort the stack of cards into piles in front of one or another of the stimulus cards. The subject is told whether the sorting choice is correct or incorrect. The test follows this principle: the correct solution is first color; once the subject has figured out this solution, without warning the correct solution then becomes form. Thus, the subject must now inhibit classifying cards on the basis of color and shift to classifying on the basis of form. Once the subject has succeeded at selecting form, the correct solution again changes unexpectedly, now to the number of elements.

Shifting response strategies is difficult for patients with frontal lobe dysfunction. In the affected schizophrenic twin, prefrontal activation correlated strongly with both left and right hippocampal volumes; a relationship that was not found in the unaffected twins. These data suggest that schizophrenia could result from a dysfunction of a distributed neural network involving the prefrontal cortical areas and the limbic structures.

Molecular studies also have demonstrated schizophrenia to be a complex genetic disorder and have implicated several possible susceptibility loci, including regions on chromosomes 1q, 6p, 8p, 13q, and 22q. Of genes mapped, the 22q11 gene (a common functional polymorphism of catechol-O-methyltransferase (COMT), which is a methylation enzyme that metabolizes released dopamine) has been a popular candidate because of the long-hypothesized role of dopamine in schizophrenia.

### *Sex Hormones May Influence Neurodevelopmental Disorders*

There are gender differences in the occurrence of neurodevelopmental disorders. The gender ratio of incidence is skewed toward boys for a variety of developmental disabilities, including severe mental retardation (1.3 boys/1 girl), speech and language disorders (2.6/1), learning difficulties (2.2/1), dyslexia (4.3/1), schizophrenia (1.9/1), and autism (4/1). Why? Although the existence of sex differences in the area of language and learning disorders has been contested on the grounds that it is a result of teacher and clinician bias in identifying these disorders, studies have supported the existence of a significant gender difference in the incidence of these disorders (Flannery *et al.*, 2000). Moreover, gender differences are also seen in clear-cut phenomena such as complications of pregnancy and birth, which are more common in male infants, and these differences cannot be explained as a reflection of investigator or clinician bias. Several theories have attempted to explain these gender differences.

One theory posits that male but not female fetuses invoke a form of "antigenic" response from the mother during pregnancy, being recognized by the immune system as "foreign." The hostile environment thus created for the male fetus *in utero* would explain not only a higher incidence of developmental disorders among boys, but also the finding that later-born sons are increasingly likely to be affected adversely (consistent with increased immune responsiveness on repeated exposure).

Another theory (the Geschwind theory, as it came to be known, after the neurologist Norman Geschwind) proposed that the uneven gender ratios in developmental disorders are associated with exposure to some "male factor" (possibly androgen) during the last trimester of fetal development. This factor acts to slow cortical maturation in male fetuses, particularly in the left hemisphere, rendering them more susceptible to perturbation during the normal course of development. This exposure to a male hormone would explain the higher incidence of developmental disorders among boys. Conversely, faster central neurons system development in female fetuses would enable them to better withstand insult during late pregnancy and birth. This idea is supported by evidence that female infants appear to show better cognitive recovery than male infants from intracranial hemorrhage associated with prematurity.

### **Summary**

This section examined two forms of developmental abnormalities: autism and schizophrenia. In both cases

it is possible to link the behavioral manifestations of the disorder to anomalies in neurobiological systems and to identify a genetic component. In both disorders, too, affected individuals do not show localized damage in circumscribed brain regions, but show evidence of cellular disturbance early in brain development (i.e., during neuromigration), which gives rise to pervasive and dysfunctional reorganization of critical neural systems underlying complex behaviors. Emerging evidence suggests that similar mechanisms may characterize other developmental disabilities, including dyslexia, mental retardation, and attention deficit disorders. Current findings also support the existence of sex differences in brain development and organization, which may in turn differentially affect the response of the brain to early injury.

### **Pathological Manifestations of Cognitive Aging: Dementia**

Dementia is a generic term that refers to debilitating deterioration in more than one domain of cognitive function. The involvement of multiple capacities distinguishes dementia from other disorders, such as amnesia and aphasia, that affect a single functional domain (memory and language, respectively). Approximately 50 disorders are known to cause dementia. Most of these are progressive in nature, increasing in severity over time. The age at onset and the rate of progression of symptoms differ dramatically among the major dementing disorders. Most have an insidious onset and develop slowly, sometimes over a period of many years. These include Alzheimer's disease, Huntington's disease, frontotemporal dementia, and the dementia observed in a subpopulation of patients with Parkinson's disease. The rare neurodegenerative disorder Creutzfeldt-Jakob disease also develops insidiously, but is distinguished by a very rapid rate of progression, often spanning a year or less from the onset of dementia to death. Vascular dementia (or multi-infarct dementia) follows still another pattern of decline. Initial cognitive symptoms develop acutely, but in this case the clinical course typically proceeds in a step-wise fashion over many years, with periods of relative stability punctuated by abrupt deterioration. Age is a major risk factor for dementing illnesses, and the following sections focus on the most prevalent example of age-related dementia, Alzheimer's disease.

#### *Alzheimer's Disease Is the Most Common Cause of Dementia*

In 1906, the German scientist Alois Alzheimer reported a case study of a woman in her late 40s who developed memory impairment and deficits in other

mental faculties that progressively worsened in severity until her death in her early 50s. Subsequent neuropathological examination of this patient's brain revealed grossly apparent and widespread neocortical atrophy that Alzheimer concluded was inconsistent with any previously described disease. Although the disorder that would come to bear Alzheimer's name originally was thought to be quite rare, it is now recognized as the most common form of dementia, accounting for an estimated 50% of all cases. Current estimates are that more than 4 million people in the United States, and 26 million people worldwide, suffer from Alzheimer's disease. The prevalence of the disease is tightly coupled to age, and increases after the fourth decade of life. The disease affects about 10% of persons over the age of 65, and by 85, at least one in four individuals is afflicted. Demographic trends indicate that the elderly comprise the fastest growing segment of the population, and as a consequence, the number of people suffering the devastating impact of Alzheimer's disease is projected to quadruple by 2050. Not surprisingly, efforts to understand the basis of this and related disorders are among the most active research areas in modern neuroscience.

#### *Memory Impairment Is a Central Feature of Alzheimer's Disease*

Alzheimer's original case study provided an accurate description of the clinical course for many patients with this disease. Impairment in establishing and maintaining memories for recent events is frequently the initial sign that brings the patient to the attention of health care professionals. At this early stage, memory for the remote past is relatively preserved, as are other forms of memory that do not require medial temporal lobe structures. Thus, the neuropsychological profile of the Alzheimer's patient provides important clues about the neuropathological progression of this disorder, suggesting that the systems responsible for declarative memory are especially vulnerable. Neuroanatomical studies of the diagnostic hallmarks of Alzheimer's disease confirm this proposal (described in the next section). Progression of the disorder is marked by inexorable decline across multiple cognitive capacities. Although generally alert and responsive in early and middle phases of the disorder, Alzheimer's patients often experience difficulty identifying the meaning of simple words, uses for common household objects, or the meaning of numbers. Other accompanying disturbances can include general confusion, agitation, delusions, social disinhibition, and paranoia. Language abilities can deteriorate progressively, and at the end stage of disease, patients are often mute and densely amnesic for both recent and

more remote events. As might be predicted on the basis of this broad profile of impairment, the distribution of neuropathology in individuals dying with late-stage Alzheimer's disease is extensive, involving widespread areas of the limbic system and association cortices, along with many subcortical brain regions, including the basal forebrain cholinergic system, striatum, thalamus, and cerebellum.

#### *Amyloid-Containing Plaques and Neurofibrillary Tangles Are Diagnostic Hallmarks of Alzheimer's Disease That Preferentially Target Memory-Related Brain Regions*

There are two types of neuropathological lesions that, when present in sufficiently high numbers, are the diagnostic hallmarks of Alzheimer's disease (Fig. 45.6). Plaques comprise extracellular deposits of amyloid  $\beta$ -protein ( $A\beta$ ) that, in their mature form, typically are surrounded by a shell of dystrophic neurites (Fig. 45.6B). The neuritic component of plaques consists of morphologically abnormal dendrites and axons of multiple neuronal types, typically associated with substantial numbers of glial cells. The amyloid core of plaques can contain multiple species of  $A\beta$ , including a form ending at amino acid 42 that is prone to aggregation ( $A\beta_{42}$ ), and a slightly shorter species ( $A\beta_{40}$ ) that is normally produced more abundantly in neurons. Plaques vary substantially in size, and although the time it takes for mature neuritic plaques to form is not known precisely, they are likely to evolve slowly, over many years.

In contrast to extracellular plaques, the second neuropathological hallmark of Alzheimer's disease

**FIGURE 45.6** Photomicrographs of neurofibrillary tangles (A) and amyloid-containing plaques (B) in the hippocampal formation of a patient that died with late-stage Alzheimer's disease. Note that the size and morphological characteristics of plaques in B vary widely. Scale bar: 50  $\mu\text{m}$ . Courtesy of P. Hof, Mount Sinai School of Medicine.

is localized intracellularly. Termed neurofibrillary tangles, these are composed of densely packed, abnormal fibers that occupy much of the cytoplasm and proximal neuronal processes of affected cells (Fig. 45.6A). Indeed the density of these fibers in many tangle-bearing neurons is sufficiently high that the cell body appears swollen and the nucleus displaced. The term paired helical filaments (PHF), sometimes used to describe this type of pathology, derives from electron microscopic evidence that tangles consist of pairs of twisted filaments with a highly regular periodicity. Studies using biochemical and immunocytochemical methods have demonstrated that PHF are composed of a cytoskeletal protein found in normal, healthy neurons; the microtubule-associated protein tau. Cytoskeletal abnormalities can disrupt intracellular trafficking of materials that are critical for cell viability, culminating in neuron death. Defining the mechanisms that initiate the hyperphosphorylation of tau and its aggregation into mature neurofibrillary pathology is a prominent avenue of research on Alzheimer's disease.

Investigations aimed at mapping the neuroanatomical distribution of pathology during early and later stages of Alzheimer's disease help account for the progression of clinical symptoms in patients with this disorder. Early in the course of the disease, when memory impairment is often the predominant complaint, plaques and tangles are particularly abundant in the entorhinal cortex and associated projection targets in the hippocampus. Indeed, in many cases virtually all of the neurons that originate the perforant path projection to the hippocampus exhibit neurofibrillary tangles. Thus, the neuropathology of Alzheimer's disease appears to initially target circuitry critical for normal declarative memory, disrupting a major source of neocortical input that the medial temporal lobe system uses to establish memory for ongoing events. As the severity of cognitive impairment progresses, the distribution of neuropathology becomes more widespread, affecting cortical and subcortical systems that support language, semantic knowledge, abstract reasoning, and other capacities.

#### *Genetic Contributions to Alzheimer's Disease*

Important clues about the basis of Alzheimer's disease have come from the study of people afflicted with an "early onset" form of the disorder that emerges before the age of 65. This relatively rare and aggressive condition exhibits an increased prevalence in certain families and therefore is thought to have a significant genetic component. To date, three gene mutations linked to early onset Alzheimer's have been identified: one involving the amyloid precursor protein gene on

chromosome 21, another in the presenilin 1 gene on chromosome 14, and the third in the presenilin 2 gene on chromosome 1. Each of these mutations is expressed in an autosomal-dominant fashion such that half the offspring of an affected parent will develop the disease. Importantly, the common thread among gene mutations associated with early onset Alzheimer's disease is that each of them influences processing of the amyloid precursor protein (Selkoe, 2001).

Several additional lines of evidence support the suggestion that the deposition of amyloid is central to the pathogenesis of Alzheimer's disease. By far the most common form of the disorder (accounting for an estimated 98% of cases) has a relatively late onset, after age 65. Among a number of recently identified candidate genes, one risk factor for late-onset Alzheimer's disease is the allelic composition of the apolipoprotein E gene on chromosome 19 (ApoE); that is, a gene that codes for a glycoprotein involved in cholesterol transport and metabolism. The ApoE gene has three alleles (designated ApoE2, ApoE3, and ApoE4), and patients with Alzheimer's disease carry the ApoE4 allele with a frequency greatly exceeding individuals without the disease. Moreover, the risk of disease is coupled to the number of copies of this specific allele: individuals with no copies of ApoE4 are less likely than the general population to develop Alzheimer's disease, the presence of one ApoE4 allele increases the disease risk four times, and people with two copies of ApoE4 are eight times more likely than the population at large to develop Alzheimer's. Although the precise mechanism by which ApoE4 mediates disease susceptibility is the subject of intensive investigation, one hypothesis is that it involves the disruption of processes responsible for scavenging and clearing amyloid peptide from the extracellular space in brain.

Additional findings relevant to the role of amyloid in Alzheimer's disease come from research on Down's syndrome. Down's syndrome results from the presence of an extra copy of the same chromosome that carries the gene for the amyloid precursor protein; chromosome 21. Thus, it is of considerable interest that people with Down's syndrome who survive until the fourth decade of life invariably develop a distribution of amyloid plaques in the brain similar to that observed in Alzheimer's patients. To the degree that aberrant processing or clearance of amyloid comprises the single common pathogenic mechanism of Alzheimer's disease, current findings encourage the view that interventions targeting this pathway might be developed to prevent or reverse this defect, realizing an effective treatment for the most common cause of age-related dementia.

### *Prospects for the Treatment of Alzheimer's Disease*

Although Alzheimer's disease is presently incurable, several pharmacological treatments have been approved for the clinical management of cognitive impairment associated with the disorder. These interventions all target the function of the neurotransmitter acetylcholine. Although available treatments offer modest, transient benefit for certain Alzheimer's patients, they fall far short of an effective cure or prevention. Encouraging preliminary progress toward the latter goal is based on the proposal that aberrant amyloid deposition represents the central pathogenic event responsible for the disorder. Whereas laboratory animals fail to develop Alzheimer's disease spontaneously, one can take advantage of a transgenic mouse model that accumulates amyloid-containing plaques in an age-dependent manner. These mice also develop spatial learning deficits relatively early in life, in temporal correspondence with the emergence of amyloid deposits. When transgenic animals were vaccinated at multiple time points during the first four months of life with  $A\beta$ , and subsequently examined for the effects of immunization on behavior and neuropathology, treatment attenuated the spatial learning deficits substantially (Janus *et al.*, 2000). Nevertheless, performance remained mildly impaired relative to nontransgenic controls. This partial protection from cognitive decline was also accompanied by roughly a 50% reduction in the number and size of mature,  $A\beta$ -containing plaques, relative to nonimmunized, age-matched transgenic controls.

Related findings using a similar experimental approach also demonstrate that immunization with  $A\beta$  is even effective in reducing the degree and progression of amyloid deposition when provided to older animals at a point in the life span when this pathology is already well established (Selkoe, 2001). The development of similar approaches for clinical use faces significant hurdles, including early indications that parallel treatment in humans can produce life threatening cerebral inflammation. Nonetheless, the recent findings from animal models encourage the view that vaccine therapies might ultimately yield an effective route for the treatment and prevention of Alzheimer's disease.

### **Summary**

This chapter has considered the neurobiological basis of cognitive development and aging. Early cognitive development is marked by the emergence of a remarkably complex set of adaptive capacities, including language skills, reasoning abilities, attention,

declarative memory, and executive functions. The vast majority of neurons—the essential building blocks of the central nervous system—are present at birth in humans, and rather than depending on the recruitment of new neurons, cognitive development appears to involve the fine tuning and establishment of appropriate circuitry among existing cells. Given this complex orchestration of processes, it is not surprising that many major disorders affecting cognitive function appear to result from a disruption of normal neurodevelopmental events. Higher order cognitive capacities are also vulnerable to deterioration during normal aging. Whereas widely distributed neuron death was previously presumed to underlie these deficits, it now appears that regionally selective changes in connectivity and cell biological function in critical circuits are the causative factors. Aging is also associated with some of the most devastating pathological conditions affecting cognitive function, including Alzheimer's disease. The dramatic progress realized in recent years, for the first time, has established a basis for the rationale development of strategies for disease prevention and treatment.

## Visual Perception of Objects

### THE PROBLEM OF OBJECT RECOGNITION

Accurate perception and recognition of objects is a crucial ability for visually dependent organisms such as humans—but it is also a complex one. As object and viewer move with respect to one another, the images cast by the object on the retinas of the observer can change radically. Not only will image position and size change, but surfaces may be foreshortened, occluded, or newly revealed. Similarly, changes in ambient illumination can reveal new surfaces, hide others in shadow, or introduce spurious edges where light ends and shadow begins. Despite this, human and nonhuman primates recognize objects quite accurately. This means that the visual system is able to extract a reasonably constant “representation” for the shapes and identities of meaningful objects despite such transformations. Image processing by the retina, visual thalamus, and primary visual cortex begins this process by extracting features and representing them over progressively larger receptive fields. However, in order to understand how the brain represents the identity of an object—its defining, invariant features of shape, relations among parts, and its significance—one must examine how circuits beyond the primary visual cortex encode and retain crucial information of a more global or “high-level” nature.

Visual processing can be subdivided into low-level, intermediate-level, and high-level components. The initial, low-level stages are those in which the brain extracts information about the physical properties of the stimulus, such as the edges, brightness, color, and motion of objects present in scenes (Chapter 27). This

processing often is described as *bottom up* because it can proceed from low (input) levels up through the visual system without feedback from cognitive processes such as memory. Intermediate-level vision involves combining information about these physical properties in order to detect global properties of an object, such as object shape and the orientation of the object in depth. High-level processes include those that endow the stimulus with meaning, leading to object recognition and classification. For example, recognition and classification depend on object knowledge and context, and can therefore be considered *top down* because the neural processing is influenced directly and profoundly by cognitive factors. Other top-down mechanisms, such as selective attention, can operate at even early stages of visual processing (Chapter 48).

This chapter is concerned primarily with the neural basis of the high-level components of object vision. First, historical evidence is reviewed that helped localize the crucial circuitry involved to the ventral parts of the temporal lobes. Next, from studies in nonhuman primates, the main pathways are described for object perception and recognition, in addition to neural codes that lead to object vision. Then, neuroimaging and electrophysiological studies are reviewed to show that very similar processing pathways and mechanisms exist in humans. In addition, human studies are reviewed to consider how the brain may treat special categories of objects and the ways in which experience with objects tunes their neural representations. Finally, visual object perception is considered in the broader context of general object knowledge and memory.

## SUBSTRATES FOR OBJECT PERCEPTION AND RECOGNITION: EARLY EVIDENCE FROM BRAIN DAMAGE

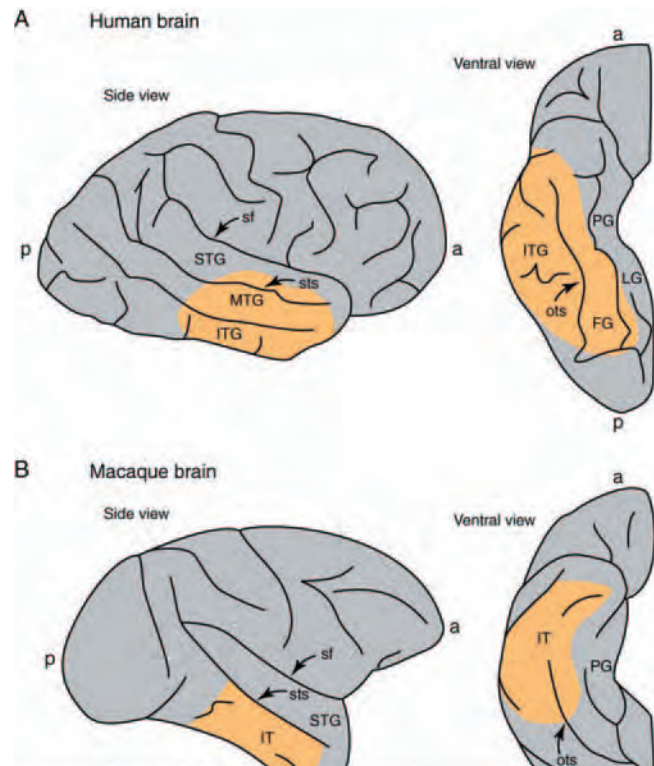

### Early Studies of Human Patients Pointed to the Inferior Temporal Cortex as a Site for Object Agnosia

The earliest clues about the neural bases of object perception and recognition came from the study of brain-damaged humans with *visual agnosia*. Visual agnosia refers to a set of disorders affecting object recognition, in which elementary visual capacities such as acuity and visual fields are preserved or grossly intact (for review, see Farah, 1990). Early attempts to localize the lesions in such cases appeared mainly in the German neurological literature of the early 1900s. Writers as early as Potzl in 1928 noted the importance of inferior regions of the temporal lobes, along with adjacent ventral occipital cortex, in most cases of visual agnosia. Subsequent studies upheld these general findings and confirmed the central role of the lingual and fusiform gyri (Fig. 46.1). Patients with visual agnosia typically have bilateral (or, less commonly, right-sided) damage to these regions.

### Two Types of Visual Agnosia Have Been Distinguished Historically

Lissauer is credited with the first detailed discussion of visual agnosia in 1890. He distinguished between two types, which he termed *apperceptive* and *associative*; these terms are still used commonly today. Agnosic patients, whose elementary perception of shape is impaired (despite intact or roughly normal visual acuity), are classified as apperceptive agnosics because their impairment is presumed to be at an early stage of the perceptual processing needed for object recognition. Patients with such deficits are relatively rare. Usually they have suffered diffuse brain damage, often from carbon monoxide poisoning, as opposed to the more localized damage to posterior cortex and inferior temporal regions seen in the majority of agnosics. Agnosics whose elementary shape perception is grossly intact are classified as associative agnosics, following Lissauer's contention that they cannot associate a percept with its meaning (i.e., its visual representation stored in memory).

Although the notion that these latter patients show a deficit in association *per se* has been called into question, the impairments they show reveal critical features of how the object recognition system tends to break down. To be considered an associative visual agnostic,

**FIGURE 46.1** (Top) Region of the human brain (in shading) within which large bilateral or right-sided lesions cause associative visual agnosia. FG, fusiform gyrus; ITG, inferior temporal gyrus; LG, lingual gyrus; MTG, middle temporal gyrus; PG, parahippocampal gyrus; STG, superior temporal gyrus; ots, occipito-temporal sulcus; sf, Sylvian or lateral fissure; sts, superior temporal sulcus. (Bottom) Region in the macaque monkey (in shading) referred to as the inferior temporal cortex, within which bilateral lesions cause visual discrimination and recognition deficits analogous to agnosic syndromes in humans. a, anterior; p, posterior.

the patient is tested to determine the presence of the following features. First, the patient must show difficulty recognizing visually presented objects, as measured by both naming and nonverbal tests of recognition, such as sorting objects by category (e.g., grouping kitchen utensils together, separate from sports equipment) or pantomiming the uses of the object. Second, the patient must show knowledge of the objects through sensory modalities other than vision; that is, be able to recognize items by sound or touch or through verbal questioning ("What is an egg beater?"). Third, the patient must have sensory and perceptual capacity sufficient to allow him or her to describe the appearance of an unrecognized object, to draw it, or identify whether it is the same as or different from a second item. An illustrative case of associative visual agnosia is summarized in Box 46.1. Figure 46.2 shows some copies drawn by this patient, who

## BOX 46.1

## CASE STUDY OF ASSOCIATIVE VISUAL AGNOSIA

The subject was a 47-year-old man who had suffered an acute loss of blood pressure with resulting brain damage. His mental status and language abilities were normal, and his visual acuity was 20/30, with a right homonymous hemianopia (blindness in the right visual hemifield). His one severe impairment was an inability to recognize most visual stimuli. For the first three weeks in the hospital, the patient could not identify common objects presented visually and did not know what was on his plate until he tasted it. He identified objects immediately on touching them.

When shown a stethoscope, he described it as "a long cord with a round thing at the end" and asked if it could be a watch. He identified a can opener as a key. Asked to name a cigarette lighter, he said, "I don't know" but named it after the examiner lit it. He said he was "not sure" when shown a toothbrush. He was never able to describe or demonstrate the use of an object if he could not name it. If he misnamed an object, his demonstration of use would correspond to the mistaken identification. Identification improved very slightly when given the category of the object (e.g., something to eat) or when asked to point to a named object instead of being required to give the name. When told the correct name of an object, he usually responded with a quick nod and often said, "Yes, I see it now." Then, often he could point out various parts of the previously unrecognized item as readily as a normal subject (e.g., the stem and bowl of a pipe and the laces, sole, and heel of a shoe). However, if asked by the examiner, "Suppose I told you that the last object was not really a pipe, what would you say?" He would reply, "I would take your word for it. Perhaps it's not a pipe." Similar vacillation never occurred with tactilely or aurally identified objects.

After he had spent three weeks on the ward, his object naming ability improved so that he could name many common objects, but this was variable; he might correctly name an object at one time and misname it later. Performance deteriorated severely when any part of the object was covered by the examiner. He could match identical objects but could not group objects by categories (clothing, food). He could draw the outlines of objects (key, spoon, etc.) that he could not identify.

He was unable to recognize members of his family, the hospital staff, or even his own face in the mirror. Sometimes he had difficulty distinguishing a line drawing of an animal face from a man's face but always recognized it as a face. The ability to recognize pictures of objects was impaired greatly, and after repeated testing he could name only one or two of 10 line drawings. He was always able to name geometrical forms (circle, square, triangle, cube). Remarkably, he could make excellent copies of line drawings and still fail to name the subject. He easily matched drawings of objects that he could not identify and had no difficulty discriminating between complex nonrepresentational patterns, differing from each other only subtly. He occasionally failed in discriminating because he included imperfections in the paper or in the printer's ink. He could never group drawings of objects by class unless he could first name the subject. Reading, both aloud and for comprehension, was limited greatly. He could read, hesitantly, most printed letters but often misread "K" as "R," and "L" as "T," and vice versa. He was able to read words slowly by spelling them aloud.

*Luiz Pessoa, Roger B. H. Tootell, and Leslie G. Ungerleider*

Excerpted from Rubens, A. B. and Benson, D. F. (1971). Associative visual agnosia. *Arch. Neurol.* **24**, 305-316.

nevertheless did not recognize the pictures he copied.

### Associative Visual Agnosia Involves Deficits in Invariant Object Representations

Closer examination of the manner in which agnosics copy and match pictures they cannot identify shows that they are often abnormally attentive to the small details of the image, rather than being guided by the overall shape or "gestalt" of the object itself. This

copying is done in a slow, line-by-line fashion, and patients may classify two pictures as different because of a small flaw in the printing. These observations suggest that the associative agnosic patients are unable to match what is in front of them to a unified, stored visual representation of the object. Such stored representations likely include knowledge about the *invariant*, distinguishing visual attributes (such as the general body shape and relative placement of features of the pig in Fig. 46.2) and/or stored semantic knowledge (the identity of the object as a pig). The underlying

FIGURE 46.2 Pictures that a patient with associative visual agnosia did not recognize but was able to copy. Asterisks indicate the patient's copies. From Rubens and Benson (1971).

problem in visual agnosia could thus result from an inability to generate a high-level representation of the object (a perceptual deficit), a permanent loss of previously stored representations (a memory deficit), or an inability to link the two. In fact, some evidence suggests that different agnosic patients are impaired in distinct stages of visual processing and storage. At the same time, recent work suggests that, at the neural level, “perceptual” and “memory” processes for objects may use the same circuitry (and thus, might be experimentally inseparable), as discussed later in this chapter.

### Object Recognition in Monkeys Depends on the Inferior Temporal Cortex

Ablation studies in monkeys have (1) confirmed the crucial role of the temporal lobes in visual object perception and recognition, and (2) clarified the nature of the visual representations used in the object recognition process. One of the earliest experimental studies on the role of the temporal cortex in visual recognition was that of Klüver and Bucy, who described in the 1930s what is now known as the Klüver–Bucy syn-

drome. When these researchers removed the temporal lobes of monkeys bilaterally, the monkeys demonstrated complex changes in visual, social, sexual, and eating behavior. These changes appeared to result from a combination of perceptual, memory, and motivational impairments. Subsequent research eventually identified the region now known as inferior temporal (IT) cortex as the critical area for producing the visual component of the syndrome. Monkeys with bilateral IT lesions are impaired both in learning to distinguish between different visual patterns or objects, and in retaining previously acquired visual discriminations. Figure 46.1 shows the location of this area in the macaque brain, relative to the areas implicated in agnosia in humans.

What type of stimulus representation is impaired after IT lesions? A great deal of research has been devoted to this question. Generally, such experiments measure whether monkeys can discriminate different stimuli, before and after experimental lesions in IT cortex—and from any such differences, object-processing mechanisms are inferred. A current summary might be that the IT cortex represents aspects of the intrinsic shape of the stimulus that are useful for recognition (e.g., the salient features in a face and their relative positions), generalizing across idiosyncratic aspects of stimulus appearance that depend on specific viewing conditions (see later).

Position in the visual field (retinotopy) is one of these specific visual properties that is independent of object identity, and normal monkeys will easily generalize a visual discrimination learned in one part of the visual field to the other. For example, if monkeys learn to tell apart stimuli in one half of visual space, they will easily be able to perform the discrimination when the same stimuli are presented to the other half of visual space. However, monkeys with IT lesions are impaired at this generalization; presumably they have lost representations that are invariant across visual field locations. Retinal image size of a stimulus is a related visual property that depends on viewing conditions and not just intrinsic object geometry, and this is another perceptual distinction that is difficult for monkeys with IT lesions. For example, monkeys trained to discriminate between two disks of different absolute sizes are unable to perform the discrimination when those disks are presented at variable distances (hence with variable retinal image sizes). Instead, they respond on the basis of retinal size or distance. This result implies that representations within IT cortex normally encode the absolute size of an object, an intrinsic object property useful for recognition, rather than its distance *per se* or its retinal image size. Finally, variations in illumination prevent monkeys with IT

lesions from seeing the equivalence of objects, implying that representations in IT cortex are unaffected by patterns of shadow and light falling on object surfaces.

### Summary

Studies of brain damage in humans, and experimental lesions in monkeys, both point to the crucial role of the inferior temporal cortex during object perception and recognition. In both species, analysis of the ensuing deficits suggests that this region participates in creating and storing neural representations of the defining features and invariant aspects that identify a visual object or class of objects.

## VISUAL PATHWAYS FOR OBJECT PROCESSING IN NONHUMAN PRIMATES

### The Visual Cortex of Monkeys Can Be Divided into Occipitotemporal and Occipitoparietal Pathways

Much of our detailed knowledge of visual cortical organization derives from studies of Old World monkeys of the genus *Macaca*. Similar regions and processing stages are now known to exist in both New World species (Chapter 44) and in humans, as described later in this chapter. The original evidence that the visual cortex is divided into separate processing streams was based on the contrasting effects of inferior temporal and posterior parietal cortex lesions in monkeys. For example, inferior temporal lesions cause severe deficits in visual discrimination tasks, but they do not affect animals' performance on visuospatial tasks (e.g., visually guided reaching and judging which of two objects lies closer to a visual landmark). In contrast, parietal lesions do not affect visual discrimination ability but instead cause severe deficits on visuospatial performance. On the basis of behavioral results such as these, Ungerleider and Mishkin (1982) proposed the existence of two processing streams: an occipitotemporal or ventral processing stream for mediating the visual recognition of objects ("what" an object is) and an occipitoparietal or dorsal processing stream for mediating the appreciation of the spatial relationships among objects and the visual guidance toward them ("where" an object is). Goodale and Milner (1992) have proposed a modification of this model, emphasizing "perception" vs. "action" for ventral and dorsal processing

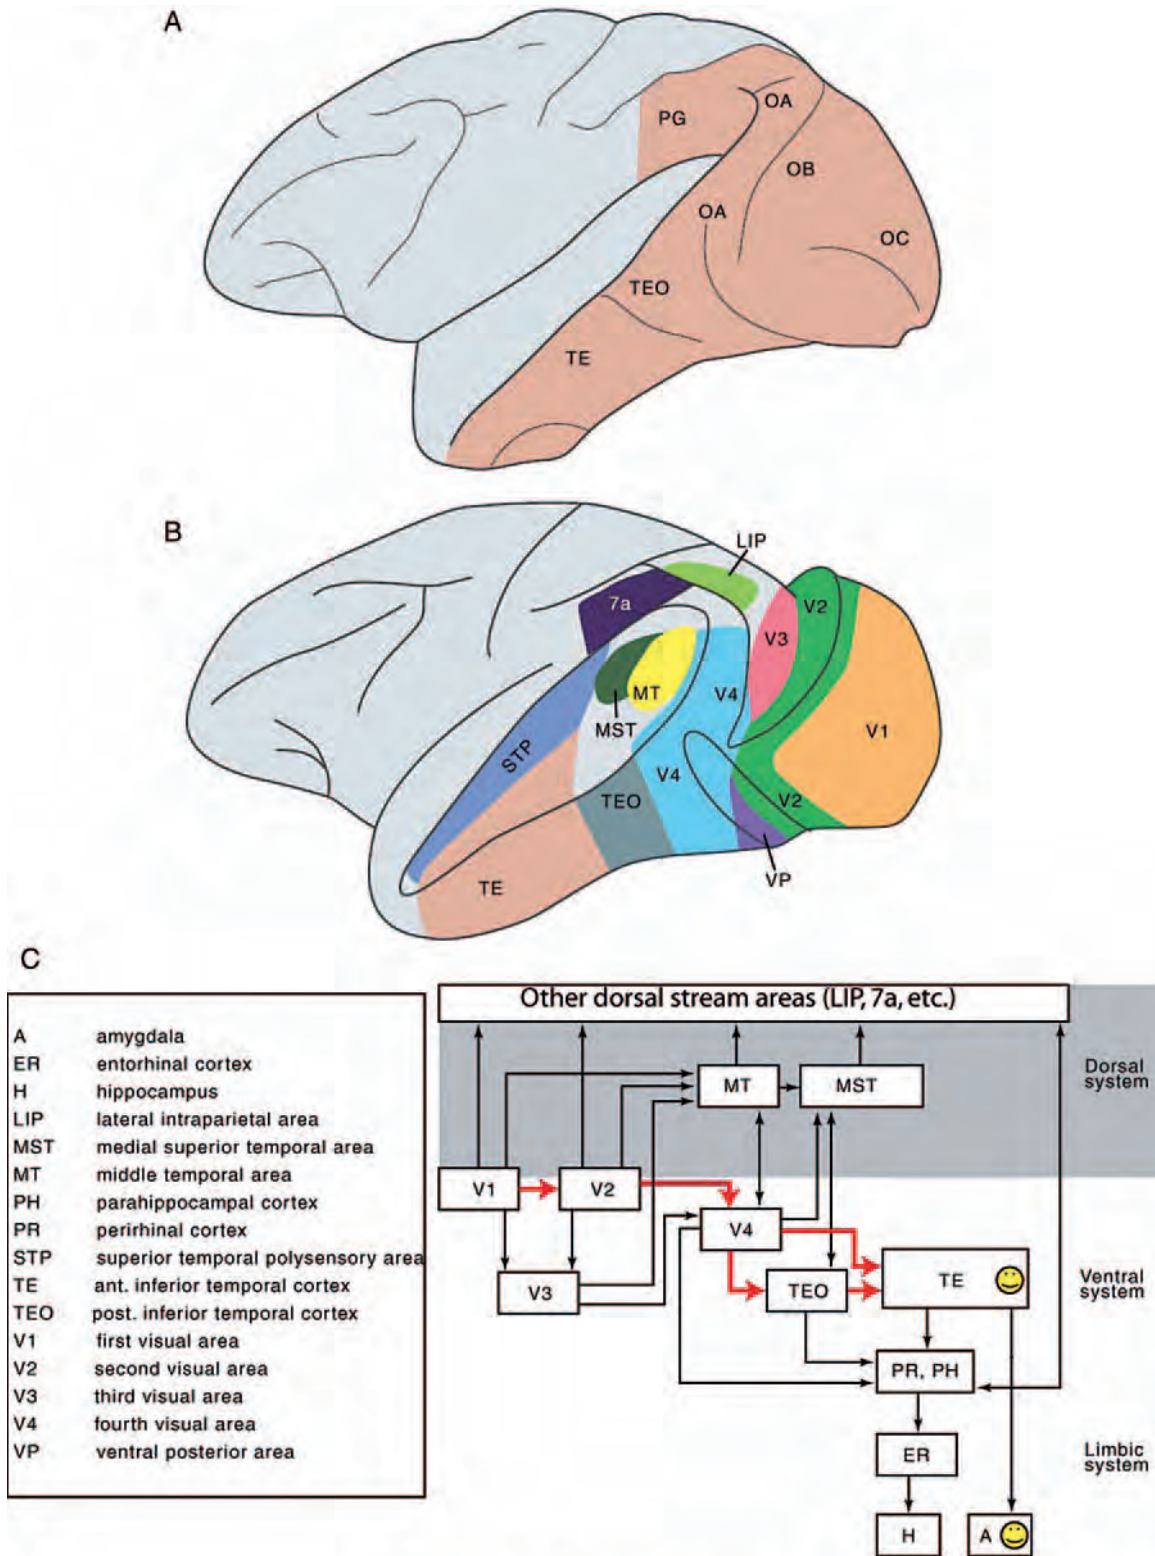

streams, respectively. The dorsal processing stream and its importance for spatial cognition is the topic of Chapter 47.

As described in Chapter 27, physiological studies of cell properties also support the functional distinction between ventral and dorsal pathways. Neurons within the ventral stream (in distinct modules within V1 and V2, area V4, and inferior temporal areas TEO and TE) respond selectively to visual features relevant for object identification, such as color, shape, and texture. Neurons within the dorsal stream (in other modules within V1 and V2, areas V3, V3A, middle temporal area MT, medial superior temporal area MST, and additional areas in inferior parietal cortex) instead respond selectively to spatial aspects of stimuli, such as the direction and speed of stimulus motion. Such cells also respond when the animal visually tracks a moving target. The remainder of this section describes the anatomy of the *occipitotemporal pathway* for object recognition.

### The Object Recognition Pathway in Monkeys Consists of an Interconnected Set of Cortical Areas

In both monkeys and humans, cortical regions comprising the object recognition pathway lie directly adjacent to the primary visual cortex (V1) in the occipital lobe, extending progressively into more anterior and ventral portions of the temporal lobe. Figure 46.3 illustrates the location of these areas and diagrams the forward flow of information within this occipitotemporal pathway in monkeys (see also Fig. 46.10). The cortical analysis of objects begins in V1, where information about contour, orientation, color composition, and brightness is represented in subsets of neurons coding for each point in the visual field (Chapter 27). Information from V1 projects forward to neural subdivisions—interdigitating thin, thick, and interstripe regions—within V2 (Chapters 27 and 44). From the thin and interstripe regions in V2 (specialized, respectively, for color and form information, roughly speaking), neural signals proceed forward to area V4 on the lateral and ventromedial surfaces of the hemisphere and to a posterior inferior temporal area just in front of V4, area TEO. From both V4 and TEO, signals related to object form, color, and texture proceed forward to area TE, the last exclusively visual area within the ventral stream for object recognition. Together, areas TEO and TE constitute the IT cortex.

Progressing forward along the occipitotemporal pathway from V1 to TE, there is a gradual shift in the nature of connectivity, which is significant for the

◀ **FIGURE 46.3** (A) Schematic diagram of the macaque monkey brain illustrating the two cortical visual system model of Ungerleider and Mishkin (1982). According to this model, there are two major processing pathways, or “streams,” in the visual cortex, both originating in the primary visual cortex: a ventral stream, directed into the temporal lobe and crucial for the identification of objects, and a dorsal stream, directed into the parietal lobe and crucial for spatial perception and visuomotor performance. The shaded region indicates the extent of the visual cortex in the monkey, and the labels (OC, OB, OA, TEO, TE, PG) indicate cytoarchitectonic areas according to the nomenclature of von Bonin and Bailey. Adapted from Mishkin *et al.* (1983). (B) A lateral view of the monkey brain illustrating the multiplicity of functional areas within both processing streams. (C) Some of the pertinent connections of the inferior temporal cortex with other cortical areas and medial temporal lobe structures. Red lines indicate the main afferent pathway to area TE, which includes areas V1, V2, V4, and TEO. For simplicity, only projections from lower order to higher order areas are shown, but each of these feed-forward projections is reciprocated by a feedback projection. Faces indicate areas in which neurons selectively responsive to faces have been found. Adapted from Gross *et al.* (1993).

eventual extraction of invariant object features. At successive stages, patterns of cortical projections become successively less topographic or “point to point.” While connections from V1 to V2 maintain topographic order, the organization becomes looser between V2 and V4, and inputs to area TE from V4 and TEO retain no obvious retinotopic organization. Likewise, pathways interconnecting areas of the ventral stream on the two sides of the brain via the corpus callosum and/or the anterior commissure tend to be restricted to the representation of the midline of visual space early in the pathway, but their representation becomes more widespread at higher levels in the pathway. This loss of retinotopy within area TE means that single neurons respond to objects anywhere in the visual field. This evidence suggests that the initial explicit information about spatial position in the visual field (“retinotopy”) has been converted to information about object identity, in at least some parts of IT cortex.

However, neural processing in the object recognition pathway is not a simple elaboration of information from lower order to higher order areas. At all stages, the neural connections are reciprocal, such that an area receiving feedforward projections from an area earlier in the ventral stream also provides feedback projections to that area. Long-range nonreciprocal connections, such as from area TE back to V1, also exist. On the one hand, feedforward projections provide bottom-up, sensory-driven inputs to subsequent visual areas, and severing these projections disconnects subsequent areas from their visual input. On the other hand, the precise functions of reciprocal,

feedback projections are still unknown. Probably these feedback projections play a top-down role in vision (as in selective attention) by modulating activity in earlier areas of the ventral pathway (Chapter 48). In addition to feedforward and feedback projections, there also appear to be “intermediate-type” projections that link areas at the same level of the visual hierarchy. These are seen most notably between areas of the dorsal and ventral streams. For example, area V4 is interconnected with motion-sensitive areas MT and MST. Thus, an anatomical substrate exists for interactions between the two processing streams, and these might serve to integrate what an object is with where an object is.

All areas within the ventral stream also have heavy interconnections with subcortical structures, notably the pulvinar, claustrum, and basal ganglia. In addition, each ventral stream area also receives subcortical modulatory inputs from ascending cholinergic projections from the basal forebrain, and ascending noradrenergic projections from the locus coeruleus. These projections are thought to play a role in the storage of information in the cortex, and the influence of arousal on information processing, respectively. Finally, visual information is sent *from* IT cortex to the most ventral and anterior reaches of the temporal lobe, notably the perirhinal cortex and parahippocampal areas TF and TH. These regions in turn project, via the entorhinal cortex, to medial temporal lobe structures, such as the hippocampus, which contribute to forming long-term memories of visual objects and their contexts (Chapter 50). Information is also sent from IT cortex to the prefrontal cortex, which plays an important role in working memory, holding an object briefly in mind when it is no longer visible (Chapter 52). Finally, there are direct projections from IT cortex to the amygdala, which is important for attaching emotional valence to a stimulus (Chapter 50).

## Summary

Areas along the occipitotemporal pathway of the monkey are organized hierarchically proceeding from V1 > V2 > V4 > TEO > TE. At progressively higher stages of this hierarchy, there is a corresponding loss (or conversion) of retinotopic information, such that information about the spatial location of the object is gradually changed. In addition to this bottom-up information (supplied by feedforward projections from lower order to higher order visual areas within this pathway), there are also reciprocal, feedback projections from higher order to lower order visual areas. These latter projections are thought to play a top-down role in vision.

## NEURONAL PROPERTIES WITHIN THE OBJECT RECOGNITION PATHWAY

### Cells along the Occipitotemporal Pathway Are Sensitive to Increasingly More Complex Physical Features of Objects

The different cortical areas in the occipitotemporal pathway share a number of physiological characteristics. Consistent with a role in object recognition, all areas in the pathway contain populations of cells sensitive to the shape, color, and/or texture of visual stimuli. However, at progressively higher levels, cells have larger receptive fields and their stimulus selectivity is more complex to characterize. Thus, higher order properties (consistent with invariant representation of objects) usually are attributed to cells in higher tier areas. For instance, many V1 neurons function as local spatial filters, signaling the presence of contours at particular positions and orientations in the visual field. In contrast, an increasingly higher proportion of cells in higher tier areas (e.g., V2 and beyond) apparently respond to *illusory* contours (i.e., contours implied by stimulus context and higher-order properties, not due to simple light-dark contrast), across increasingly larger regions of the visual field.

Additional higher-order, object-related properties are also seen at higher tier cortical levels. One of these properties is increasing stimulus invariance, namely, similar shape selectivity despite variations in the type of lower-order cues used to generate the shape (such as luminance, color, motion, etc). Another of these properties is increasingly strong, silent suppressive zones surrounding the classical, excitatory receptive field of cells. These zones are called silent because visual stimulation of them normally does not cause any change from the baseline activity of the cells—although it can nevertheless powerfully affect responses to a stimulus placed in the classical receptive field. For example, many V4 cells respond maximally to a stimulus only if it stands out from its background based on differences in form—as in the well-known perceptual phenomenon of figure/ground segregation, a computation that remains difficult to achieve in machine-based object recognition.

Farther forward in area TEO of the occipitotemporal pathway, and then into posterior and anterior portions of area TE, there are further increases in the complexity of the critical features needed to activate many neurons, and relative increases in the proportion of cells that are selectively driven by some kind of complex pattern or object (Gross *et al.*, 1972). Thus at the highest levels, it can become very difficult to discover (or prove) the

optimal stimulus for a given single cell, by simply testing various visual stimuli and intuiting the response constraints, because the number of possible test stimuli is literally infinite.

This experimental problem is related to the idea, developed sometime in the late 1960s, that every object would be coded by maximal firing in a single cell in IT cortex; this was termed the “grandmother cell” hypothesis because each “grandmother” was thought to cause maximal firing in a single cell (Gross, 2002). This idea, which was controversial from its inception, is considered by most researchers to be overly simplistic. Indeed, there simply are not enough neurons to represent all the different objects we can recognize. Instead, a “population code” is more likely, in which each specific object (and perhaps each viewpoint) causes a correspondingly unique pattern of firing in multiple cells that share connections and overlapping functional selectivity.

This latter idea is supported by evidence suggesting that IT cells are anatomically grouped into functionally similar patches, columns, or areas (see later). Based on findings from single-unit and optical recording, Tanaka (1996) has suggested that IT cells that respond to common visual features are grouped together into cortical columns that run perpendicular to the cortical surface (Fig. 46.4). This object-column model is similar to that for other well-known columns in early visual areas, which are selective either for orientation, ocular dominance, spatial frequency, or direction of motion. However in Tanaka’s model, there is a continuous mapping of complex feature space within a larger region that contains several partially overlapping columns (Fig. 46.4), rather than just one periodic feature, such as orientation, mapped repeatedly. Newer evidence from functional magnetic resonance imaging in awake monkeys confirms that cells with common functional properties are grouped together in IT cortex (see later)—although details of this organization remain incompletely understood.

Thus, a given object is apparently not represented by the activity of a single cell, but by the activity of many cells across different columns or regions. This unique-but-overlapping population code satisfies two otherwise conflicting requirements in visual recognition: robustness to subtle changes in input, and precision of representation. Although the image of an object projected on the retina changes in response to variations in illumination and viewing angle, the pattern of activity in IT cortex will be largely maintained, insofar as the clustering of cells with overlapping but slightly different selectivity serve as a buffer to absorb such changes.

**FIGURE 46.4** Schematic diagram illustrating the columnar organization in area TE of the monkey. Cells with similar but slightly different selectivity tend to cluster in elongated vertical columns perpendicular to the cortical surface. Stimuli shown are examples of the critical features for the activation of single cells in TE. Most cells, as shown, require moderately complex features for their activation, although some can be driven by simpler stimuli, such as color, orientation, and texture. Adapted from Tanaka (1996).

### Some Cells in the Occipitotemporal Pathway Are Face Selective

One of the more striking characteristics of monkey temporal cortex is the presence of neurons with responses selective for face stimuli, first described by Bruce *et al.* (1981) and Perrett *et al.* (1982). For several decades, such cells were found by recording blindly, but recently it has been shown that such cells are organized into several column-sized patches in macaque IT cortex, in which up to 97% of the cells are selective for faces (Tsao *et al.*, 2003, 2006). These “face patches,” located largely within the superior temporal sulcus, are embedded within a large swath of object-selective cortex extending from V4 to anterior TE. As described later, the macaque face patches appear homologous to face-selective regions in human cortex.

Face-selective cells vary in the degree and nature of their preference for face stimuli. Many respond well to both real faces or face pictures, but give little or no response to any other stimuli tested, including other complex objects, texture patterns, and images in which the features making up the face are rearranged or scrambled (Fig. 46.5). Thus, at least some face-selective neurons appear to be sensitive to very general or global

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 46.5** Activity of an STP neuron that responded better to faces than to all other stimuli tested. Removing eyes on a picture or representing the face as a caricature reduced the response. Cutting the picture into 16 pieces and rearranging the pieces eliminated the response. All the unit records are representative ones chosen from a larger number of trials. The receptive field of the neuron is illustrated on the lower right. C, contralateral; I, ipsilateral visual field. From Bruce *et al.* (1981).

aspects of a face, such as the prototypical arrangement of the eyes, nose, and mouth into a face-like configuration. Other neurons respond to specific face components, such as the presence of eyes *per se*, the distance between the eyes, or the extent of the forehead. Although such neurons may merely be sensitive to facial features, they are nonetheless likely to participate in circuits responsible for recognizing a particular individual. Indeed, recent work has demonstrated that electrical microstimulation of face-selective cells biases object categorization in the direction of face perception, thus establishing a causal relationship between face-selective neurons and face perception (Afraz *et al.*, 2006).

One subset of face-selective cells appears especially sensitive to the direction of gaze of the eyes (looking back directly or turned to the side), which is an important social signal for both monkeys and humans. Other neurons apparently respond selectively to *biological motion*; that is, motion patterns consistent with what one sees when one observes the gait of another animal. Such cells respond when viewing a monkey or human walking, or to equivalent motion patterns generated by so-called Johanssen point-light stimuli (i.e., stimuli generated by attaching lights to the joints of a moving animal, which is otherwise in the dark).

Together, these observations have led to the proposal that the primate temporal lobe has evolved specialized mechanisms for the encoding and recognition of biologically significant stimuli, especially faces. Are such regions innate, or recruited and trained as a result of experience? This is another form of the classical nature-versus-nurture question. Some evidence (e.g., preferential looking at faces in newborns) suggests that face-selectivity may indeed be innate. Alternative interpretations of such *category-specific* phenomena also are discussed later, which take into account the learning history of the individual.

### The Occipitotemporal Pathway Extracts Some Invariant Aspects of Objects

As suggested at the start of the chapter, visual information impinging on the retina is a two-dimensional projection of a three-dimensional world—a projection that varies dramatically due to changes in the position, distance, illumination, and orientation of an object relative to the viewer. Thus, the function of the occipitotemporal pathway can be defined in large measure as determining and encoding those *invariant* features of objects that are useful for recognition across myriad circumstances. Exactly how this might be accomplished is unclear even at a theoretical level. However, several findings suggest how this process might at least begin.

As described earlier, as one progresses forward from V1 to TE, receptive fields become larger and the retinotopic maps less precise. By area TE, receptive fields are large and bilateral, typically encompassing the central 20° or more—up to the entire visual field in far anterior TE. As we have seen, the large receptive fields of TE neurons signal the presence of a given feature, collection of features, or object, regardless of where they fall in the visual field. In other words, they exhibit invariance of stimulus coding across changes in retinal position.

In addition to invariance over retinal position, many neurons in TE show maintained selectivity for their

“preferred” stimuli over more complex kinds of transformations, such as size, distance from the subject in depth, or degree of ambient illumination; thus, they show invariance over a number of the changes that normally take place as a moving object is viewed under naturalistic conditions. Also, many TE neurons show *form-cue invariance*: for example, a neuron selective for a particular shape defined by luminance borders (e.g., a white star on a black background) will also respond selectively to the same form when it is instead defined by relative texture and motion cues (e.g., a star-shaped region of speckles of the same average luminance as the background, moving in a direction different from the background). Taken together, these various types of response invariance or *generalization* can explain the various deficits seen in experimental monkeys when IT cortex is removed, as described earlier.

As discussed in Box 46.2, one central question in object recognition has been the degree to which neural representations of objects are object-centered (view independent) or viewer-centered (view dependent). The question of *view dependence* has been addressed by a number of single-unit studies of neurons in TE. For example, in one study, monkeys were trained to recognize specific novel three-dimensional objects from any viewpoint after experience with a few prototypical views in a discrimination task (Logothetis *et al.*, 1995). After months of such training, the monkeys were found to have neurons in TE that exhibited strong selectivity for precisely those views on which the animal had been trained. These results support the view-dependent account of object recognition. Studies of face-selective neurons in area TE also initially provided strong support for view dependence by finding separate populations of cells tuned for front and profile views. However, other studies have shown that at least small subsets of TE neurons respond to faces or objects independent of view, providing evidence for view-independent representations as well. Overall, the issue of view dependence remains an open question, with some evidence for both accounts to be found in the neurophysiological literature as well as in psychophysical studies (Fig. 46.6).

### Response Properties of Cells in the Object Recognition Pathway Are Affected by Experience

The previous sections illustrate how the object recognition pathway, especially area TE, represents features that are useful for recognition. For example, some neurons respond selectively to the salient features in a face, or their relative positions, while ignoring aspects of stimulus appearance that depend on viewing

## BOX 46.2

## THE ISSUE OF VIEWPOINT DEPENDENCE IN OBJECT RECOGNITION

Although we know something of the underlying anatomy and physiology, the mechanisms by which object recognition actually is accomplished by the brain have been a matter of heated debate. The pioneering theoretical work of Marr in the late 1970s set the stage for current theories, which can be divided into two main groups: object-centered (view independent), and viewer-centered (view dependent) theories.

According to *object-centered* accounts, objects are represented in the brain as hierarchies of parts that are, to a large degree, independent of any particular viewpoint. One of the best known examples is Biederman's (1990) recognition by components (RBC), which postulates that objects can be defined as a set of 30 or so primitive shapes, so-called *geons*. In this theory, geons are three-dimensional component building blocks, which, when combined, form the objects that we know (Fig. 45.6). Thus, any arbitrary object may be described as a collection of elementary geons. For example, the telephone in Figure 45.6 can be constructed from geons 1, 3, and 5. One compelling feature of geons for object recognition is that particular ones can be inferred from the presence of *nonaccidental relations* between image contours or parts. Nonaccidental relations are those unlikely to occur by chance, such as parallel or colinear edges, closure, and symmetry. Also, because the same nonaccidental features can be derived across a wide range of image variations, detection of geons and their spatial relations would be preserved over changes in position, distance, illumination, and orientation; the telephone, for example, looks pretty much the same (in terms of its constituent geons and how they sit relative to one another) from a variety of angles. Therefore, according to RBC, recognizing an object amounts to determining the set of geons that compose the object and determining the spatial relations between them.

*Viewer-centered* theories, however, suggest that recognition is linked to the appearance of objects as originally seen. In other words, the brain is not thought of as storing a central, invariant representation of an object, but instead as storing information from multiple independent views (e.g., a view of the telephone as in the figure, but also an end-on or side view, a view from above, etc.). A potential problem with this idea is that it might seem that for reliable object recognition, stored representations for *all* views of objects would need to exist. The solution is to

suggest that a small set of characteristic or *prototypical* views would suffice. Proponents of this approach have offered a variety of different theoretical normalization mechanisms for generalizing from unfamiliar views to the familiar, prototypical stored views (Bulthoff *et al.*, 1995). For example, the visual system might mentally rotate the object as currently seen to bring it into line with a prototypical view or do an interpolation or comparison of the current view with multiple stored views. Therefore, according to viewer-centered theories, recognizing an object amounts to explaining the appearance of an incoming stimulus in terms of transformations or combinations of previously stored representative views.

At first glance, object-centered theories appear more compelling, as they attempt at the outset to solve the central problem associated with object recognition, namely reliable recognition despite variation in the precise retinal image. However, one serious challenge is how the brain chooses the correct structural interpretation among the possible ones, as a given set of geons may be compatible with several different objects. Psychophysical testing also indicates that object-centered encoding is not the whole story; studies have shown substantial and robust viewpoint effects even for extremely simple three-dimensional volumes resembling proposed geon primitives.

However, viewer-centered approaches also face challenges. Viewer-centered theories have been most successful in accounting for *exemplar-level* recognition; that is, discriminating between individual visually similar objects within a relatively homogeneous class of objects such as faces, cars, or birds. Though recognition at the exemplar level is often important, there is little question that so-called *class-level* recognition actually constitutes much of the job of recognition. For example, for objects such as chairs, telephones, and toasters, we rarely need to discriminate two instances of the class and instead we learn to recognize such objects at a basic category or class level. Viewer-centered models suggest that the brain represents the appearance of a specific individual example of an object from specific viewpoints, and thus seem unsuitable or unnecessary for class-level recognition. Moreover, even for a single exemplar, it is uncertain how many prototypical views are enough for robust recognition. One solution would be to store as many views of an object as possible so that new views would always be similar

(continues)

## BOX 46.2 (cont'd)

enough to some previously stored view. However, it is unclear that there can ever be sufficient memory to do so for all the objects that the observer becomes proficient at recognizing under varied conditions.

conditions, such as absolute size and luminance. However, in ecological terms, what is useful and salient within the image of an object or scene changes with experience and context, and these changes are reflected in the way the brain represents stimuli over time. Neurons in IT cortex and the adjacent perirhinal cortex show effects of both recent viewing history and long-term experience with stimuli.

Experiments by Miller and Desimone (1994) have shown how short-term changes in response properties of temporal neurons encode aspects of both stimulus recency and short-term stimulus significance. For example, for many of these cells, responses to an object that is presented repeatedly *decrease* in a systematic fashion, potentially signaling that the object has been seen recently. Such reduced signals may be useful for redirecting attention to novel objects. This kind of response decrement, termed *repetition suppression*, has

been found both under anesthesia and for stimuli that an awake animal is trained to ignore. This habituation-like response is therefore a passive, largely automatic mechanism by which the visual system edits out recently seen objects. In contrast, if a monkey is trained to do a matching task in which it must hold a particular visual pattern in memory over a short delay, some temporal neurons *increase* their firing rates specifically when the to-be-remembered stimulus is recognized. This phenomenon, termed *mnemonic enhancement*, can be thought of as a mechanism in which bottom-up processing of the stimulus is affected by top-down, cognitive factors, namely, expectation of the relevant stimulus (Fig. 46.7). Stimuli that are repeated but are not behaviorally relevant in the context of the task do not show this enhancement effect.

Experiments such as these demonstrate that the magnitude of neuronal responses can be affected by the experience of the subject with the stimulus and by its significance, at least in the short term. Other studies suggest that the kind of familiarity gained over longer periods of time—akin to the development of “expertise” as discussed later in the chapter—can also be reflected in the responses of TE cells. For example, in monkeys that have been trained for as long as a year to discriminate between objects, more than 30% of the cells show selectivity for those objects compared to untrained monkeys in which roughly 10% of the cells show such selectivity (Kobatake *et al.*, 1998).

Intriguingly, some TE and perirhinal cells can represent the *history of association between objects* in the activity patterns they exhibit in response to members of a set of stimuli. Some research groups have examined mechanisms of visual memory by using *paired-associate* tasks, in which monkeys are trained to associate arbitrary patterns with one another for reward. In one experiment, monkeys were first shown one member of a learned pair and then were required to choose the associated “match” from a display of two stimuli while single-unit activity was recorded in ante-

**FIGURE 46.7** Experiment demonstrating mnemonic enhancement. (A) On each trial, the monkey was shown a sample stimulus, and then between zero and four intervening nonmatching items appeared before the matching stimulus was presented. Repeated nonmatches appeared after zero (as shown) or one intervening stimulus between them. The task of the monkey was to respond to the matching test stimulus and ignore repeated nonmatches. (B) Responses of a neuron to a single stimulus appearing as a match, nonmatch, and repeated nonmatch. Horizontal bars under the histograms indicated when the stimuli were on, which was 500ms for nonmatch and repeated nonmatch stimuli. The match stimulus was terminated when the animal made its response. Results show mnemonic enhancement to the match stimulus but not to a stimulus that repeats but is not held in mind (i.e., repeated nonmatch). Adapted from Miller and Desimone (1994).

rior IT cortex (Sakai and Miyashita, 1991). Across all cells recorded, the authors found neurons that responded best to stimuli that had been paired together during training. In other words, some cells in temporal cortex developed conjoint selectivity (*pair coding*) for the members of associated pairs. It was shown that pair coding by TE cells was decreased by surgically interrupting the feedback projections to them from the perirhinal and entorhinal cortices. Thus, return projections appear to play a specific role in associating objects because the pair-coding property depends on them.

Although associative learning effects typically have been seen in studies after weeks or months of training, there is evidence that small but detectable shifts in neuronal population selectivity occur after only a day or so of experience; this suggests that TE cells tend to develop pair-coding properties more rapidly than previously thought (Ericksen *et al.*, 2000; Messinger *et al.*, 2001). Thus, the pattern of selectivity shown by TE cells at any given moment in time may partly reflect a

record of their exposure to stimuli seen together. Overall, TE circuits appear to represent not only complex visual features, but also the history of their meanings and relationships in a behavioral context.

### Summary

At successive levels of processing along the occipitotemporal pathway, increasingly complex kinds of information about objects are extracted. In area TE of IT cortex, some neurons are preferentially responsive to faces and other biologically significant stimuli. In addition, TE neurons apparently extract some invariant aspects of objects. For example, TE neurons show similar selectivity for object shape, regardless of large changes in their retinal position, size, distance in depth, and degree of ambient illumination. Finally, as the result of experience, some TE neurons come to represent novel objects and/or the associative relations between objects.

## FUNCTIONAL NEUROIMAGING AND ELECTROPHYSIOLOGY OF OBJECT RECOGNITION IN HUMANS

### The Human Brain Also Has Ventral and Dorsal Processing Streams

The differential visual impairments produced by focal lesions in clinical cases suggest that the human visual cortex, like that of the monkey, contains two anatomically distinct and functionally specialized pathways: the ventral and dorsal streams. For example, one study demonstrated a double dissociation of visual recognition (face perception camouflaged by shadows) and visuospatial performance (maze learning) in two men with lesions of the occipitotemporal and occipitoparietal cortex, respectively, confirmed by postmortem examination (Newcombe *et al.*, 1987). The specific clinical syndromes produced by occipitotemporal lesions include visual object agnosia, as noted earlier, as well as prosopagnosia, an inability to recognize familiar faces, and achromatopsia, or cortical color blindness. In contrast, syndromes produced by occipitoparietal lesions include optic ataxia (misreaching), visuospatial neglect, constructional apraxia, gaze apraxia, akinetopsia (an inability to perceive movement), and disorders of spatial cognition. Interestingly, imagery disorders involving descriptions of either objects (especially faces, animals, and colors of objects) or spatial relations (geographic directions) are also dissociable following temporal and parietal lesions, respectively.

The development of functional brain imaging, including PET (positron emission tomography) and fMRI (functional magnetic resonance imaging), has made it possible to map the organization of the human visual cortex with far greater precision than is possible with human lesion studies, and without the confounding influence of compensatory responses to brain injury. For instance Haxby and colleagues (Haxby *et al.*, 1994) were able to confirm a functional difference between ventral (object) and dorsal (spatial) pathways in humans, by measuring PET activity while subjects performed object identity and spatial location tasks (Fig. 46.8). The results identified occipitotemporal and occipitoparietal regions associated with face and location matching, respectively. In addition, regions in the ventral and dorsal frontal cortex were also selectively activated by face and location matching, respectively. These findings thus indicate the existence in humans, as in monkeys, of two functionally specialized and anatomically segregated visual processing pathways. The findings further suggest the extensions of each into the frontal lobe, which plays a role in working

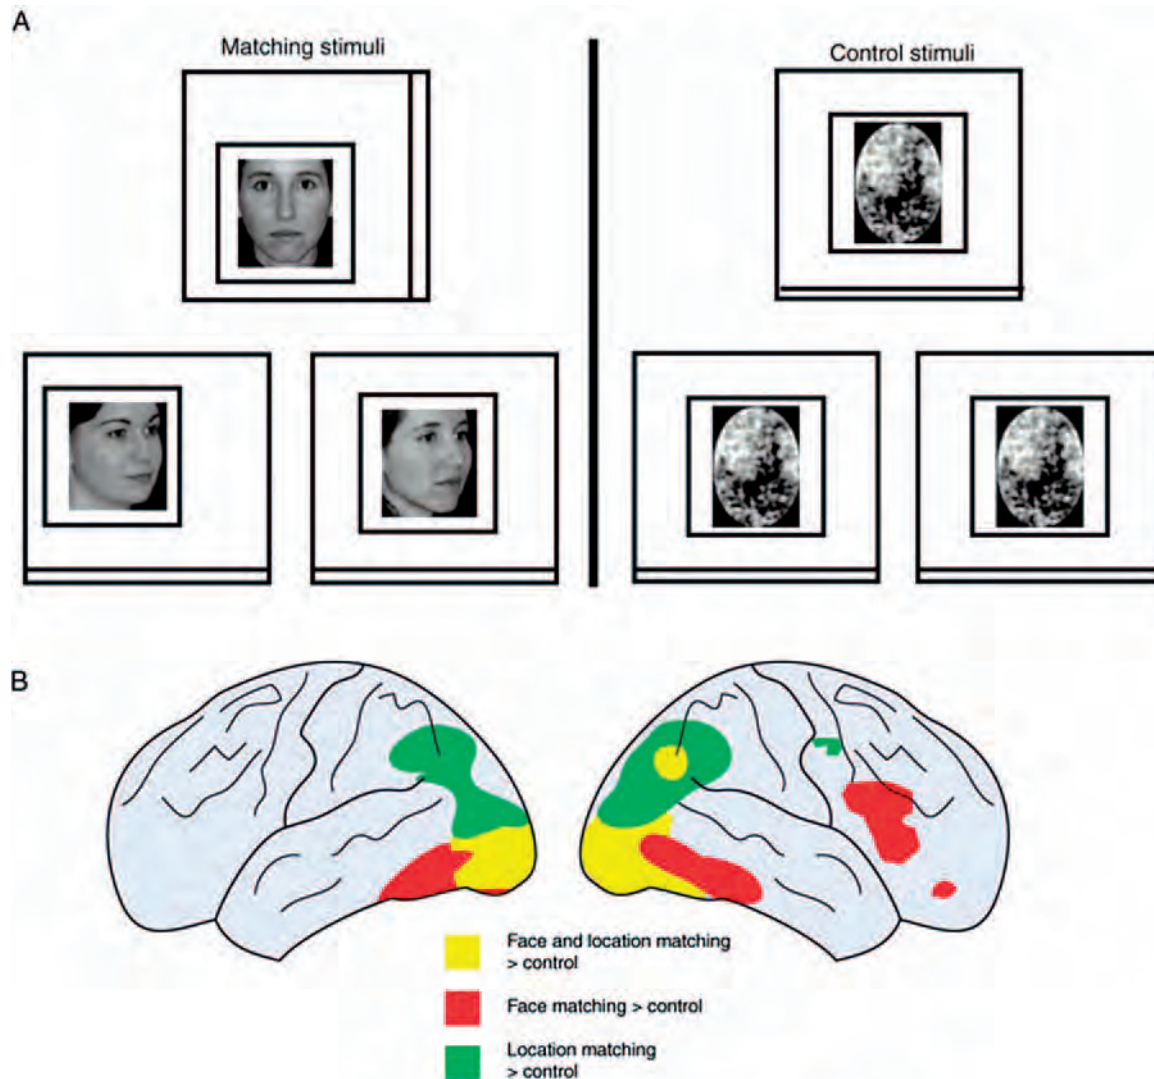

memory for objects and their spatial locations (Chapter 52).

### The “Building Blocks” of Object Recognition in Human Cortex Include Early Visual Areas and the Lateral Occipital Complex (LOC)

Functional neuroimaging studies have also revealed a number of distinct visual areas within the ventral and dorsal streams in humans. Many of these areas appear to be equivalent (and perhaps homologous) to specific monkey visual areas, including V1, V2, V3, V3A, V4v, and the middle temporal area (MT) (see also Fig. 46.10). As in monkeys, most of these areas have been defined on the basis of retinotopic maps (Serenio *et al.*, 1995). Area MT, a small area with somewhat disorganized retinotopy, instead has been defined on the basis of its distinctive functional properties (strong selectivity for visual motion and direction) in both human neuroimaging and single-unit recordings in macaque.

As described earlier, receptive field size increases, and stimulus requirements become more stringent, as one progresses from V1 through various stages of the ventral stream. For instance, single units in macaque IT cortex do not respond to “scrambled” versions of object images (e.g., Fig. 46.5). To test for analogous regions in human visual cortex, Malach and colleagues (Malach *et al.*, 1995) compared responses evoked by a range of images to activations evoked by “scrambled” versions of those same images, while attempting to equate several image properties (such as size and contrast). Regions responding more to objects than to scrambled stimuli were interpreted as being involved in object-related processing; collectively these regions were named the lateral occipital complex (LOC) because of their anatomical location (Fig. 46.9). Later neuroimaging studies revealed that the cortical regions activated by such stimuli includes classical IT cortex in macaques (Tootell *et al.*, 2003; Denys *et al.*, 2004); see Figure 46.10.

A number of fMRI findings suggest that the LOC is an important stage in human object processing. First, whereas early visual areas V1–V3 respond similarly to intact, recognizable stimuli and highly scrambled, unrecognizable pictures (scrambled pictures tend to elicit even stronger responses), the LOC exhibits a high sensitivity to image scrambling (in fact, the LOC often is defined by contrasting objects to scrambled objects). Second, a fourfold change in visual object size does not affect the LOC activation, although it changes some stimulus properties greatly (e.g., local contrast); responses in the LOC also exhibit some invariance to changes in image position. Third, the LOC responds

**FIGURE 46.8** Ventral and dorsal processing streams in the human cortex, as demonstrated in a PET imaging study of face and location perception. (A) Sample stimuli used during the experiment. (Left) Stimuli for both face and location matching tasks. During face matching trials, subjects had to indicate with a button press which of the two faces at the bottom was the same person shown at the top. In this example, the correct choice is the stimulus on the right. During location matching trials, subjects had to indicate with a button press which of the two small squares at the bottom was in the same location relative to the double line as the small square shown at the top. In this example, the correct choice is the stimulus on the left. (Right) Control stimuli. During control trials, subjects saw an array of three stimuli in which the small squares contained a complex visual image. In these trials, which controlled for both visual stimulation and finger movements, they alternated left and right button presses. (B) Areas shown in red had significantly increased activity during the face matching but not during the location matching task, as compared with activity during the control task. Areas shown in green had significantly increased activity during the location matching but not during the face matching task, as compared with activity during the control task. Areas shown in yellow had significantly increased activity during both face and location matching tasks. Adapted from Haxby *et al.* (1994).

to multiple visual cues. For example, the shape of an object can be defined by luminance, by texture, or by motion cues alone; objects defined by any one or more of these cues reliably evoke responses in the LOC. Fourth, objects that vary widely in their recognizability (e.g., famous faces and unfamiliar three-

dimensional abstract sculptures) produce similar activations in the LOC. Together, these findings indicate that the LOC is an intermediate link in the processing of objects; that is, a stage following low-level processing and preceding object processing stages that involve memory.

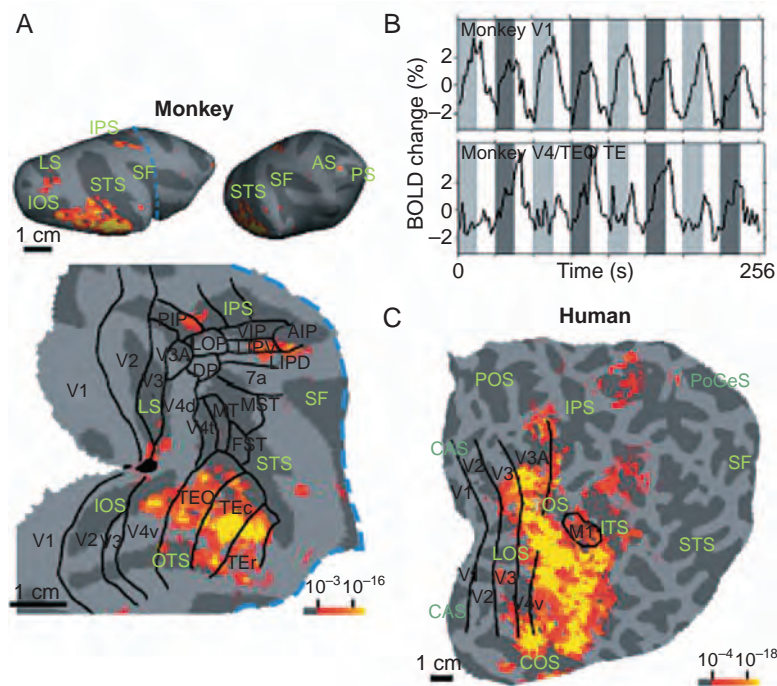

**FIGURE 46.9** Shape processing in the lateral occipital cortex (LOC). (Top) Visual stimuli that were used to investigate the effects of image scrambling on activity in the LOC, as measured by fMRI. Subjects viewed the stimuli and were instructed to covertly name them, even the scrambled images. Stimulus 1 is the original image, and stimuli 2–5 are increasingly scrambled. (Bottom) fMRI time series illustrating the averaged activations in V1 and the LOC to each of the images shown at the top. Note that LOC is very sensitive to image scrambling, whereas V1 is not. Adapted from Grill-Spector *et al.* (1998).

Although the processing of general object shape observed in the LOC appears to be important for object perception and recognition, the LOC probably is not responsible for object recognition *per se*. Whereas the LOC responds to essentially any three-dimensional shape, areas in the ventral stream anterior to the LOC, most notably on the fusiform gyrus in the ventral temporal cortex, respond preferentially to recognizable objects. It therefore is thought that object recognition is critically dependent on the ventral temporal cortex. Indeed, as later sections describe, it is likely that the storage of object representations takes place in the ventral temporal cortex as well. The next section considers the processing of specific categories of objects and the functional architecture of the ventral temporal cortex.

## Summary

Evidence from lesion studies and neuroimaging studies confirms the existence in humans, as in macaques, of two visual processing pathways: a ventral stream for object vision and a dorsal stream for spatial vision. Within the ventral stream, early visual areas, including V1–V4, are organized retinotopically and appear to be homologous to areas studied in monkeys. The LOC appears to play an important role at the next stage of processing, where general object shape is processed. Activation of the LOC is highly sensitive to image scrambling, but less sensitive to variations in image size or the visual cues that define the shape of an object. Activation of the LOC, however, is not sensitive to object recognizability, sug-

**FIGURE 46.10** Object-selective areas in the macaque and human as revealed by fMRI. (A) Areas in the macaque brain significantly more activated by intact objects than scrambled counterparts (Fig. 45.9, top). The activation is shown on two different lateral views of the “inflated” right hemisphere (top), as well as on a “flat” map of the right visual cortex (bottom). Significant activations occurred in ventral stream areas V4, TEO, and TE. (B) Time courses of activation from macaque V1 (top) and V4/TEO/TE (bottom) to alternating blocks of intact (dark gray) and scrambled (light gray) objects, separated by epochs of a blank screen (white). (C) Activity in the right hemisphere of a human subject to the same stimulus comparison. gesting that it precedes processing stages that involve memory.

## PERCEPTION AND RECOGNITION OF SPECIFIC CLASSES OF OBJECTS

### Prosopagnosia Is a Specific Deficit of Face Recognition

Evidence from neuropsychology and neurophysiology suggests that certain kinds of objects may have special significance to primates. *Prosopagnosia*, a selective deficit in recognizing familiar faces, has been known since at least the end of the nineteenth century. Although patients with this syndrome are aware that faces are faces (i.e., they know the basic stimulus category), they fail to reliably identify (or even achieve a sense of familiarity from) the faces of coworkers, family members, famous persons, and other individuals previously well known to them. Typically, prosopagnosics also have trouble forming memories of new faces, even

if other new objects can be learned. Because the voice of a visually unrecognized person usually enables the patient to identify and feel familiar with that person, prosopagnosia (face agnosia) appears to be a specifically visual impairment.

A number of explanations have been offered for the apparent selectivity of the prosopagnosic deficit. One explanation is that face perception and recognition are indeed unique behavioral capacities and reflect unique, dedicated neural circuits that can be selectively damaged. Such dedicated neural circuits may have developed through evolution due to the biological significance of faces and facial expressions for social communication. A second explanation suggests that face processing reflects subtle and difficult discriminations between highly similar exemplars within a category and that it is this general capacity, not the processing of the facial configuration *per se*, that is disrupted in prosopagnosia. This second view is consistent with the observation that prosopagnosia often is accompanied by varying levels of object agnosia. A third, and related, suggestion (see later) is that face processing represents the acquisition of a type of expertise derived from very

protracted experience with a category of complex visual stimuli. Reports of persons with prosopagnosia who have associated deficits in types of object recognition in which they had previously acquired expertise over long periods of time (e.g., a show dog expert who lost the ability to differentiate breeds) are consistent with this idea. Note that the second view may be considered as a specific form of the expertise hypothesis.

Since the 1980s, a number of cases with prosopagnosia have come to autopsy. The damage common to these lay within the *lingual and fusiform gyri* (Fig. 46.1), ventrally and medially within the cortex at the occipitotemporal junction. In all such cases, this area (or at least the underlying white matter) was damaged bilaterally, and consequently bilateral damage was thought by many to be a necessary precondition for prosopagnosia. Additional cases with prosopagnosia and right cortical damage alone, along with the results of neuroimaging studies (see later), have reopened the debate over the locus of the critical lesion in prosopagnosia.

Several recent reports of developmental prosopagnosia have provided invaluable information concerning the perceptual deficit observed in these patients. Developmental prosopagnosia is characterized by severely impaired face recognition in individuals with no detectable brain damage (i.e., presumably intact visual systems). Many developmental prosopagnosics have normal or relatively good object recognition, indicating that their impairments are not the result of deficits to a unitary visual recognition mechanism. Indeed, extensive testing of particular individuals has revealed especially pure face processing deficits (Duchaine and Nakayama, 2006). In such individuals, the results strongly suggest that faces are recognized by a content-specific, face-processing mechanism. However, it should be noted that neuroimaging studies have demonstrated a variety of neural profiles in developmental prosopagnosia, which is consistent with behavioral studies indicating that, in general, developmental prosopagnosia is a heterogeneous disorder (i.e., in some cases deficits are not restricted to faces).

### Neuroimaging and Electrophysiological Studies Also Suggest Specialized Processing Regions

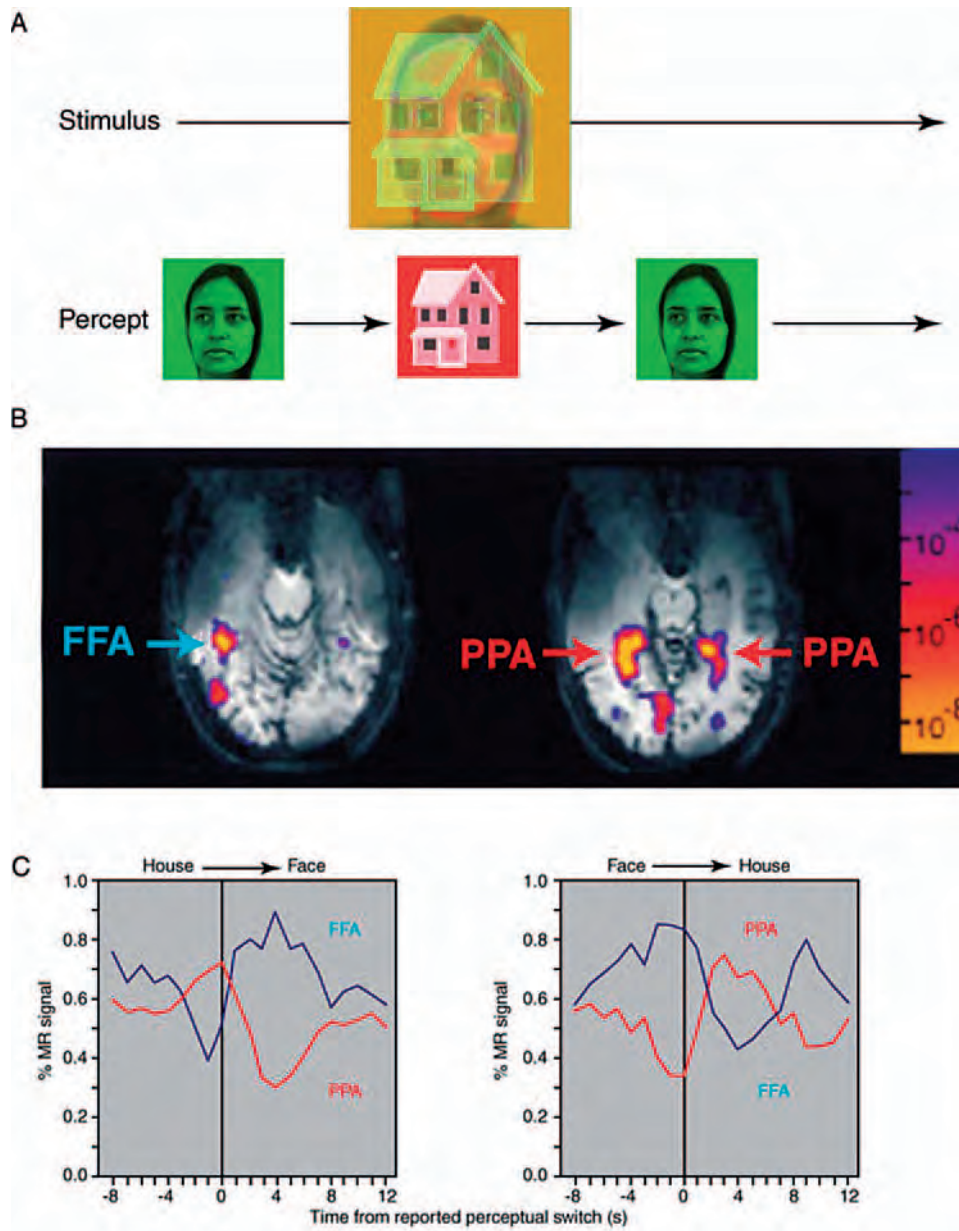

The existence of prosopagnosia suggests that certain regions of the ventral stream should be very responsive to faces. This is exactly what has been observed in neuroimaging studies. For example, a number of early neuroimaging studies revealed that a region on the fusiform gyrus of the right hemisphere is significantly more active when subjects view faces, compared to when they view common nonface objects. This region was called the “fusiform face area” (FFA) by

Kanwisher and colleagues (Kanwisher *et al.*, 1997). In addition, the FFA is more active during face matching than location matching, and during the viewing of faces than during the viewing of scrambled faces, letter strings, or textures. Thus, in humans, both lesion and neuroimaging evidence converges to suggest a face-selective region in/near the fusiform gyrus. A similar region containing single units selective for faces has been demonstrated in macaques.

Furthermore, the face selectivity of the FFA has been linked closely to conscious face perception in humans. In one neuroimaging study, the differential sensitivity of the ventral cortex to different visual stimuli was explored in a *binocular rivalry* paradigm in which different stimuli (faces and houses) were presented to the right and left eyes (Tong *et al.*, 1998; Fig. 46.11). During binocular rivalry, the resulting percept is not a combination of the two stimuli. Instead, subjects report that the actual percept alternates between the two stimuli, every few seconds—even though the dual retinal stimulation is kept constant. As expected, subjects’ perceptions fluctuated between faces and houses. Critically, while changes from house to face percepts were accompanied by increasing activation in the right FFA, perceived changes from a face to a house led to decreases in FFA responses. This suggests that the right fusiform gyrus plays an important and specialized role in conscious face perception.

Evidence from electrophysiological recordings in patients with implanted electrodes (as part of the preparation for neurosurgery to treat epilepsy) also reveals face-selective processing in the ventral stream (Allison *et al.*, 1999). A large evoked potential, called the *N200* because it occurs roughly 200 ms after stimulus onset, is generated in small regions (i.e., typically at only one electrode within an electrode array) in the ventral occipitotemporal cortex. The selectivity of the *N200* has been studied most thoroughly for face stimuli (Fig. 46.12). In this case, it has been found that the *N200* amplitude does not vary substantially whether evoked by colored or gray-scale faces, by normal, blurred, or line-drawn faces, or by faces of different sizes. The *N200* amplitude is largest to full faces and decreases progressively to eyes, face contours, lips, and noses viewed in isolation. Interestingly, a region just lateral to face-selective *N200* sites is more responsive to internal face parts than to faces, and some sites in ventral occipitotemporal cortex appear to be face-part specific.

In other small, circumscribed locations in the ventral occipitotemporal cortex, *N200* potentials are elicited selectively by visual stimuli other than faces, such as letter strings (including words and nonwords), numbers, complex objects, and gratings. Importantly,

**FIGURE 46.11** Design and results from an fMRI experiment on binocular rivalry. (A) The top illustration shows the ambiguous face/house stimulus used to produce rivalry. When viewed through red and green filter glasses, only the face could be seen through one eye and only the house through the other eye. This arrangement led to binocular rivalry, with a face percept alternating with a house percept every few seconds. (B) Two adjacent axial slices through the brain of a single subject showing, in the left slice, the area on the fusiform gyrus that responded more to faces than houses (FFA) and, in the right slice, the area on the parahippocampal gyrus that responded more to houses than to faces (PPA). In the slices shown, left is the right hemisphere and right is the left hemisphere. (C) fMRI time series showing FFA and PPA activity for a single subject illustrating that the activity in these two regions correlated with the subject's visual percept. PPA, parahippocampal place area. Adapted from Tong *et al.* (1998).

the responses are not elicited by control stimuli, such as scrambled versions of the stimuli. The small regions, which vary in their exact location among individuals, are reminiscent of clumps of object-selective neurons found in area TE of monkeys.

### Specialized Processing Likely Involves Other Categories

In addition to faces, other visually complex and behaviorally important classes of stimuli may also

**FIGURE 46.12** (A) Event-related potential specific to faces (red line) elicited from the occipitotemporal cortex of humans. Potentials elicited by other stimuli are also shown. (B) Summary of locations (black dots) on the ventral surface of the human brain from which a surface-negative potential (N200) was recorded when patients were shown faces but not when other categories of objects were tested. Locations are primarily along the fusiform gyrus. Adapted from Allison *et al.* (1999).

have specialized substrates in the ventral stream. These include “places,” words, and, possibly, human body parts.

Neuroimaging studies have revealed a region within the human parahippocampal cortex that is significantly more active when subjects view complex scenes (such as rooms, landscapes, and city streets) than when they view objects, faces, or other kinds of visual stimuli. This region has been named the parahippocampal place area (PPA) because it responds strongly whenever subjects view an image of a place (Epstein and Kanwisher, 1998). Consistent with the neuroimaging data, damage to the lingual/parahippocampal region may result in landmark agnosia.

Recent findings also suggest that some extrastriate visual areas may respond selectively when viewing human body parts (such as an isolated foot or arm) relative to viewing objects (including man-made objects and food). The region that is activated is located in the lateral occipitotemporal cortex (near the middle occipital gyrus) in an area that does not appear to have evident retinotopy. Continuing with the tradition of naming regions, this region has been called the extrastriate body area (EBA; Downing *et al.*, 2001). Interestingly, it also appears that the EBA is strongly modulated by limb (arm, foot) movements, even in the absence of visual feedback from the movement.

Finally, studies of brain lesions in patients suggest that there is a specialized region for the processing of *written words* in the inferior temporal lobe. Patients with *alexia* cannot read normally despite intact visual capabilities, and despite their ability to understand spoken language and to write. Accordingly, alexia has been conceptualized as essentially a visual agnosia for verbal material. Studies investigating the neural substrates of the processing of words and letter strings have compared activations elicited by (unpronounceable, nonword) letter strings with activations elicited by face and texture stimuli. Regions responding more strongly to letter strings primarily involved the left occipitotemporal and inferior occipital sulci. The suggestion is that these regions comprise a prelexical, pre-semantic stage of word-form processing in the reading system (Cohen *et al.*, 2002).

Because learning to read is a very recent event in evolution, regions of the cortex specialized for words and letter strings are presumably not present at birth. Thus, if such regions exist, word-selective regions must develop through protracted experience with written words, demonstrating that the environment helps shape the architecture of the visual system. Stimuli within a category, such as letters, tend to occur together and would therefore be encoded in close temporal proximity. In this view, many years of repeated

experience with letters could lead to regions in the ventral temporal cortex specialized to process letters, similar to the development of conjoint selectivity by monkey TE cells for visual images that are repeatedly shown together. Consistent with this proposal, brain damaged patients can be selectively impaired at letter recognition compared to, for example, number recognition and vice versa.

Collectively, the evidence suggests that the visual system is organized such that some object categories are represented in a relatively specialized fashion: faces, places, body parts, and words appear to have dedicated neural mechanisms for their representation. Of these, the evidence is perhaps strongest for faces, at least in some individuals with relatively pure forms of prosopagnosia. Not surprisingly, alternative proposals have been advanced concerning the organization of ventral visual cortex. We briefly discuss two of them now.

### Alternative Proposals to Category-Specific Representations

It has been proposed that the FFA is specialized not for the processing of faces *per se* but rather for the processing of objects with which one has acquired expertise (Gauthier *et al.*, 1998, 1999). The idea that expertise underlies responses in ventral temporal cortex raises an important distinction between two interpretations. One interpretation suggests that activation is based on visual features (e.g., the visual features composing a face, such as eyes, nose, and mouth). Another interpretation emphasizes the *processes* associated with perceiving or recognizing objects. In this latter view, the ventral stream contains areas that are best suited for different computations, which may be recruited as one acquires expertise with specific types of visual objects. This might involve encoding subtle differences between visually similar objects or, conversely, finding underlying similarities between visually dissimilar objects. In particular, the expertise view may help explain why some patients with prosopagnosia may also have associated deficits in areas of acquired expertise, such as the show dog expert mentioned earlier who lost the ability to differentiate breeds.

According to another alternative framework, the functional architecture of the ventral stream is viewed not as being composed of category-specific regions but instead as containing a distributed representation of information about object form (Ishai *et al.*, 1999; Haxby *et al.*, 2001). Each category is associated with its own pattern of response across the ventral temporal cortex with a highly consistent spatial arrangement across subjects. In this view, the representation of an object is

not restricted to a region that responds maximally to that object, but rather is distributed across a broader expanse of cortex. Within this distributed system, however, the representation of faces would be less extensive as compared to the representation of nonface objects, helping explain why it is possible for lesions to produce prosopagnosia while leaving the recognition of nonface objects largely intact.

### Object Knowledge Is Stored in a Distributed Network of Cortical Areas

Although the distinction between perception and memory might seem sharp, in reality these two processes are intimately connected. Indeed, each time one identifies an object, one implicitly retrieves stored knowledge about that object. In other words, identifying an object necessarily implies knowing what that object is. Further, it is generally believed that the same neural tissue devoted to object processing also serves to store the long-term representations of objects. For example, when a subject mentally imagines faces or houses (requiring the retrieval of stored object representations from long-term memory), the same patterns of activation across ventral temporal cortex are seen as those observed when actually viewing faces or houses.

Object knowledge implies not only familiarity with the shape of an object, but also other attributes, such as its typical color and function. For example, how does one know that bulldozers are usually yellow and are used for digging? One neuroimaging study that examined this question asked subjects to name either the associated color or the associated action in response to the presentation of black and white line drawings of objects (Martin *et al.*, 1995). By associated action the investigators meant the typical motion associated with an object, such as the motion produced by the arm of the bulldozer digging. Results showed that the generation of color names associated with objects selectively activated a region in the ventral occipital cortex just in front of the area involved in the perception of color, whereas the generation of action names activated a region dorsally in the middle temporal gyrus just in front of the area involved in the perception of motion. These findings suggest that information about the different attributes of an object is not stored in a unified fashion in any single area of the cortex. Rather, object knowledge seems to be stored in a distributed fashion such that information about specific attributes is stored close to the specific regions of the cortex that mediate the perception of those attributes.

These neuroimaging results provide a basis for understanding category-specific disorders of knowledge resulting from patterns of focal brain damage.

This type of deficit, seen most commonly for animals and tools, involves a selective difficulty in naming and retrieving information about objects from a single category. If the distinction between different categories of objects, such as animals and tools, is dependent on access to information about different types of attributes, and if such attributes (e.g., form, color, motion and object-use associated motor movements) are stored in separate regions of the brain, then one may find a category-specific deficit depending on the site of the lesion. Indeed, consistent with neuroimaging data, it has been found that the locations of lesions in patients with impaired recognition and impaired naming of drawings of animals included the medial aspects of the occipital lobe, nearly the same region active during animal naming. In contrast, the locations of lesions in patients with impaired recognition and impaired naming of drawings of tools all included the middle temporal gyrus, nearly the same region active during tool naming (Tranel *et al.*, 1997). It is important to note that the impairment in patients with category-specific deficits is not limited to visual recognition. These deficits occur when knowledge is probed visually or verbally, and therefore they reflect disorders of stored knowledge and not simply disorders of perception.

### Summary

Prosopagnosia, a selective deficit in recognizing faces, is associated with damage to the occipitotemporal cortex, including the fusiform gyrus. Consistent with this impairment, neuroimaging and electrophysiological studies have demonstrated that the fusiform gyrus responds selectively to faces and that this activation is linked to face perception. Although these findings suggest the existence of a specialized region for processing faces, an alternative interpretation is that the fusiform gyrus performs specialized computations associated with perceiving certain objects, including but not limited to faces. Such computations would presumably apply to many objects with which one has expertise. Moreover, the existence of a region in the left occipitotemporal cortex selectively activated by letter strings and words demonstrates the role of experience in shaping the functional architecture of the object recognition pathway.

### OVERALL SUMMARY

Early studies of brain damage in humans and lesions in monkeys pointed to the crucial role of tissue in the ventral parts of the temporal cortex for object perception and recognition. After many decades of intensive

research, one can now say that the ventral portions of the temporal cortex form the last stations of an occipitotemporal ventral pathway, beginning in the primary visual cortex and progressing through multiple visual areas beyond it. In macaque monkeys, important regions for object perception and recognition include areas TEO and TE of the inferior temporal cortex. In humans, homologous circuits appear to exist in both occipital and temporal regions, including the lateral occipital complex, the fusiform gyrus, and nearby regions in the ventral temporal cortex.

Single-unit recording studies in monkeys show a progressive increase in the complexity of object features needed to “trigger” cells at progressively more anterior stations in the occipitotemporal pathway. Many TE neurons show preservation of their selectivity over transformations that change the physical stimulus, such as retinal position, size, distance in depth, and degree of ambient illumination. At the highest levels of the pathway, within area TE, some neurons are preferentially responsive to faces and other biologically significant stimuli.

More recently, neuroimaging and evoked potential studies in humans with implanted electrodes have also shed light on the mechanisms by which the primate brain represents objects. Descriptions of prosopagnosia, a selective deficit of face recognition that is associated with damage to ventral occipitotemporal cortex, foreshadowed discoveries of cortical zones that are activated preferentially by face stimuli. At the same time, selectivity for letter strings and even for learned arbitrary stimuli has suggested that experience also influences activity in the ventral pathway and, in the long term, may tune representations. Finally, more general knowledge about objects (what they are used for and how to manipulate them) appears to be stored across a distributed network of sensory and motor cortical areas.

## Spatial Cognition

As we move through the world, new visual, auditory, vestibular, and somatosensory inputs are continuously presented to the brain. Given such constantly changing input, it is remarkable how easily we are able to keep track of where things are. We can reach for an object, look at it, or even kick it without making a conscious effort to assess its location in space, but how do we construct a representation of space that allows us to act so effortlessly? This chapter outlines the contributions of several brain areas in the parietal, frontal, and hippocampal cortices to spatial representation, spatial memory, and the generation of actions in space.

### NEURAL SYSTEMS FOR SPATIAL COGNITION

#### Dorsal Stream Areas Process Visuospatial Information

Within the cerebral hemispheres, visual information is processed serially by a succession of areas beginning with the primary visual cortex of the occipital lobe. Within this hierarchical system, there are two parallel chains, or streams, of areas: the ventral stream, leading downward into the temporal lobe, and the dorsal stream, leading forward into the parietal lobe (Ungerlieder and Mishkin, 1982) (Chapter 46). Although the two streams are interconnected to some degree, it is a fair first approximation to describe them as separate parallel systems. Areas of the ventral stream play a critical role in the recognition of visual patterns, including faces, whereas areas within the dorsal stream contribute selectively to conscious spatial

awareness and to the spatial guidance of actions, such as reaching and grasping. Dorsal stream areas have at least two distinctive functional characteristics: (1) they contain a comparatively extensive representation of the peripheral visual field and (2) they appear to be specialized for the detection and analysis of moving visual images. Both traits would be expected in any system processing visual information for use in spatial awareness and in the visual guidance of behavior.

Although visual input is important for spatial operations, awareness of space is more than just a visual function. It is possible to apprehend the shape of an object and know where it is, regardless of whether it is seen or sensed through touch. Accordingly, spatial awareness, considered as a general phenomenon, depends not simply on visual areas of the dorsal stream but rather on the higher order cortical areas to which they send their output. The transition from areas serving purely visual functions to those mediating generalized spatial awareness is gradual, but has been accomplished by the time the dorsal stream reaches its termination in the association cortex of the posterior parietal lobe.

#### Association Areas Responsible for Spatial Cognition Form a Tightly Interconnected System

The posterior parietal cortex is considered to be preeminent among cortical areas responsible for spatial awareness because lesions of the posterior parietal cortex lead to the most devastating and specific impairments of spatial cognition. However, numerous other association areas in the cerebral hemisphere mediate cognitive functions that depend in some way on the use of spatial information. These areas occupy a

continuous region of the cerebral hemisphere, encompassing large parts of the frontal, cingulate, temporal, parahippocampal, and insular cortices. They are connected to each other anatomically and to the parietal cortex by a parallel distributed pathway through which signals shuttle back and forth (Goldman-Rakic, 1988). The functions of some parts of this system are especially well understood. For example, the frontal cortex is involved in the generation of voluntary behavior, and the medial temporal lobe, including the hippocampus, is important for memory. In most individuals, the association areas of the right hemisphere are particularly important for spatial cognition. In nonhuman species, lateralization is much less pronounced. In general, spatial functions are represented in the same cortical areas in humans, monkeys, and rats. The following sections describe the spatial functions of the parietal cortex; how frontal areas program voluntary movements in spatial terms; and, finally, how the hippocampus and associated cortical areas mediate the formation of memories with a spatial component.

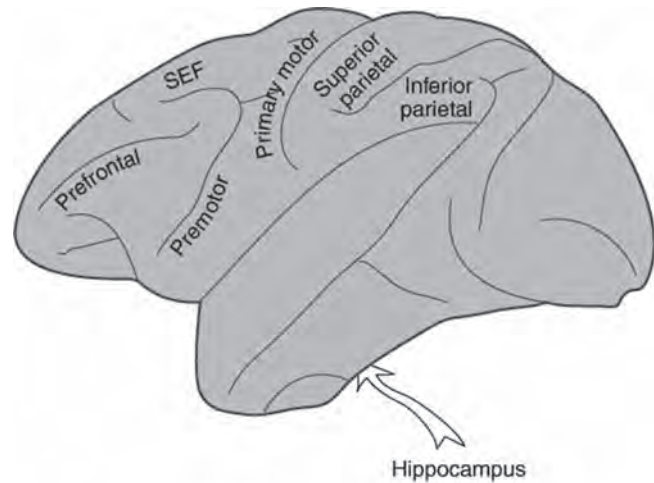

## PARIETAL CORTEX

### The Parietal Cortex Contributes to Spatial Perception and Attention

The parietal lobe is divided into superior and inferior parietal lobules. Within each lobule, several subdivisions are distinguished by anatomical and functional properties (Colby and Duhamel, 1991). In both humans and monkeys, the superior parietal lobule serves functions related primarily to somesthesia, or tactile perception, whereas the inferior parietal lobule serves functions related primarily to visuospatial cognition (Fig. 47.1). The intraparietal sulcus runs in between the superior and the inferior lobules. Within the sulcus there are several functionally distinct areas with independent representations of space. In monkeys, these include the lateral intraparietal area (LIP), which is important for spatial attention, and the ventral intraparietal area (VIP), where visual and somatosensory representations of space are brought together. Recent functional imaging studies suggest that there are corresponding cortical areas in humans.

### Injury to the Human Posterior Parietal Cortex Causes Impairments of Spatial Function

The neurologist Balint in 1909 first described a group of behavioral impairments specifically associated with damage to the parietal lobes. Balint's syn-

drome includes difficulty in executing eye movements to engage visual targets (ocular apraxia), an inability to perceive multiple objects at the same time (simultanagnosia), and inaccuracy in reaching for visual targets (optic ataxia). This collection of symptoms reflects an impairment in the visual guidance of movement and, more generally, in spatial cognition. Another major class of spatial deficits is known as neglect, the failure to attend to portions of space. Many other deficits in spatial behavior and cognition have been observed in patients with parietal damage, such as the inability to judge distances between objects. The following sections describe three specific impairments of spatial behavior known to arise from injury to the parietal lobe.

### Simultanagnosia: An Inability to See Multiple Objects Simultaneously

After injury to the posterior parietal cortex, some patients experience difficulty in the visual perception of spatial relations. They can see objects, but cannot judge whether two objects are the same size or which of two objects is closer. When asked to copy simple line drawings, they may omit or transpose parts, as if unable to judge accurately the spatial arrangement of the object's components. In some patients, failure on visuospatial tests arises from a specific inability to see more than one object at a time (Coslett and Saffran, 1991). This condition, called simultanagnosia, com-

monly is observed after bilateral damage to the parietal cortex. When looking at the flame of a match, a patient with simultanagnosia may be unable to see the hand holding it. When tested in controlled situations, simultanagnosic patients demonstrate a profound inability to perceive more than one object simultaneously (see Box 47.1).

A particularly illuminating test carried out on simultanagnosic patients is shown in Figure 47.2 (Humphreys and Riddoch, 1993). When patients were presented with a set of randomly intermingled red and green circles (random condition), they were unable to say whether the circles were of different colors. Presumably this was because they could see only one circle at a time. When the circles were joined by line segments into red or green barbells (single color condition), these patients still could not say that more than one color was present. Only when pairs of circles of different colors were joined by line segments, unifying them into a single object, were patients able to report that there were different colors present (mixed condition). Note that the average distance between circles of different colors was the same in all three conditions. This indicates that the inability of patients to see and compare pairs of circles in the random and single conditions was the result of the circles belonging to sepa-

rate objects and not simply a result of their being separated by a certain distance. Simultanagnosia, by preventing simultaneous vision of two objects, gives rise to poor performance on tests requiring a comparison between objects. However, when tests are confined to a single object, this condition appears to leave spatial perception intact. Simultanagnosic patients are able to make accurate judgments of spatial relations so long as the judgments pertain to a single object.

### Optic Ataxia: An Impairment of Visually Guided Reaching

After damage to the parietal cortex, some patients experience difficulty in making visually guided arm movements. This condition is referred to as misreaching, or optic ataxia (Perenin and Vighetto, 1988). Patients with optic ataxia experience difficulty in real-life situations requiring them to reach accurately under visual guidance. For example, a patient cutting food with a knife and fork may miss the plate altogether and hit the table when attempting to move the knife toward the food. Neuropsychologists have been able to characterize the reaching deficits of such patients in considerable detail by testing them in controlled situations.

#### BOX 47.1

### SIMULTANAGNOSIA

Disorders of spatial awareness arising from parietal lobe injury are not merely a laboratory phenomenon, but can have a profound impact on the patient's daily life, as described in the following case study of simultanagnosia (from Coslett and Saffran, 1991).

When first examined by the authors four months after a right hemisphere infarction, the patient's major complaint was that her environment appeared fragmented; although she saw individual items clearly, they appeared to be isolated and she could not discern any meaningful relationship among them. She stated, for example, that she could find her way in her home (in which she had lived for 25 years) with her eyes closed, but she became confused with her eyes open. On one occasion, for example, she attempted to find her way to her bedroom by using a large lamp as a landmark; while walking toward the lamp, she fell over her dining room table. Although she enjoyed listening to the radio, television programs bewildered her because she could only "see" one person or object at a time

and therefore could not determine who was speaking or being spoken to; she reported watching a movie in which, after hearing a heated argument, she noted to her surprise and consternation that the character she had been watching was suddenly sent reeling across the room, apparently as a consequence of a punch thrown by a character she had never seen. Although she was able to read single words effortlessly, she stopped reading because the "competing words" confused her. She was unable to write, as she claimed to be able to see only a single letter; thus when creating a letter, she saw only the tip of the pencil and the letter under construction and "lost" the previously constructed letters.

**FIGURE 47.2** Three stimuli used for assessing simultanagnosia in human patients. Patients were consistently able to report that circles of different colors were present only in the mixed condition, in which red and green circles were unified into a single object by connecting line segments. From Humphreys and Riddoch (1993).

**FIGURE 47.3** A test for optic ataxia. Patients can reach accurately (A and D) when using the ipsilesional hand in the ipsilesional visual field, but they make errors of hand orientation (B and E) and of direction (C and F) when reaching into the contralesional visual field. The top and bottom rows show the performance of two different patients. From Perenin and Vighetto (1988).

In the test illustrated in Figure 47.3, patients were required to reach out and insert one hand into a slot in the center of a disk held by the experimenter. The disk could be held in either the right or the left visual hemifield, and the patient could be asked to reach with either the right or the left hand. To perform the task, the patient had to direct the hand toward the center of the slot and orient the hand correctly so that it would pass into it. Pictures in the top row of Figure 47.3 show a patient with right parietal lobe damage reaching with the left hand. When the disk was positioned in the right (ipsilesional) visual field, the patient was able

to reach accurately (Fig. 47.3A). And yet, when the disk was in the left (contralesional) visual field, the patient committed errors of hand orientation (Fig. 47.3B) and of reaching direction (Fig. 47.3C). The lower row of Figure 47.3 shows reaching by a patient with damage to the left parietal lobe. When using the left hand in the left (ipsilesional) visual field, this patient was also able to reach accurately (Fig. 47.3D). However, when using the right hand in the right (contralesional) visual field, the patient committed errors of hand orientation (Fig. 47.3E) and of reaching direction (Fig. 47.3F).

These results demonstrate that optic ataxia may be lateralized, occurring only when the patient is required to point to targets in one visual hemifield or only when one hand is used for pointing. In cases where the deficit is restricted to a single hemifield or a single arm, the affected hemifield or arm is usually opposite the injured parietal lobe. This is what would be expected if the parietal lobe of each hemisphere mediates communication between more posterior visual areas (which represent the contralateral half of visual space) and more anterior motor areas (which represent the contralateral arm). There are, however, cases in which the problem is bilateral or occurs for specific combinations of arm and hemifield. Optic ataxia is not simply a problem with visuospatial perception, as indicated by the fact that performance with one arm may be perfectly normal. Nor is it simply a motor problem, as indicated by the fact that patients unable to reach accurately for visual targets can commonly touch points on their own bodies accurately under proprioceptive guidance. Optic ataxia is best characterized as an inability to use visuospatial information to guide arm movements.

### **Hemispatial Neglect: Unawareness of the Contralesional Half of Space**

Hemispatial neglect is a classic symptom of injury to the posterior parietal cortex. It is a condition in which a lateralized failure of spatial awareness is present. The most common form of neglect arises from damage to the right parietal lobe and is manifested as a failure to detect objects in the left half of space. Patients with neglect experience problems in daily life, such as colliding with obstacles on the contralesional side of the body or mistakenly identifying letters on the contralesional side of a written word. When asked to copy pictures or to draw simple objects from memory, they leave out details on the affected side. When asked to say whether two objects are the same or different, they tend to indicate that two dissimilar objects are the same if the differentiating details are on the contralesional side. Whether the problem underlying neglect is a failure of attention to one half of space or a failure of the ability to form a mental representation of that half of space is not clear.

Neglect involves more than just a defect of attention to contralesional sensory events. For example, patients fail to report detail on the left half of an object even when they are asked to form a mental representation of the object by viewing it one part at a time as it passes slowly behind a vertical slit. In a famous set of experiments, patients were asked to imagine themselves in a familiar public setting and then to report what they

would be able to see around them (Bisiach and Luzzatti, 1978). When they imagined standing at one end of the town square, patients described the buildings on the right side and failed to report buildings on the left. However, when instructed to imagine themselves standing at the other end of the square, facing the opposite direction, they now failed to mention buildings on the left that they had described just moments before and were able to describe buildings on the right that they had previously omitted.

Given that neglect affects the half of space opposite an injured parietal lobe, each parietal lobe must represent the opposite half of space. On the face of it, this proposition does not sound particularly surprising. Most visual areas in each hemisphere represent the opposite half of the visual field, most somatosensory areas represent the opposite half of the skin surface, and most motor areas represent muscles on the opposite half of the body. Injury to these areas leads to a sensory loss or motor impairment that affects the opposite half of a functional space defined with respect to some anatomical reference frame (the retina, the skin surface, or the muscles). In contrast, injury to the posterior parietal cortex gives rise to a neglect that may be defined with respect to any of several spatial reference frames. These fall into two broad classes: egocentric reference frames, in which objects and locations are represented relative to the observer; and allocentric reference frames, in which locations are represented in coordinates extrinsic to the observer. Examples of egocentric reference frames include those centered on the hand or the body. Allocentric reference frames include those in environmental coordinates (for example, room centered) and those centered on an object of interest. The full range of reference frames used by the brain is just beginning to be explored. Patients with neglect often show deficits with respect to more than one reference frame. The following sections describe evidence for impairments of multiple spatial reference frames in neglect.

A patient with left hemispatial neglect, looking straight ahead at the center of some object, will tend not to see detail on its left side. This observation is open to several interpretations. The simplest interpretation is that stimuli presented in the left visual field tend not to be registered. However, the fundamental problem might actually be with registering stimuli that are to the left of the head, or to the left of the torso, or the object itself. These possibilities cannot be distinguished without disentangling the various reference frames. Experiments aimed at identifying the spatial reference frame in neglect indicate that a patient's failure to detect a stimulus is affected not only by its location relative to the retina but also by its location

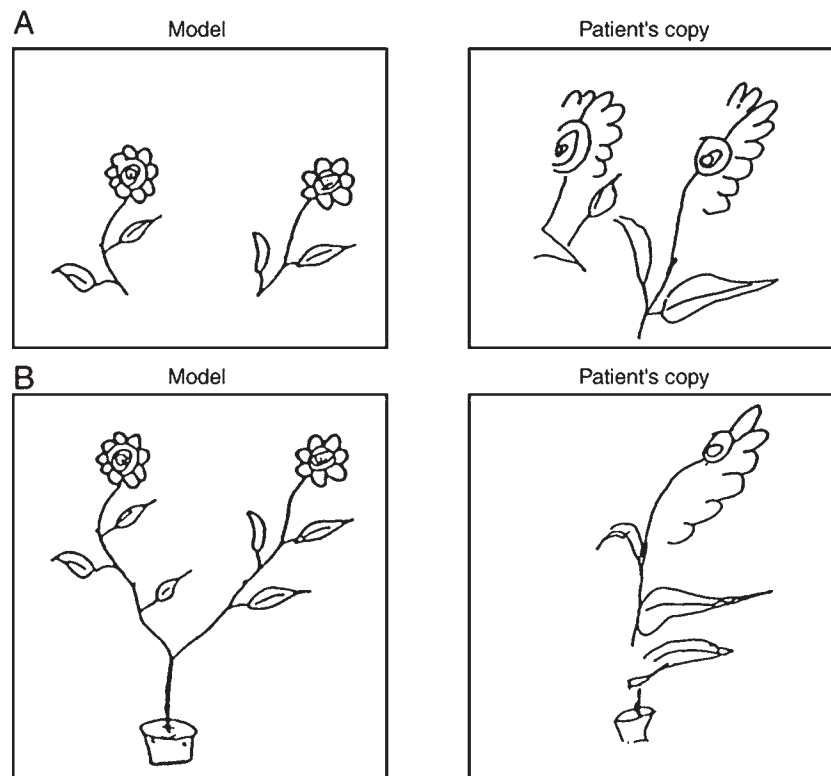

relative to the object or array within which it is contained, by its location relative to the body, and even by its location relative to a gravitationally defined reference frame. Patients span a continuum from exhibiting predominantly egocentric forms of neglect to predominantly allocentric neglect.

In many patients, a component of neglect is object centered. If these patients are presented with an image anywhere in the visual field, they tend to ignore its left side. In one experiment, patients with left hemispatial neglect were required to maintain fixation on a small spot while chimeric faces (images formed by joining at the midline half-images representing the faces of two people) were presented at various visual field locations. Their reports of what they saw were based predominantly on the right halves of the chimeric images. This was true even when the entire composite face was presented within the right visual hemifield. In a second experiment, patients with left hemifield neglect were required to maintain fixation on a small spot while four stimuli in a horizontal row were presented. One of the stimuli was a letter that was to be named aloud. When the letter was in the leftmost location, patients

were slower to name it, even when the entire array was in the right visual field.

A particularly dramatic way of demonstrating the object-centered nature of neglect is to ask patients to make copies of simple line drawings (Marshall and Halligan, 1993). When asked to copy a picture of two flowers, a patient with right parietal lobe damage saw and copied each flower but omitted the petals on the left half of each, thus showing evidence of left object-centered neglect (Fig. 47.4, top). When the same two flowers were joined by a common stem, the patient saw and copied the plant, but omitted details on its left side, including the entire leftmost flower, thus showing neglect for the left half of the larger composite object (Fig. 47.4, bottom).

Patients with parietal lobe damage can exhibit deficits with respect to other allocentric reference frames in addition to the object-centered neglect described earlier. The role of a gravitational reference frame in neglect has emerged from studies in which patients face a display screen either while sitting upright or while lying on their side (Ladavas, 1987). When the patient sits upright, the right and left halves of the

**FIGURE 47.4** A test for object-centered neglect. When asked to copy the two drawings on the left, a patient made the two copies on the right. Detail is omitted from the left half of each object rather than from the left half of the drawing as a whole. From Marshall and Halligan (1993).

screen coincide with the right and left retinal visual fields. However, when the patient lies on one side while facing the screen, the situation is changed. Reclining on the right side, the patient sees the right and left halves of the screen as being in the upper and lower visual fields, respectively. Applying this procedure to patients with left hemispatial neglect enables the investigator to pose the question: Is the neglect specific for the left retinal visual field or is it specific for the left half of the screen? Neglect turns out to depend in part on each of these factors.

Further evidence that the parietal cortex represents the locations of objects relative to an external framework comes from the observation that neglect, in some patients, is restricted to stimuli within a certain range of distances from the body. The form of neglect termed *peripersonal* or *proximal* is specific for stimuli in the immediate vicinity of the body. Another form of neglect, termed *extrapersonal*, is specific for more distant stimuli. The implication of these findings is that there is a localization of function within the parietal cortex and that neurons in discrete areas process sensory input from objects at different distances. Discrete areas of the parietal cortex are known to be specialized for relaying sensory information to different motor systems. Sensory input from *peripersonal* space is uniquely significant for guiding reaching movements. In contrast, sensory input from greater distances (*extrapersonal* space) is linked primarily to the control of eye movements.

### Lesions of the Parietal Cortex in Monkeys Produce Spatial and Attentional Problems

The original distinction between dorsal and ventral processing streams in the primate visual system was based in part on differences in the effects of lesions of the posterior parietal cortex and the inferior temporal cortex (Ungerleider and Mishkin, 1982). Monkeys with posterior parietal lesions are selectively impaired in visuospatial performance, such as judging which of two identical objects is located closer to a visual landmark. In contrast, inferior temporal cortex lesions produce deficits in visual discrimination (for example, shape or pattern recognition; see Chapter 46).

In addition to spatial perceptual deficits, parietal lesions also produce spatial motor deficits. After parietal lesions, monkeys have difficulty directing eye movements toward targets in the hemispace opposite the side of the lesion (Lynch and McLaren, 1989). Further, when two targets are presented simultaneously in the ipsilesional and contralesional fields, lesioned monkeys tend to ignore the contralesional stimulus, an effect termed *visual extinction*. Parietal

lesions also have profound effects on the ability of a monkey to reach toward an object. Lesions confined to the inferior parietal cortex impair reaching with the contralesional limb toward a target in contralesional space. Lesions extending across the intraparietal sulcus to include the superior parietal cortex produce impairments in reaching with the contralateral arm into either half of space. In sum, monkeys with parietal lesions are unable to assess spatial relations between objects or to judge locations of objects relative to themselves.

### Parietal Neurons Have Response Properties Related to Spatial Information Processing

To understand more precisely how the parietal cortex contributes to spatial cognition, several groups of investigators have measured the electrical activity of single neurons during the performance of spatial tasks. These studies were done in alert monkeys trained to make eye movements to visual targets. Because brain tissue itself has no sensory receptors, microelectrodes can be introduced into the brain without disturbing the performance of an animal on a task. By recording single neuron activity during specially designed tasks, neural activity can be related directly to the sensory, cognitive, and motor processes that underlie spatial behavior. The next four sections describe how neurons in specific areas within the parietal cortex are selectively activated during spatial tasks and how they contribute to spatial representation and cognition.

### Area VIP

The ventral intraparietal area (area VIP) is a functionally and anatomically defined area that lies at the junction of the visual and somatosensory districts within parietal cortex. Individual neurons respond strongly to moving stimuli and are selective for both the speed and the direction of the stimulus (Colby *et al.*, 1993). In this respect, VIP neurons are similar to those in other dorsal stream visual areas that process stimulus motion, especially areas MT and MST (Chapter 27). An important finding in area VIP is that most of these visually responsive neurons also respond to somatosensory stimuli (Duhamel *et al.*, 1991). These neurons are truly bimodal in the sense that they can be driven equally well by either a visual or a somatosensory stimulus. Most of these bimodal neurons have somatosensory receptive fields on the head or face that match the location of their visual receptive fields. This correspondence is illustrated in Figure 47.5, which shows visual and somatosensory receptive fields for several individual VIP neurons.

FIGURE 47.5 Matching visual and somatosensory receptive fields of neurons from area VIP. On each outline of the head of the monkey, the patch of color corresponds to the somatosensory receptive field of one neuron. On the square above the head, the patch of texture corresponds to the visual receptive field of the same neuron. The square can be thought of as a screen placed in front of the monkey so that its center is directly ahead of the monkey's eyes. From Duhamel *et al.* (1991) with permission of Oxford University Press.

Three kinds of correspondence are found in VIP neurons. First, for each neuron, receptive fields in each modality match in location. For example, a neuron that responds to a visual stimulus in the upper left visual field also responds when the left brow is touched. Second, receptive fields match in size. A neuron with a restricted visual receptive field also has a small somatosensory receptive field. The smallest visual receptive fields are those located at the fovea. It is striking that the corresponding somatosensory receptive fields for these neurons are not centered around the eye but are found around the mouth. In terms of sensitivity, the mouth can be thought of as the fovea of the facial somatosensory system. Hence it is logical that the two regions of highest spatial acuity should be linked. The third type of correspondence is in the preferred directions of movement. For example, a neuron responsive to a visual stimulus moving toward the right also responds when a small probe is brushed lightly across the face of the monkey moving to the right. In sum, visual and somatosensory receptive fields for individual VIP neurons match in location, size, and directional preference.

The correspondence in receptive field locations across modalities immediately raises a question: What

happens to the relative locations of the visual and somatosensory receptive fields when the eyes move? If the visual receptive field were simply retinotopic, it would move when the eyes do; if the somatosensory receptive field were purely somatotopic, it would be unchanged by eye movements. There could not be a consistent correspondence in location if visual receptive fields were defined only with respect to the retina while somatosensory receptive fields were defined only with respect to the skin surface.

The answer is that visual receptive fields are linked to the skin surface and not to the retina. A neuron that responds best to a visual stimulus approaching the forehead and has a matching somatosensory receptive field on the brow will continue to respond best to a visual stimulus moving toward the brow regardless of where the monkey is looking. Thus, both visual and somatosensory receptive fields are defined with respect to the skin surface. In this sense, the receptive fields are head centered: a given VIP neuron responds to stimulation of a certain portion of the skin surface and to the visual stimulus aligned with it no matter which part of the retina is activated.

In sum, neurons in area VIP encode bimodal sensory information in a head-centered representation of space.

This kind of representation would be most useful for guiding head movements. Anatomical studies indicate that area VIP sends information to premotor cortex including the specific region that is involved in generating head movements.

## Area LIP

The lateral intraparietal area (area LIP) is a functionally defined area within the visual district of parietal cortex. Neurons in LIP exhibit several different kinds of activity during spatial tasks (Colby *et al.*, 1996). First, LIP neurons, like neurons in striate and extrastriate visual cortex (Chapter 27), respond to the onset of a visual stimulus in the receptive field of the neuron. Second, these visual responses are enhanced when the monkey attends to the stimulus: the amplitude of the visual response is increased when the stimulus or stimulus location becomes the focus of attention. This enhancement occurs no matter what kind of movement the animal will use to respond to the stimulus. Regardless of whether the task requires a hand movement or an eye movement or requires that the monkey refrain from moving toward the stimulus, the visual response of an LIP neuron becomes larger when the stimulus is made behaviorally relevant. This means that the same physical stimulus arriving at the retina can evoke very different responses in cortex as a result of spatial attention.

A third important feature of LIP neuron activity is the sustained responses observed when the monkey must remember the location at which the stimulus appeared. In this task, a stimulus is flashed only briefly but the neuron continues to fire for several seconds after the stimulus is gone, as though it were holding a memory trace of the target location. A particularly intriguing question in understanding spatial representation concerns the fate of this memory-related activity in area LIP following an eye movement, as will be described later. A fourth kind of activation commonly observed in LIP neurons is related to performance of a saccade—a rapid eye movement—toward the receptive field. Some LIP neurons fire just before the monkey initiates a saccade that will move the fovea onto a target presented in the receptive field. LIP neurons have overlapping sensory and motor fields, just like neurons in the superior colliculus (Chapter 33). Finally, LIP neuron activity can be modulated by the position of the eye in the orbit (Andersen *et al.*, 1990). For instance, the visual response of a given cell may become larger when the monkey is looking toward the left part of the screen than when it is looking toward the right. This property is interesting because it suggests that neurons in area LIP may contribute to spatial repre-

sentations that go beyond a simple replication of the retinal map. This idea is discussed in more detail in the next section.

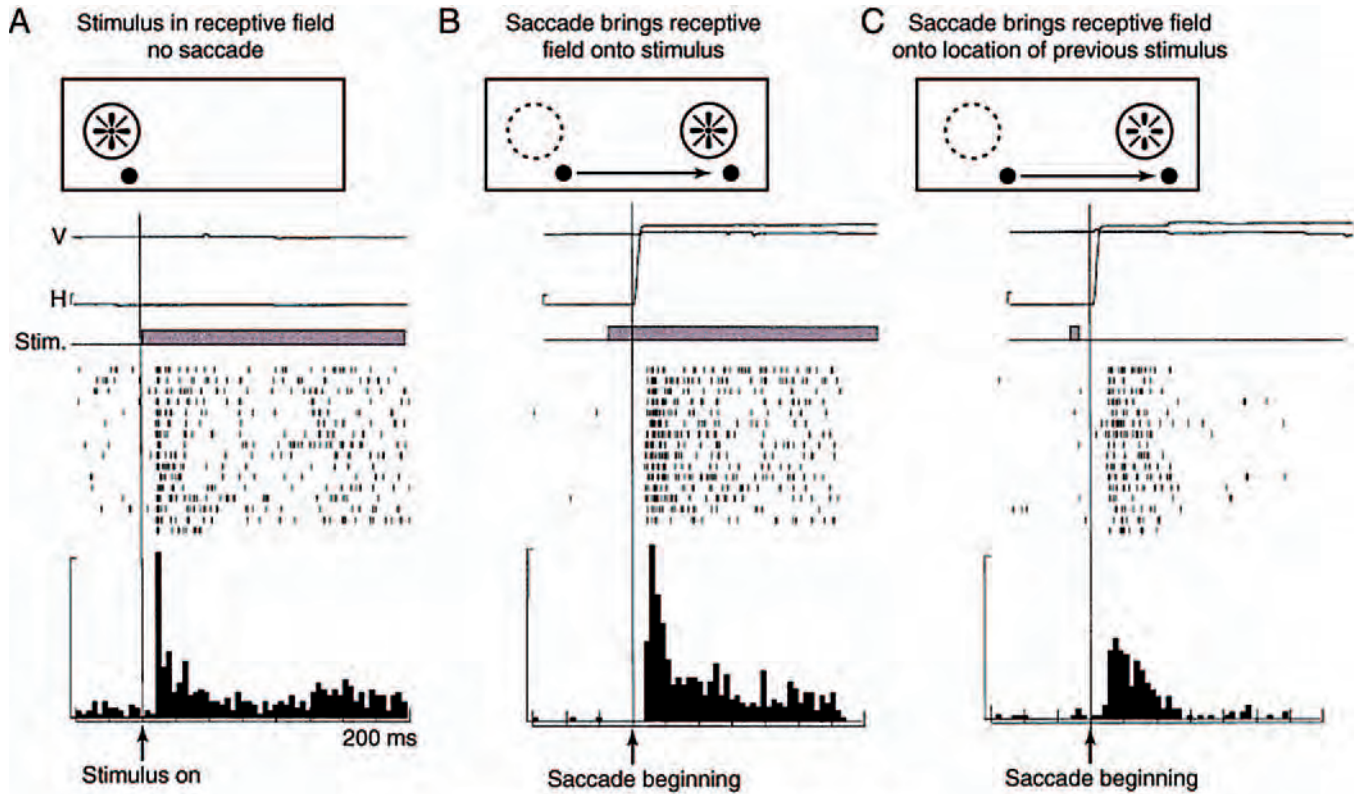

In sum, individual LIP neurons have receptive fields at particular retinal locations and carry visual, memory, and saccade-related signals that can be modulated by attention and by eye position. Activity in area LIP cannot be characterized as a simple visual or motor signal. Rather, the level of activation in a given LIP neuron reflects the degree to which attention has been allocated to a location within the receptive field.

## Spatial Representation in Area LIP

Every time we move our eyes, each object in our surroundings activates a new set of retinal neurons. Despite this ever-changing input, we experience a stable visual world. How is this possible? More than a century ago, Helmholtz proposed that the reason the world appears to stay still when we move our eyes is that the “effort of will” involved in making a saccade simultaneously adjusts our perception to take that specific eye movement into account. He suggested that when a motor command to move the eyes is issued, a copy of that command, or corollary discharge, is sent to brain areas responsible for generating our internal image of the world. This image is then updated so as to be aligned with the new visual information that will arrive in the cortex after the eye movement. A simple experiment shows that Helmholtz’s account must be essentially true. When the retina is displaced by pressing on the eye, the world does seem to move, presumably because there is no corollary discharge. Without that internal knowledge of the intended eye movement, there is no way to update the spatial representation of the world around us.

Neurons in area LIP contribute to this updating of the internal image (Duhamel *et al.*, 1992). The experiment illustrated in Figure 47.6 shows that the memory trace of a stimulus is updated when the eyes move. The activity of a single LIP neuron was recorded under three different conditions. In the first set of trials, the monkey looked at a fixed point on the screen while a stimulus was presented in the receptive field (Fig. 47.6A). In the diagram at the top of Figure 47.6A, the dot is the fixation point, the dashed circle shows the location of the receptive field, and the asterisk represents the visual stimulus. The time lines just below the diagram indicate that the vertical and horizontal eye positions remained steady throughout the trial, demonstrating that the monkey maintained fixation. The stimulus time line shows that the stimulus appeared 400 ms after the beginning of the trial and continued for the entire trial. The raster display below plots the

**FIGURE 47.6** Remapping of visual memory trace activity in area LIP. The activity of a single neuron was recorded under three different conditions. (A) Simple visual response to a constant stimulus in the receptive field, presented while the monkey is fixating. The rasters and histogram are aligned on the time of stimulus onset. (B) Response following a saccade that brings the receptive field onto the location of a constant visual stimulus. (C) Response following a saccade that brings the receptive field onto the location where a stimulus was presented previously. The stimulus is extinguished before the saccade begins so it is never physically present in the receptive field. The neuron responds to the updated memory trace of the stimulus. V, vertical eye position; H, horizontal eye position. From Duhamel *et al.* (1992).

electrical activity of a single LIP neuron in 16 successive trials. In these rasters, each small vertical line indicates the time at which an action potential occurred, and each horizontal line of dots represents activity in a single trial. In each trial there was a brief initial burst of action potentials shortly after the stimulus appeared, followed by continuing neural activity at a lower rate. The histogram at the bottom of Figure 47.6 shows the average firing rate as a function of time. The visual response in Figure 47.6A is typical of that observed in neurons in many visual areas: the neuron fired when a stimulus appeared in the receptive field of the neuron.

In the second set of trials (Fig. 47.6B), a visual response occurred when the monkey made an eye movement that brought a stimulus into the receptive field. At the beginning of the trial, the monkey looked at the fixation point on the left, and the rest of the screen was blank. Then, simultaneously, a new fixation point appeared on the right and a visual stimulus

appeared above it. The monkey made a saccade from the old fixation point to the new one, indicated by the arrow. The eye movement was straight to the right so only the horizontal eye position trace shows a change. At the end of this saccade, the receptive field had been moved to the screen location containing the visual stimulus. The rasters and histogram in Figure 47.6B are aligned on the time that the saccade began. In each trial, the neuron began to respond after the receptive field had landed on the stimulus. This result is just what would be expected for neurons in any visual area with retinotopic receptive fields.

The novel finding is shown in Figure 47.6C. In this third set of trials, the monkey made a saccade that would bring a stimulus into the receptive field, just as in the second set of trials. The only difference was the duration of the stimulus, which lasted for a mere 50 ms instead of staying on for the entire trial. As can be seen on the stimulus time line, the stimulus actually disappeared before the saccade began. This means that the

stimulus was never physically present in the receptive field. Nevertheless, the neuron fired as though there were a stimulus in its receptive field. This result indicates that LIP neurons respond to the memory trace of a previous stimulus. Moreover, the representation of the memory trace is updated at the time of a saccade. The general idea of how a memory trace can be updated is as follows. At the beginning of the trial, while the monkey is looking at the initial fixation point, the onset of the stimulus activates neurons whose receptive fields encompass the stimulated location. Some of these neurons will have tonic activity and continue to respond after stimulus offset, encoding a memory of the location at which the stimulus occurred. When the monkey moves its eyes toward the new fixation point, a copy of the eye movement command is sent to parietal cortex. This corollary discharge causes the active LIP neurons to transmit their activity to a new set of neurons whose receptive fields will encompass the stimulated screen location after the saccade. By means of this transfer, LIP neurons encode the spatially updated memory trace of a previous stimulus.

The significance of this finding lies in what it illustrates about spatial representation in area LIP. It indicates that the internal image is dynamic rather than static. Tonic, memory-related activity in area LIP not only allows neurons to encode a salient spatial location after the stimulus is gone, but also allows for dynamic remapping of visual information in conjunction with eye movements. This updating of the internal visual image has specific consequences for spatial representation in the parietal cortex. Instead of spatial information being encoded in purely retinotopic coordinates, tied to the specific neurons initially activated by the stimulus, the information is encoded in eye-centered coordinates. This is a subtle distinction but a very important one in generating accurate spatial behavior. Maintaining visual information in eye-centered coordinates tells the monkey not just where the stimulus was on the retina when it first appeared, but where it would be on the retina following an intervening eye movement. The result is that the monkey always has accurate information with which to program an eye movement toward a real or a remembered target. Further results from this series of experiments indicate that humans also depend on this kind of remapping for accurate spatial representation.

In sum, neurons in area LIP encode sensory information in an eye-centered representation of space, the format most useful for guiding eye movements. Area LIP sends projections to both the superior colliculus and the frontal eye fields, regions that are involved in generating eye movements. In addition to area LIP, the parietal cortex contains a number of functionally dis-

tinct areas, each of which may be specialized for particular types of stimuli and particular regions of space. The general point is that the problem of spatial representation may be solved in several ways, and each solution may contribute to the generation of a different kind of action.

## Parietal Cortex and Decision Processes

Spatially selective neuronal activity in area LIP is graded in strength. If the monkey's attention to a given location or intention to make a saccade in a given direction increases in strength, then the firing of LIP neurons with response fields in that direction also increases. This has been demonstrated in decision tasks—tasks requiring the monkey to decide which of several possible saccades to make. A decision can be either sensory-based or value-based. In a sensory decision task, the monkey must judge whether a visual display contains dots moving to the right or left and must report the judgment by executing a rightward or leftward saccade (Roitman and Shadlen, 2002). If the motion stimulus is weak, requiring the monkey to integrate sensory information over time, the neuronal signal reflecting the decision develops slowly. If the motion stimulus is strong, allowing the monkey to make an instantaneous decision, the neuronal signal rises sharply. Thus the evolution of the monkey's decision is reflected in the activity of spatially selective LIP neurons. In a value-based decision task, the monkey chooses between a saccade to the right and a saccade to the left on the basis of prior experience indicating that one of the saccades is more likely than the other to yield a valued juice reward (Sugrue *et al.*, 2004).

During the preparatory period of the trial, LIP neurons fire strongly if the target in their response field is associated with a valuable reward. In this task the activity of spatially selective LIP neurons reflects the value of the target. These two findings do not necessarily indicate that LIP plays a direct role in making sensory- or value-based decisions. They can also be explained on the assumption that LIP neurons mediate attention or motor preparation and that they fire more strongly when attention or motor preparation is more intense (Maunsell, 2004).

## Summary

The posterior parietal cortex plays a critical role in spatial awareness. Injury to the parietal cortex in humans and monkeys leads to deficits in spatial perception and action. Physiological studies in monkeys have shown that parietal neurons construct a representation of space by combining signals from multiple

sensory modalities with motor signals. An important physiological finding is that parietal neurons represent spatial locations relative to multiple reference frames, including ones centered on the eye and the head. In accord with these physiological findings, human neuropsychological studies have shown that neglect resulting from parietal lobe injury can be expressed with respect to several different reference frames.

## FRONTAL CORTEX

### The Frontal Cortex Contributes to Voluntary Movement and the Control of Behavior

The frontal lobe is involved in spatial functions as a natural result of its being involved in behavioral control. The three main divisions of the frontal lobe are the primary motor cortex located on the precentral gyrus; the premotor cortex, including the supplementary eye field, located in front of the primary motor cortex; and the prefrontal cortex (Fig. 47.1). The motor, premotor, and prefrontal areas all contribute to behavioral control, but they differ with respect to the quality of their contribution. This difference is seen in the effects of brain injury. Injury to the primary motor cortex leads to weakness and paralysis of the contralateral muscles. In contrast, injury to the premotor cortex leads to difficulty in producing movements in certain circumstances, for example, when the patient is asked to mime the use of a tool or to learn arbitrary associations between stimuli and responses. Finally, injury to the prefrontal cortex results in a classic syndrome characterized by a lack of drive and an impaired ability to execute plans (Chapter 52). These effects indicate that progressively more anterior parts of the frontal cortex contribute to progressively more abstract aspects of behavioral control. Each of these divisions participates in spatial processes insofar as the kind of behavioral control to which it is dedicated has a spatial component. The next four sections describe aspects of spatial representation and function in the primary motor cortex, in the premotor cortex, in the supplementary eye field, and in the prefrontal cortex. The final section examines the relation between motivational modulation of neural activity and the representation of value.

### Neurons in the Primary Motor Cortex Represent Movement Direction Relative to a Spatial Frame

The primary motor cortex contains a map of the muscles of the body in which the leg is represented

medially, the head laterally, and other body parts at intermediate locations. Within this map are patches of neurons that represent different muscles. Neurons within a given patch receive proprioceptive input from a muscle or small group of synergistic muscles and send their output back to that muscle or group of synergists by way of a multisynaptic pathway through the brain stem and spinal cord. There have been many studies in which the electrical activity of neurons in the primary motor cortex is monitored while animals move (Chapter 30). The general conclusion of these studies is that neurons in the primary motor cortex are active when the corresponding muscles are undergoing active contraction. It is important to note, however, that neurons in the primary motor cortex probably do more than simply encode the levels of activation of individual muscles. One proposal is that they encode movement trajectories. Every voluntary movement can be described in two quite different but perfectly complementary ways: in terms of the lengths of the muscles or in terms of the position of the part of the body being moved. For example, during an arm movement, changes take place both in the lengths of muscles acting on the arm and in the position of the hand. Could it be that neurons in the primary motor cortex encode a spatial variable, such as the direction of movement of the hand, rather than a muscle variable?

Evidence for the idea that neurons of the primary motor cortex encode movement direction has come from studies in which monkeys make reaching movements in various directions. Individual neurons are selective for a specific direction of movement: a given neuron may fire most strongly during movements up and to the right and progressively less strongly for movements that deviate from the preferred direction (Schwartz *et al.*, 1988). The patterns of selectivity are well defined and the preferred directions of different neurons cover the range of possible movements fairly evenly. By recording the activity of the entire population of neurons one could, in principle, quite accurately describe the movement. The question remains whether these neurons are selective for the direction of movement in space or for the specific patterns of muscle activation associated with particular movements. In an elegant series of studies, Kakei *et al.* (1999) recorded from neurons in the primary motor cortex while the monkey moved its arm in a single direction using different combinations of muscles. They discovered that the primary motor cortex contains both neurons selective for movement direction and neurons selective for patterns of muscle activation.

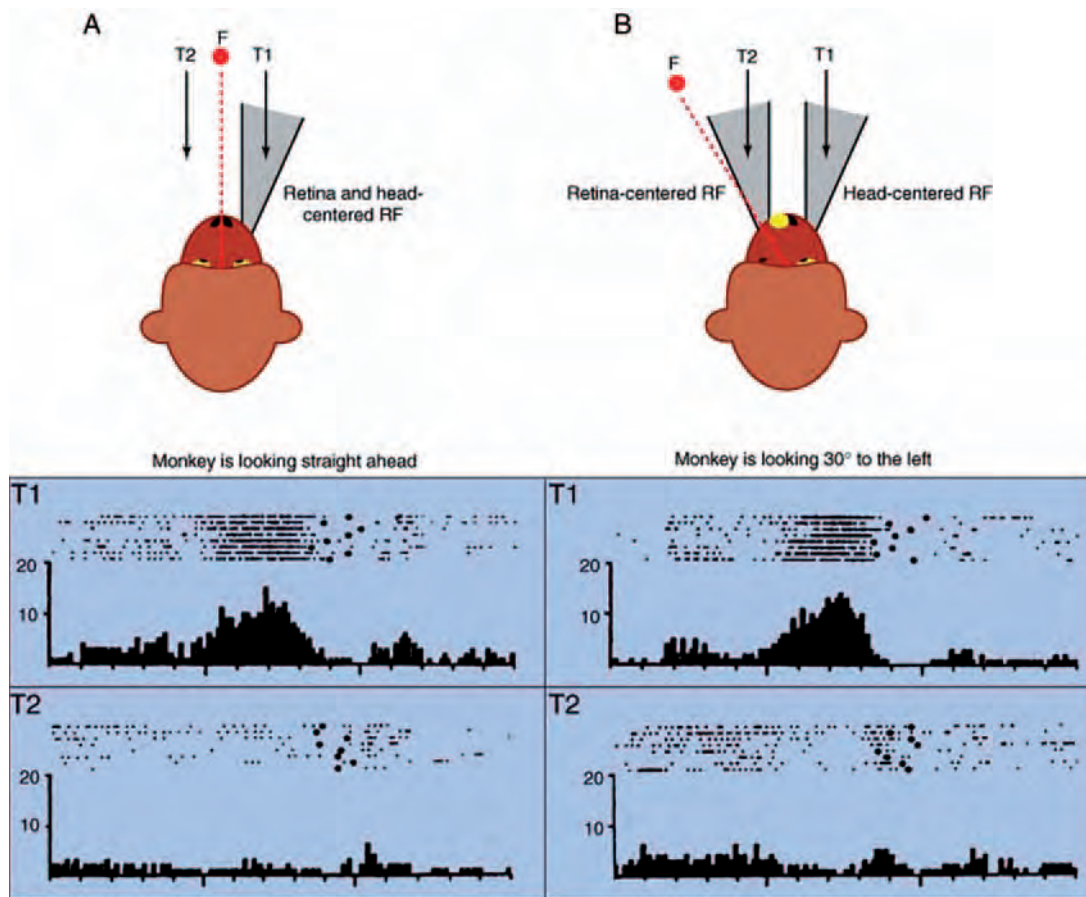

## Neurons in the Premotor Cortex Have Head and Hand-Centered Visual Receptive Fields

One of the functions of premotor cortical areas is to act as a conduit through which sensory signals are relayed to the motor system. The sensory information that reaches these areas has been highly processed already in the posterior cerebral hemispheres. Thus it is not surprising that the sensory receptive fields of some neurons in the premotor cortex are defined with respect to an external spatial framework in a form suitable for use by the motor system.

Both head and hand-centered visual receptive fields have been described in the premotor cortex. First, in portions of the premotor cortex representing orofacial movements, neurons respond to visual stimuli at a certain location relative to the head (Fogassi *et al.*,

1992). These neurons have been characterized by recording from them while objects approach the head of the monkey along various trajectories. A typical experiment is illustrated in Figure 47.7. In the first phase of the experiment, shown in the left column, the monkey looked straight ahead at a fixation target (F) while an object approached the face and then receded. The stimulus moved along a trajectory that brought it either to the right side of the head (trajectory 1) or to the left side (trajectory 2). Records of neuronal activity show that the neuron fired when the object approached along trajectory 1 but not when it approached along trajectory 2. Accordingly, it appears that the neuron had a visual receptive field located in the right visual field (shaded area in Fig. 47.7A).

To determine whether the receptive field was head or retina-centered required a second phase of testing

**FIGURE 47.7** Data from a neuron in the premotor cortex with a head-centered visual receptive field. (A) While the monkey was looking straight ahead at a fixation point (F), an object approached and receded, traveling either along trajectory 1 (T1, to the right of the head) or along trajectory 2 (T2, to the left of the head). The neuron fired strongly only when the object approached along trajectory 1. (B) When the monkey looked at a new fixation point on the far left, the neuron still responded only when the object approached along trajectory 1, indicating that the receptive field is tied to the location of the head and not to the location of the retina. The time lines above each raster and histogram show the horizontal (H) and vertical (V) eye position during one trial. The time line below shows the position of the visual object as it comes toward and then moves away from the monkey. From Fogassi *et al.* (1992).

(right column). In this phase, the monkey looked far to the left at a fixation point (F). While he maintained a leftward gaze, objects again approached the face, following trajectories 1 and 2. If the receptive field of this neuron were head centered, one would predict that it should continue to respond as the object approached along trajectory 1. However, if the receptive field were fixed to the retina, then the neuron should respond as the object approached along trajectory 2. Records of the activity of the neuron clearly indicate that the neuron had a head-centered visual receptive field. It was responsive to stimuli presented to the right of the midline of the head, but not to stimuli presented to the right of the midline of the retina. This head-centered spatial selectivity of neurons in the premotor cortex is similar to that found in area VIP. That neurons in these two areas should exhibit consistent patterns of spatial selectivity is not surprising because the parietal and premotor cortices are strongly interconnected.

A second type of body-centered spatial representation in the premotor cortex has been observed in areas representing arm movements. Here, neurons respond to visual stimuli if they are presented in the vicinity of the hand (Graziano *et al.*, 1994). When the hand moves to a new location, the visual receptive field moves with it. The visual receptive field remains fixed to the position of the hand regardless of where the monkey is looking and, thus, regardless of the part of the retina on which the image is cast. The two distinct forms of body-centered visual responsiveness seen in the premotor cortex presumably reflect the involvement of these neurons in the visual guidance of orofacial and arm movements.

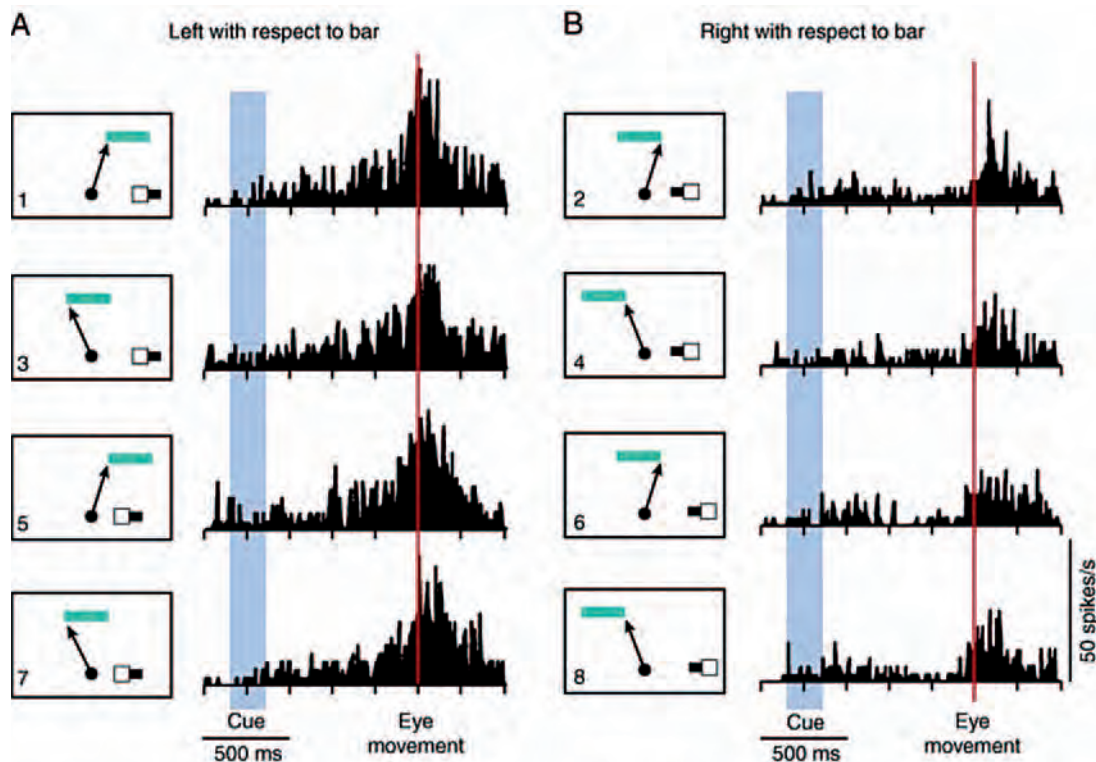

### Neurons in the Supplementary Eye Field Encode the Object-Centered Direction of Eye Movements

A particularly interesting form of allocentric spatial representation is found in the supplementary eye field (SEF). The SEF is a division of the premotor cortex with attentional and oculomotor functions. Neurons here fire before and during the execution of saccadic eye movements. Two characteristics of the SEF set it apart from subcortical oculomotor centers and suggest that its contribution to eye movement control occurs at a comparatively abstract level. First, neurons here fire while the monkey is waiting to make an eye movement in the preferred direction, as well as during the eye movement itself. Second, some SEF neurons become especially active when the monkey is learning to associate arbitrary visual cues with particular directions of eye movements.

SEF neurons exhibit a unique form of spatial selectivity in monkeys trained to make eye movements to particular locations on an object. In this context, SEF neurons encode the direction of the impending eye movement as defined relative to an object-centered reference frame (Olson and Gettner, 1995). Regardless of where in space an object appears, these neurons respond when the animal is planning to make an eye movement to a specific location on that object. An experiment demonstrating this point is shown in Figure 47.8. This figure shows the activity of a single SEF neuron while the monkey performed an eye movement task. At the beginning of each trial, the monkey fixated a dot at the center of a screen. While the monkey fixated, a sample and cue were presented in the right visual field. The cue flashed on either the right or the left end of the short horizontal sample bar. Following extinction of the sample–cue display, the monkey maintained fixation for a brief time. Then, simultaneously, the central spot was extinguished and a target bar appeared at an unpredictable location in the upper visual field of the monkey. The monkey had to make an eye movement to the end of the target bar corresponding to the cued end of the sample bar. Across the set of eight conditions, the object-centered direction of the eye movement was completely independent of its physical direction.

This situation made it possible to ask whether the activity of the neuron was related to the object-centered direction of the movement or to its physical direction. To the right of each panel in Figure 47.8 is shown the average firing rate of a single neuron as a function of time during the trial. Regardless of the direction of the physical movement of the eye, firing was clearly stronger on trials in which the monkey made an eye movement to the left end of the target bar than on trials in which the target was the right end of the bar. For example, in panels 1 and 2, the physical direction of the eye movement was exactly the same, and yet firing was much stronger when the left end of the bar was the target (panel 1) than when the right end of the bar was the target (panel 2). This neuron exhibited object-centered direction selectivity in the sense that it fired most strongly before and during movements to a certain location on an object.

Object-centered direction selectivity serves an important function in natural settings. In scanning the environment, we sometimes look toward locations where things are expected to appear, but which, at the time, contain no detail, for example, the center of a blank screen or the center of an empty doorway. Our eyes are guided to these featureless locations by surrounding features that define them indirectly. It is spe-

**FIGURE 47.8** Data from a neuron in the SEF selective for the object-centered direction of eye movements. The monkey was trained to make eye movements to the right or left end of a horizontal bar. A cue appeared on the small sample bar shown in the lower right of each panel (1–8) to tell the monkey which end of the target bar (top in each panel) was relevant on a given trial. The arrow in the panel next to each histogram indicates the direction of the eye movement. The neuron fired strongly when the eye movement was directed to the left end of the target bar (left column) regardless of whether the physical movement of the eye was up and to the right (panels 1 and 5) or up and to the left (panels 3 and 7). From Olson and Gettner (1995).

cifically in these cases that the SEF may contribute to the selection of the target for an eye movement.

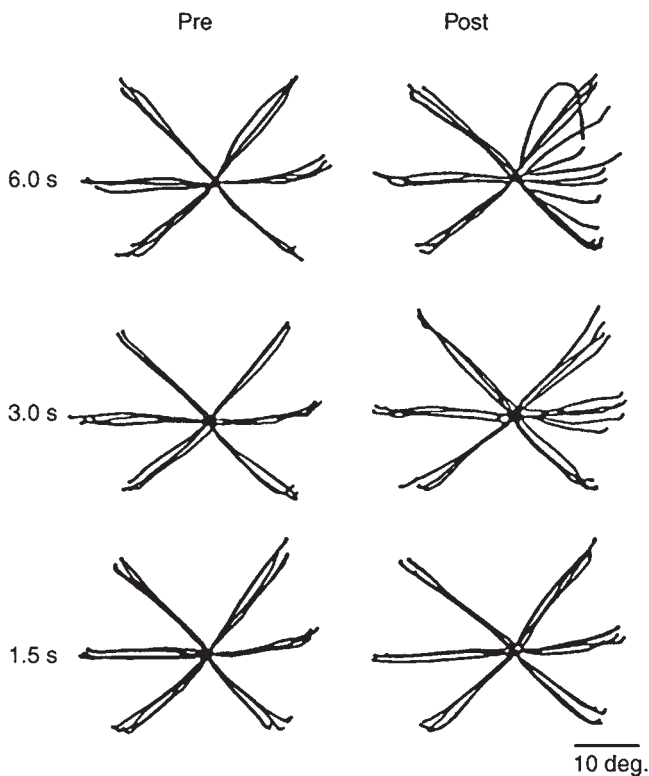

### The Prefrontal Cortex Mediates Working Memory for Spatial Information

Working memory is required to hold a plan in mind and carry it out step by step (Chapter 52). The fact that this ability is severely impaired in some patients following prefrontal injury indicates that this region plays a crucial role in working memory. Insofar as plans and working memory have a spatial component, operations carried out by the prefrontal cortex are also spatial in nature. Single neuron-recording experiments in monkeys performing delayed-response tasks have demonstrated the importance of the dorsolateral prefrontal cortex for both spatial and nonspatial forms of working memory (Funahashi *et al.*, 1991). A delayed-response task consists of several trials, each several seconds long. At the beginning of each trial, a cue is presented briefly, instructing the monkey which

response to make, but the response must be withheld until the end of the trial. Delayed-response tasks can be designed so that both the cues (for example, spots flashed to the right or left of fixation) and the responses (for example, eye movements to the right or left) are spatial. In the context of these spatial tasks, prefrontal neurons are active during the period between the cue and the signal to respond, when the monkey is holding spatial information in working memory. Just as for visual responses, some neurons are selective for the direction of the motor response. The simple interpretation of this pattern of activity is that it is a neural correlate of the monkey actively remembering the cue and holding in mind the intended response. This interpretation is consistent with results from brain imaging experiments in humans during working memory tasks.

The idea that the prefrontal cortex mediates spatial working memory has received further support from lesion experiments in monkeys. After injury to or inactivation of specific locations in the prefrontal cortex,

monkeys are impaired at remembering locations in the opposite half of space. Their delayed responses are spatially inaccurate and the inaccuracy is exacerbated by longer delays. An experiment demonstrating the importance of the prefrontal cortex for spatial working memory is illustrated in Figure 47.9, which shows behavioral data from a monkey trained to perform an oculomotor delayed-response task (Sawaguchi and Goldman-Rakic, 1994). At the beginning of each trial, the monkey fixated a spot at the center of the screen. While the monkey maintained fixation, a cue was flashed at one of six possible locations at positions. Following presentation of the cue, a delay of 1.5 to 6sec ensued before the monkey was permitted to make an eye movement to the cued location. Data

**FIGURE 47.9** Inactivation of the left prefrontal cortex disrupts spatial working memory in the right half of space. A monkey was trained to fixate a central spot while a peripheral cue was presented briefly at one of six locations. After an interval of 6, 3, or 1.5s, the fixation spot was extinguished and the monkey made an eye movement to the remembered location. Each set of diverging rays shows the trajectories of eye movements executed under a certain set of conditions. The left column shows eye movement performance before inactivation by a dopamine antagonist. The right column shows performance after inactivation. When the cue was in the right hemifield and the monkey was required to remember its location over long delays, the movements became highly inaccurate. From Sawaguchi and Goldman-Rakic (1994).

from a normal monkey are shown in the left column of Fig. 47.9. In each panel, the six bundles of radiating rays represent the eye trajectories on trials when the cue was at the six different locations. Even when required to remember the cue for 6s, the monkey made accurate eye movements. Data in the right column are from the same monkey after a dopamine antagonist was injected into the left prefrontal cortex. The ability of the monkey to remember the location of the cue remained intact when the cue was in the left (ipsilesional) visual field, as shown by the accurate eye movements. However, performance deteriorated on trials when the cue was in the right (contralesional) visual field. Especially after long delays (top panel), the direction of the eye movement began to deviate from the location of the cue, as if the working memory of the monkey were fading. The fact that this deficit was specific to long delays is noteworthy because it rules out any simple explanation based on interference with visual or motor processes as opposed to working memory itself.

Neural signals related to working memory are found in object memory tasks as well as spatial tasks (Chapter 52). In a task in which the monkey had to remember the identity of an object as well as its location, some neurons were selectively activated by remembering the object (Rao *et al.*, 1997). Prefrontal cortex is important for both kinds of working memory.

### Value Representation and Motivational Modulation in Frontal Cortex

In many areas of the frontal lobe, neurons fire more strongly when a monkey anticipates receiving a larger reward for making a saccade (Roesch and Olson, 2003). The firing of these neurons could signify either of two things. First, it might represent, in an economically meaningful sense, the value of the reward that the monkey expects to receive. The monkey might commit more or less firmly to making the saccade on the basis of how strongly the neurons are firing. Second, it might simply be related to motor planning, attention or arousal—internal states enhanced when the monkey is more motivated. That these interpretations are different can be illustrated by a simple example. The neck muscles of some monkeys grow more tense when they are planning a saccade in expectation of getting a larger reward (Roesch and Olson, 2004). The tension of the neck muscles obviously reflects motivation and does not represent value in an economically meaningful sense. Whether the activity of frontal neurons represents value or reflects motivation cannot be determined by experiments manipulating solely the size of

the expected reward because, as value increases, so does motivation.

This issue has been resolved by manipulating independently the size of the reward promised in the event of the monkey's successfully completing the trial (one or three drops of juice) and the size of the penalty threatened in the event of failure (a one-second or eight-second time-out). A large promised reward and a large threatened penalty have opposite value but both act to increase motivation. Spatially selective neurons in premotor cortex fire more strongly when either a large reward has been promised or a large penalty has been threatened (Fig. 47.10). In other words, activity in these neurons is modulated by the animal's level of motivation. In contrast, neurons in orbitofrontal cortex fire most strongly when a large reward has been promised and least strongly when a large penalty has been threatened. In other words, they represent anticipated value. The orbitofrontal cortex is a part of the limbic system known to be involved in emotional processes. Presumably, when the monkey considers an action that would lead to an outcome, neurons in orbitofrontal cortex signal the emotion that would be elicited by the outcome, thus representing its value. Value representations in orbitofrontal cortex presumably give rise to motivational modulation in premotor cortex.

### Summary

Neurons in the frontal cortex represent spatial information as a natural consequence of their role in controlling behavior. Neurons in the primary motor cortex encode the directions of movements. Neurons in the premotor cortex encode locations relative to the body, even when these locations are not the immediate targets of actions. SEF neurons encode locations in an allocentric, object-centered representation. Neurons in the prefrontal cortex encode the locations of and identity of objects being held in short-term memory. Finally, the strength of neural activity in premotor cortex is modulated by the monkey's level of motivation while neurons in orbitofrontal cortex encode the anticipated value of the expected reward.

## HIPPOCAMPUS AND ADJACENT CORTEX

### The Hippocampal System Is Associated with Memory Formation

Spatial functions of the hippocampus center on its role in memory formation (Chapter 50). The hippo-

campus is an area of primitive cortex, or allocortex, hidden on the underside of the temporal lobe. It is connected to a set of immediately adjacent cortical areas, including the perirhinal, entorhinal, and parahippocampal cortices (Zola-Morgan and Squire, 1993).

### Amnesia Resulting from Hippocampal Injury in Humans Includes a Spatial Component

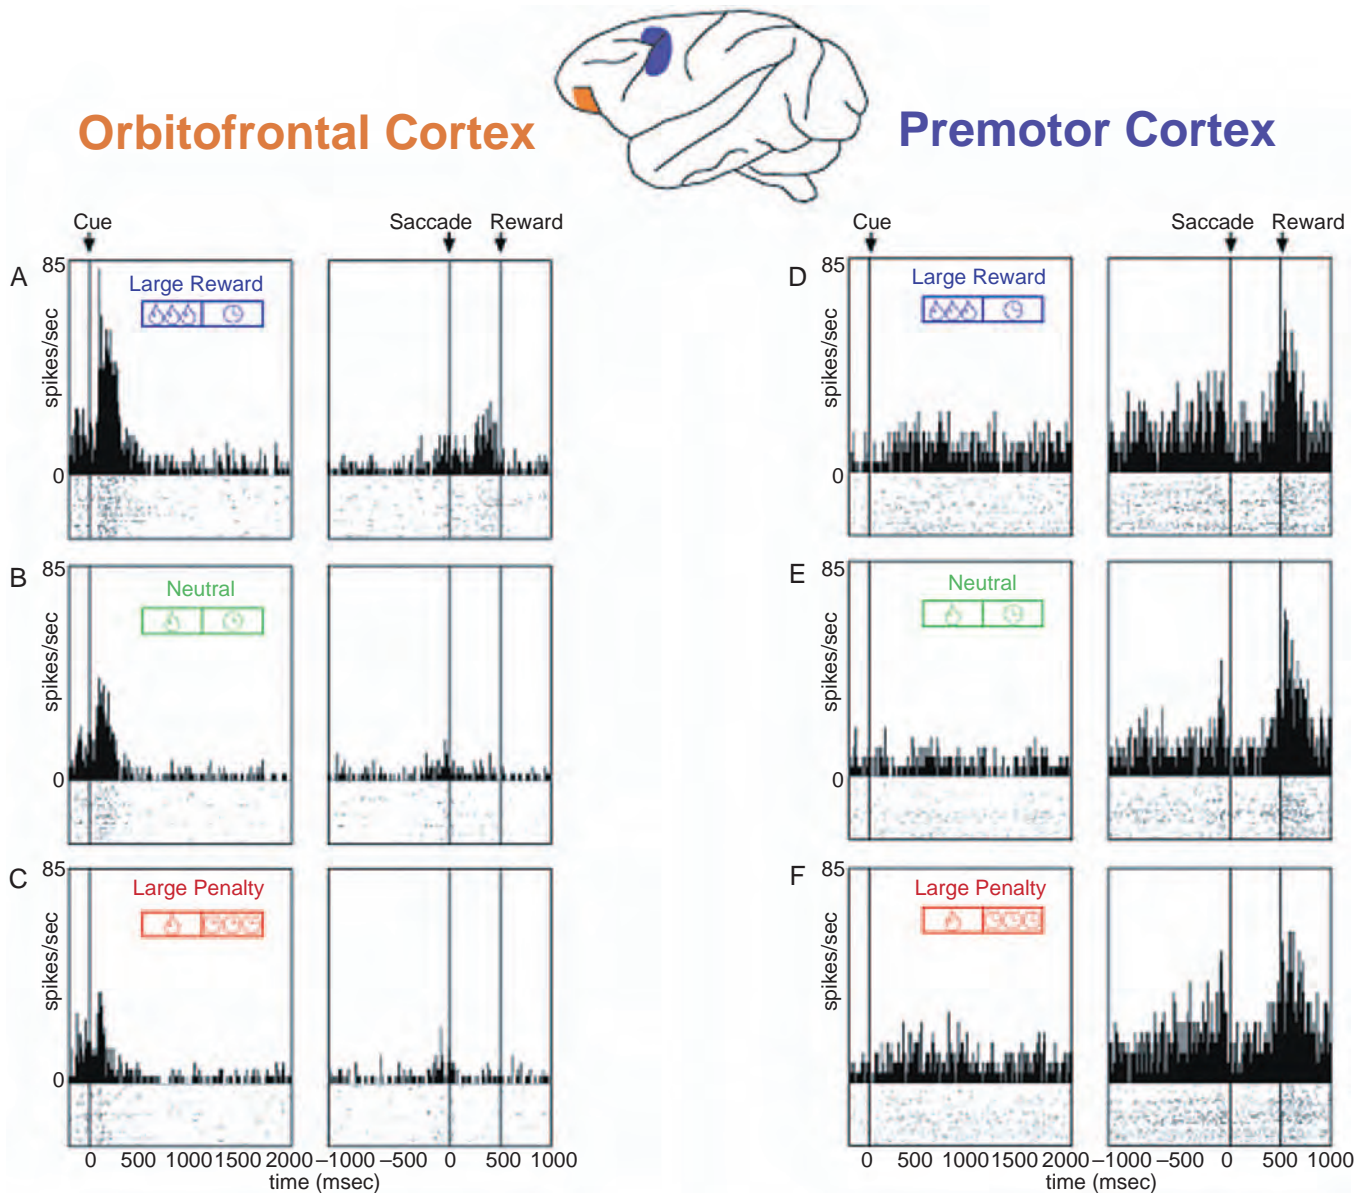

Extensive evidence implicates the hippocampus and related medial temporal structures in the formation of declarative memories in humans. Memories dependent on the hippocampus include, although they are by no means restricted to, memories for spatial material. In addition to many other impairments, the amnesia of the noted patient H.M. was evident in his inability to learn to find his way through new neighborhoods. Patients with damage to the hippocampus, especially the right hippocampus, are impaired on tests requiring them to inspect a scene with many objects and then to recall the locations of individual objects.

The hippocampus has a role in both spatial and nonspatial memory. In rats, as described in Chapter 50, the hippocampus is essential not only for remembering locations but also for remembering odors and for learning associations between stimuli and rewards (Bunsey and Eichenbaum, 1996). Likewise, in humans, memories of many kinds depend on the hippocampus. Patient EP, profoundly amnesic after extensive medial temporal damage resulting from a viral encephalitis, suffers from problems with spatial memory. He cannot learn the layout of the new neighborhood where he now lives (Teng and Squire, 1999). However, he is not impaired at spatial navigation in itself. He is able to find his way around the neighborhood where he grew up and can describe it in detail. Moreover, his deficit extends beyond spatial memory. Like patient HM, he fails to recognize someone to whom he was introduced only minutes before. How the hippocampus uses spatial information, along with nonspatial information, to form new memories is taken up in Chapter 50.

### Neurons of the Hippocampal System Have Place Fields and Are Sensitive to Directional Orientation of the Head

Recordings from hippocampal neurons in rats running mazes or exploring open areas have revealed a remarkable degree of spatial selectivity. Many neurons in the hippocampus have place fields: a given neuron will fire most strongly when the rat is within

**FIGURE 47.10** Evidence that orbitofrontal neurons encode expected value whereas premotor neurons are subject to motivational modulation. A cue presented early in each trial instructed the monkey whether to make a rightward or leftward saccade at the trial's end. It also indicated whether making the instructed saccade would lead to a large or small reward (three drops or one drop of juice). Finally, it indicated whether failure to make the saccade would lead to a large or small penalty (a one-second or eight-second time-out). After a delay of several seconds, the monkey was permitted to respond. For a saccade in the instructed direction, the monkey received the promised reward. For any other response, the monkey incurred the threatened penalty. The orbitofrontal neuron encoded the value of the outcomes predicted by the cue. It responded most strongly when the combined predicted outcome was best (A: large reward promised and small penalty threatened), at an intermediate level when it was middling (B: small reward promised and small penalty threatened) and least strongly when it was worst (C: small reward promised and large penalty threatened). The premotor neuron fired during the delay period at a rate that reflected how motivated the monkey was. It fired most strongly when the monkey had something significant to work for, either earning a large reward (D) or avoiding a large penalty (F) and least strongly when little was at stake (E). In each panel, time is on the horizontal axis. The histogram represents the average firing rate of the neuron as a function of time during the trial. In the underlying raster display, each horizontal line corresponds to a single trial and each dot represents an action potential. From Roesch & Olson (2004).

a certain sector of the workspace (Chapter 50). Different neurons have distinct place fields so that, collectively, they cover the workspace. Place fields are defined relative to prominent environmental landmarks. When a radially symmetric eight-arm maze is rotated relative to a surrounding room containing salient landmarks the place fields remain fixed with respect to the room. Even in darkness, neurons continue to fire when the rat is in their place field, indicating that these responses are not simply visual. If the rat is placed in a new environment, hippocampal neurons develop new place fields rapidly. The location of the place field of a neuron relative to the new environment is not predictable from its location relative to the old environment. This is true even in cases where the workspace is changed without any change in the surrounding room, for example, through replacement of an eight-arm radial maze by an open field.

Neurons in other regions of the hippocampal system are sensitive to the direction in which the head is pointing. Sensitivity to heading is common in the postsubiculum, a cortical area adjacent to and closely linked to the hippocampus. Each postsubicular neuron fires most strongly when the head of the rat is pointing in its preferred direction and fires progressively less strongly as the orientation of the head of the rat deviates farther from that direction. In a room that is suddenly darkened, postsubicular neurons remain sensitive to the heading of the rat so long as the rat retains a sense of spatial orientation, as reflected by error-free performance on spatial tests. When the sense of spatial orientation drifts away from veridicality during prolonged darkness, as evidenced by the occurrence of systematic errors on spatial tests, then the preferred headings of postsubicular neurons exhibit a commensurate drift. These observations establish that neurons of the hippocampal system are sensitive to the spatial orientation of the rat. The place cells in the hippocampus and the head-direction cells encode complementary forms of spatial information.

As an animal moves through space it can keep track of the route it has taken by combining information from place cells and head-direction cells. This path integration produces a sense of position that is independent of the immediate visual environment. The path integration system is thought to depend on grid cells in the medial entorhinal cortex, an area of high-order neocortex adjacent to the hippocampus (Hafting *et al.*, 2005). In contrast to place cells, which generally have single firing fields, grid cells have a multitude of firing fields arranged in a strikingly regular hexagonal grid pattern. Moreover, the grid patterns exist at multiple scales. This is what allows the rat to derive unique location codes for every point in a large environment.

The map in medial entorhinal cortex, like that in other regions, is anchored to external landmarks but, unlike the map in other areas, it persists in the absence of landmarks. The grid cells constitute a map of relative spatial location that is independent of external sensory cues and the specific environment.

### Summary

The hippocampal system mediates the formation of memories, including memories with spatial content. Injury to the hippocampal system, both in humans and in other animals, leads to profound deficits of memory, especially navigational memory. In accord with these findings, single neuron recording in rats has revealed that neurons of the hippocampal system have place fields, encoding the location of the rat in its environment, and directional sensitivity, encoding head direction relative to the environment. Information from these neurons is combined so that animals can keep track of their position in space over time.

## SPATIAL COGNITION AND SPATIAL ACTION

---

The preceding sections described how spatial information is processed in cortical areas that serve distinct functions, such as motor control, attention, and working memory. Even within the motor system, there appears to be a fractionation of spatial functions in that neurons controlling movements of the eyes, head, and arm represent the locations of visible targets relative to eye, head, and hand-centered reference frames, respectively. In addition to these distinctions, there may be another fundamental distinction within brain systems mediating spatial functions. Areas mediating conscious awareness of spatial information may be partially separate from those mediating the spatial guidance of motor behavior. These functions may seem inseparable insofar as one must be aware of the location of a thing in order to look at it or reach for it. However, this is not necessarily the case. An indication that spatial awareness and spatially programmed behavior are distinguishable has come from studies of patients with "blindsight" (Weiskrantz, 1996). This condition arises as a result of injury to the primary visual cortex. Patients experience a scotoma, an area of blindness, in the part of the visual field represented by the injured cortex. The blindness is total in the sense that patients do not report seeing visual stimuli when stimuli are presented within the confines of the scotoma. Nevertheless, if patients are asked to look

toward or to reach for an unseen stimulus, choosing the target by guesswork, their responses are directed to the correct location.

Similar findings have been reported in patients with diffuse pathology affecting widespread areas, including the prestriate visual cortex. One such patient, DF, has been extensively studied in spatial tasks (Goodale *et al.*, 1994). These studies reveal an important distinction between spatial performance and spatial cognition. When asked to express spatial judgments (for example, to indicate the size of a visible object by spreading the thumb and forefinger), DF performs poorly. Nevertheless, when asked to make visually guided movements (for example, to reach for an object), she accurately adjusts her grip size and hand orientation under visual control to grasp the object efficiently. The fact that intact visuomotor performance coexists with profoundly impaired visuospatial perception in some patients seems to argue for the existence of distinct brain systems specialized for conscious spatial awareness and motor guidance. Many lines of evidence indicate that conscious spatial awareness depends on relatively lateral regions of parietal cortex, whereas motor guidance depends on more medial regions of parietal cortex. Conscious spatial vision is distinct from conscious visual recognition, which depends on occipitotemporal cortex (Chapter 46).

## Summary

Spatial cognition is a function of many brain areas. No one area is uniquely responsible for the ability to carry out spatial tasks. Nevertheless, some generalizations can be made about the part of the problem that is solved in each brain region. The parietal lobe plays a crucial role in many aspects of spatial awareness, including spatially focused attention. The representation of space in the parietal cortex takes several forms. Each subdivision within the parietal cortex contributes to different kinds of spatial representations, designed to help guide different kinds of actions.

In contrast to the parietal cortex, the frontal lobe transforms spatial awareness into actions. The motor cortex uses a spatial framework to encode intended actions. The premotor cortex contains a set of separate spatial representations to generate eye, hand, and arm movements. The SEF contains neurons with very high-order, abstract spatial representations. Prefrontal cortex mediates spatial working memory. Finally, the hippocampus mediates spatial declarative memories, including those that underlie spatial navigation.

Beneath the unity of our spatial perception lies a diversity of specific representations. The distributed

nature of spatial cognition and the many purposes it serves means that we construct internal representations of space not once but many times in parallel. A challenge for the future is to understand how these many representations function together so seamlessly.

# Attention

---

---

## INTRODUCTION

---

Intuition, together with cognitive and psychophysical experiments, shows that the brain is limited in the amount of information that it can process at any moment in time. For instance, when people are asked to identify the objects of a briefly presented scene, they become less accurate as the number of objects increases. Similarly, when people concentrate on one demanding task (e.g., mental arithmetic) this typically comes at the expense of performance on other simultaneous activities (e.g., recalling a familiar tune). Limitations on the ability to simultaneously carry out multiple cognitive or perceptual tasks reflect the limited capacity of some stage or stages of sensory processing, decision-making, or behavioral control. As a result of such computational bottlenecks, it is necessary to have neural mechanisms in place to ensure the selection of stimuli, or tasks, that are immediately relevant to behavior. "Attention" is a broad term denoting the mechanisms that mediate this selection.

Over the past several decades, research has concentrated on the relation between attention and sensory perception. Clearly, it is possible to focus on selected stimuli in any sensory modality—sights, sounds, smells, and touch. Most studies, however, have examined vision, the dominant sensory modality for humans and nonhuman primates. These experiments have investigated visual attention at multiple levels, ranging from behavior to the single neuron. This chapter outlines the view of attention that has emerged from these studies.

A key observation is that attending to an object greatly enhances the ability to perceive and report the

object's visual attributes; conversely, withdrawing attention, either by force of the behavioral context or following certain brain lesions, can render observers practically blind to certain visual events. A second key point is that the attentional processes that underlie perceptual selection may also guide the voluntary eye movements with which foveate animals, such as monkeys and humans, scan the environment. In terms of neural organization, although some neural centers have been closely linked with the control of attention, attention appears to affect the activity of neurons at almost all levels of the visual system.

---

## VARIETIES OF ATTENTION

---

In natural behavior, individuals have great flexibility as to how and when they attend and what they attend to. Attending to an object often is accompanied by overt orienting toward that object using the eyes and possibly also the head and body. When a person enters a room, it is natural to turn in that person's direction. However, one can also attend covertly to objects that are not in the center of gaze, without looking directly at them. When driving, one can monitor a passing car while continuing to look straight ahead. Covert attention can improve peripheral visual acuity, thereby extending the functional field of view. Although one can direct attention without moving the eyes, the converse does not appear to be true: experiments show that covert attention must be deployed to an object before that object can be targeted with an eye movement. Indeed, saccades—rapid eye movements used most commonly for scanning the environment—

may be considered a motor manifestation of visual attention, a relationship that is discussed in more detail later.

Certain external stimuli can summon attention in and of themselves. These can be physically salient objects, such as especially large, bright, or loud objects, or stimuli with special learned significance, such as one's own name or a mother's face. This mode of attentional engagement, known as *exogenous* or *stimulus driven*, ensures that salient and potentially important external events do not pass unnoticed even if they are not being actively sought out. However, purposeful behavior often requires that attention be directed voluntarily, or *endogenously*, based on internally defined goals and against potential external distractions. When reading, one purposefully directs one's attention from one word to the next, tuning out noise and other distractions. In natural behavior, endogenous and exogenous factors interact continuously to control the allocation of sensory processing (Egeth and Yantis, 1997).

Another important issue is *what* is attended. Attention can be directed to a location in space, regardless of what happens to be at that location. It can also be directed to a feature, as when one searches within a complex scene for an object of a particular shape or color. Finally, attention can select whole objects, as demonstrated by studies showing that when attention is directed to one feature of an object, the other features

of the same object are selected automatically for visual processing, and by studies finding that when attention is directed to one of two semitransparent objects, attending to a feature of one object impairs processing of the features of the other object. In each of these cases, attention has been found to facilitate processing of the attended location, feature, or object, as assessed at the behavioral and neural levels (Reynolds and Chelazzi, 2004).

Attention is thus highly flexible and can be deployed in a manner that best serves the organism's momentary behavioral goals: to locations, features, or objects, based on internal goals or the external environment, with or without accompanying orienting movements. It is important to keep in mind that although these phenomena can be isolated in laboratory experiments, all varieties of attention operate seamlessly during natural behavior.

### NEGLECT SYNDROME: A DEFICIT OF SPATIAL ATTENTION

Studies of patients with brain lesions have identified regions of the brain that are involved in attention (see Fig. 48.1, which shows the major divisions of the human cortex). Unilateral lesions in the parietal lobe,

Copyright © 2002, Elsevier Science (USA). All rights reserved.

FIGURE 48.1 Lateral view of a human brain. Frontal (purple), parietal (orange), temporal (blue), and occipital (yellow) lobes are outlined.

the frontal lobe, and the anterior cingulate cortex (Heilman, 1979; Vallar, 1993) in humans may cause a profound inability to attend to certain spatial regions, a syndrome known as spatial neglect. At the subcortical level, lesions of the basal ganglia or of the pulvinar thalamic nucleus, which is heavily connected with the parietal cortex, can also cause neglect. In severe cases, patients with neglect behave as if the world contralateral to their lesioned hemisphere (the contralesional world) has ceased to exist. For example, a patient with neglect following a right hemisphere lesion may fail to read from the left side of a book, may ignore the food on the left side of the plate, or may remain unaware of the numerals on the left side of a clock (Fig. 48.2). Neglect patients may also be reluctant to initiate movement in contralesional space, with or without external sensory stimulation. Because the critical feature causing an object to be ignored is its location, this type of neglect is thought of as primarily a disorder of spatial attention.

The behavioral impairments in neglect cannot be explained by simple sensory or motor deficits (Mesulam, 1999). Neglect patients have normal vision in the contralesional visual field once their attention has been directed there, and they have no hemiparesis that could account for their reluctance to move. In addition, the extent of their difficulty is not immutable, as a sensory or motor deficit would be, but is strongly affected by the goals, expectations, and motivational state of the patient. Thus, neglect represents a failure to select, in some circumstances, the appropriate portions of a sensory representation. Neglect operates on

high-level representations that differ considerably from the raw sensory input. For example, visual neglect is not confined only to retinal visual coordinates (affecting only objects in the contralesional visual field), but can affect objects in the contralesional space relative to the patient's body, relative to the patient's gaze, or relative to an external object or scene. Thus, neglect affects a visual representation that incorporates information about the position of the body with high-level visual information. Neglect affects not only the perception of the present sensory environment, but also the processing of memorized or imagined scenes.

A related but milder attentional deficit, known as extinction, can follow more limited brain lesions or can occur during recovery from the acute phase of neglect. In visual extinction, patients are able to orient toward a contralesional stimulus presented in isolation, but fail to notice it if the same stimulus is presented simultaneously with an ipsilateral distracter. Extinction-like deficits are demonstrated readily with the spatial cuing task (Posner *et al.*, 1984). In these tasks, subjects are cued to attend to the left or right visual field. Unimpaired observers are better able to process information at the cued location, but can also detect stimuli at an uncued location. Compared to unimpaired observers, neglect patients are slowed only mildly in their ability to detect targets in the contralesional visual field following valid symbolic or peripheral cues in the same field. However, they have enormously prolonged latencies for detecting contralateral targets if their attention had been misdirected to the ipsilesional field by means of an invalid cue. No impairment is seen

**FIGURE 48.2** Two drawings that were made by a patient with spatial neglect. The patient was asked to copy the two models (clock, house). In each case, the copies exclude important elements that appeared on the left side of the model, indicating that the patient was unable to process information about the left side of the model.

when patients are cued to the contralesional field but asked to detect an ipsilesional target. Extinction-like phenomena also have been demonstrated in search tasks in which patients are asked to find a target object located at various locations in a complex scene. The time needed to find a target in contralesional space increases in proportion with the number and salience of ipsilesional distracters.

### SINGLE UNIT RECORDING STUDIES IN NONHUMAN PRIMATES PROVIDE CONVERGENT EVIDENCE FOR A FRONTO-PARIETAL ATTENTIONAL CONTROL SYSTEM

Studies in monkeys have supported the conclusion that frontal and parietal cortices play a role in controlling the allocation of attention. These studies point to two interconnected areas, one in the parietal cortex, the lateral intraparietal area (LIP), and one in the frontal lobe, the frontal eye field (FEF), as being important for spatial attention. Many neurons in FEF and LIP have visual receptive fields, meaning that they respond to visual stimuli that activate a limited region of the retina. These receptive fields are mostly contralateral, so that the FEF and LIP in one side of the brain represent the locations of objects in the contralateral portion of the visual field. Receptive fields are retinotopic, that is they are linked to the retina and move relative to the external world every time the eye moves. Thus, during natural behavior LIP and FEF neurons are stimulated by numerous objects that enter or exit their receptive field by virtue of the observers' own movement.

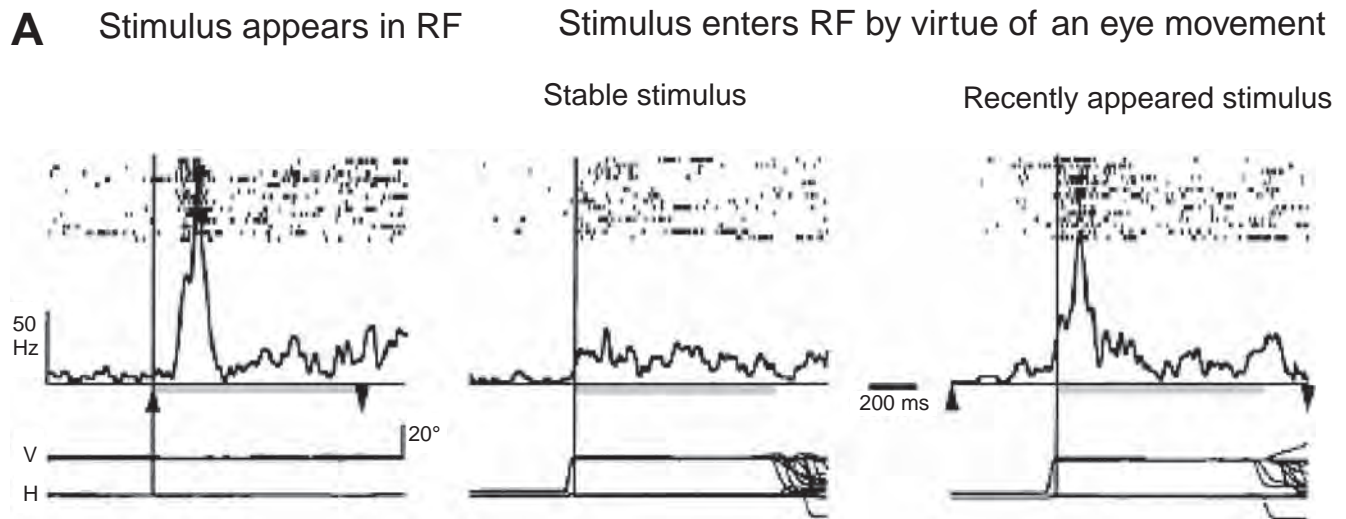

Despite this continuous visual stimulation, LIP neurons respond little to most objects during natural viewing. For instance, the LIP neuron in Figure 48.3 responded robustly whenever an object was flashed in its receptive field (A, left). However, the neuron responded little if the same object was stable in the environment and entered the receptive field by virtue of an eye movement (A, center). The neuron responded very reliably if the object in the receptive field was rendered salient by blinking it on and off on every trial (A, right) or if it was rendered task relevant by being designated as the target for the next eye movement (B). Thus, LIP neurons respond very selectively to objects that attract attention—either by virtue of their intrinsic conspicuity or by becoming relevant to the behavioral task. These findings have given rise to the proposal that LIP encodes a “salience representation,” or a “priority map” that specifies only a small

**FIGURE 48.3** LIP neurons encode a spatial salience representation. (A) LIP neurons are sensitive to the physical conspicuity of objects in the receptive field. An LIP neuron responds strongly when a visual stimulus is flashed in its receptive field (left). The same neuron does not respond if the physically identical stimulus is stable in the world and enters the receptive field by virtue of the monkeys' eye movement (center). The neuron again responds if the stimulus entering the receptive field is rendered salient by flashing it on and off on each trial (before it enters the receptive field). In each panel, rasters show the times of individual action potentials relative to stimulus onset (left) or the eye movement that brings the stimulus in the receptive field (center and right). Traces underneath the rasters show average firing rate. Bottom traces show the horizontal and vertical eye position. The rapid eye movement (saccade) that brings the stimulus in the receptive field is seen as the abrupt deflection in eye position traces. (B) LIP neurons are sensitive to the behavioral relevance of objects in the receptive field. Traces show average firing rate of an LIP neuron when the monkey is cued to make a saccade to a stimulus in the receptive field. In the left panels the monkey is fixating and a stable stimulus is in the receptive field. The neuron has low firing rate. In the center panel the monkey receives a cue instructing him to make a saccade to the receptive field. The neuron gradually increases its response. In the right panel the monkey executes the instructed saccade. The neural response remains high until after the eye movement.

number of objects and locations worthy of immediate attention. A similar proposal has been advanced for the FEF, and may also hold for area 7a, a parietal area adjacent to LIP.

In the example shown in Figure 48.3B the object in the receptive field became behaviorally relevant by being designated as the target of the next eye movement. Thus, the selective LIP response in this case may have contributed to the attentional selection of an eye movement target. However, LIP neurons, like visually responsive neurons in the FEF also respond strongly to task-relevant objects even when monkeys covertly attend to a stimulus without making eye movements or when they purposefully move their eyes away from an attended cue. Taken together these observations suggest that LIP neurons and visually responsive neurons in the FEF are not limited to guiding eye movements, but play a key role in attentional control, regardless of the ensuing behavior.

A number of studies have shown that directly manipulating activity in the LIP and FEF can affect the distribution of attention. Reversible inactivation of the LIP or FEF using microinjections of the GABA agonist, muscimol, produces deficits in target selection during either saccade-based or covert visual search tasks. In addition, subthreshold microstimulation of FEF can bias the covert distribution of attention. These findings support the conclusion that LIP and FEF are parts of the network of areas that mediate the allocation of attention.

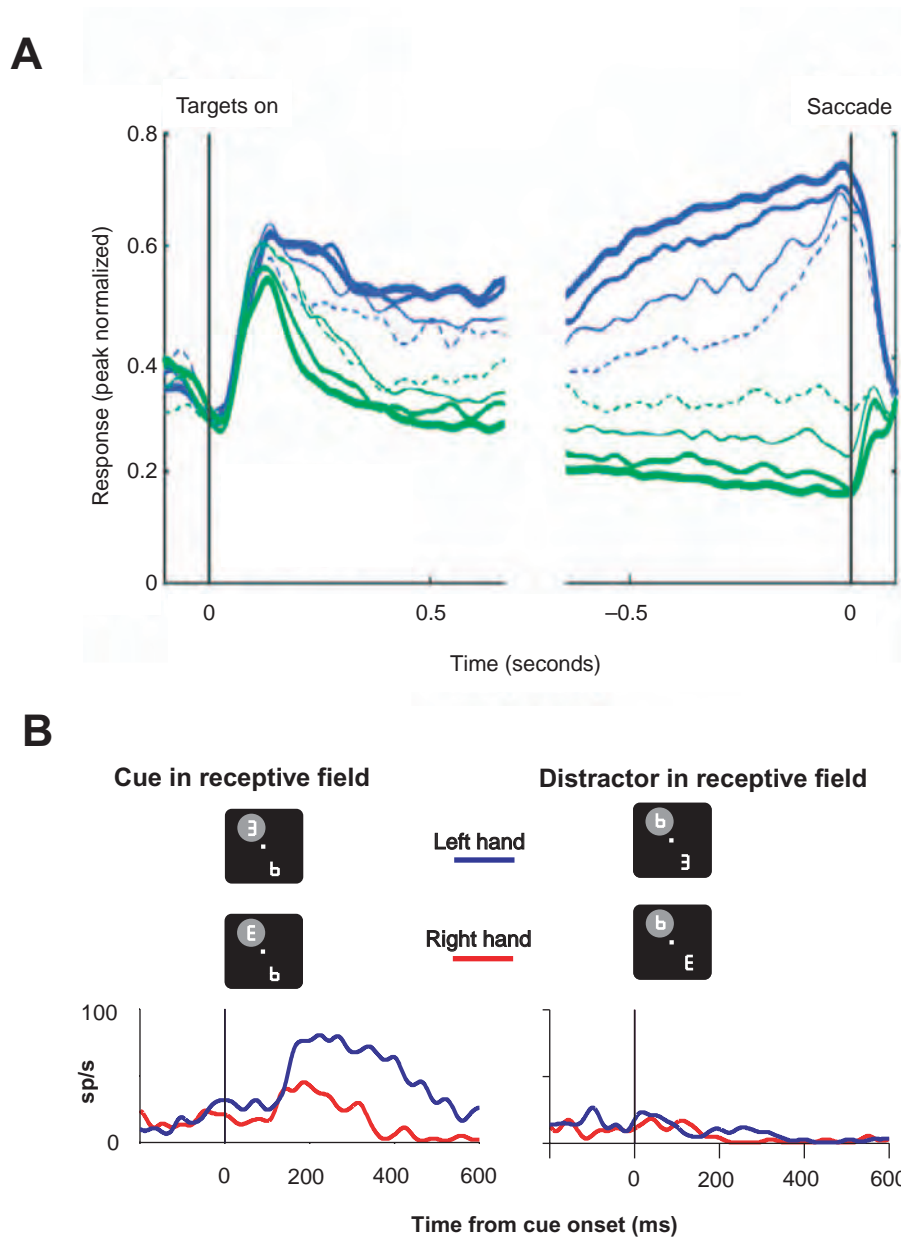

**B** Stimulus in RF is designated as saccade target

Converging evidence shows that spatially-selective responses in LIP and FEF are modulated by reward expectation, the memory—or expectation—of specific events, by contextual variables (i.e., relationship between task events), and the similarity between target and distracters. In the experiment illustrated in Figure

48.4A monkeys were free to choose between two saccade directions (either toward or away from the receptive field), and the probability that any one direction would be rewarded was systematically varied. Monkeys apportioned their choices in relation to reward probability, tending to choose the target with

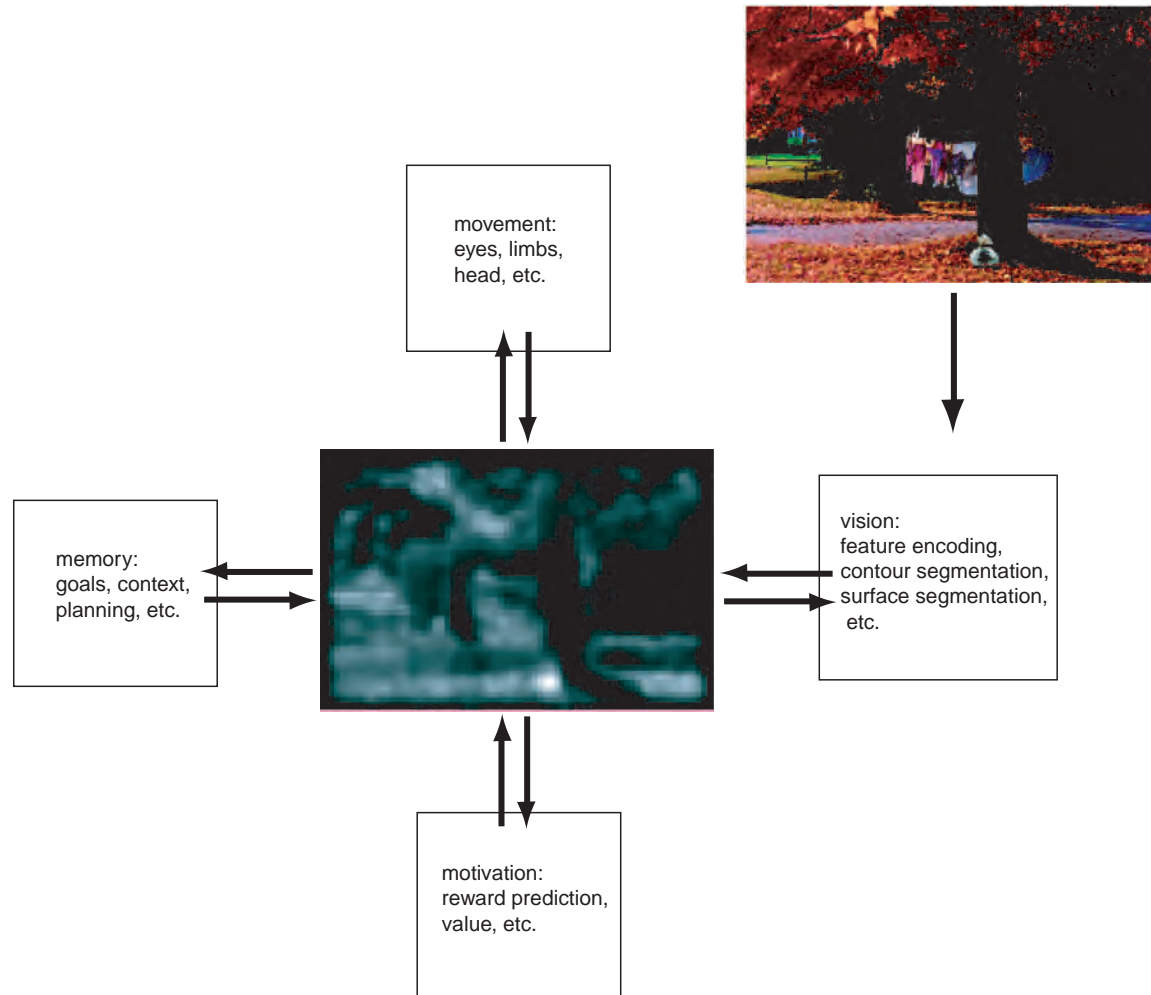

**FIGURE 48.4** (A) LIP responses are modulated by reward probability. Monkeys performed a dynamic foraging task in which they tracked the changing reward values of each of two saccade targets. Traces represent population responses for neurons with significant effects of reward probability. Blue traces represent saccades toward the receptive field, and green traces represent saccades opposite the receptive field. Traces are further subdivided according to local fractional income (reward probability during the past few trials): solid thick lines, 0.75–1.0; solid medium lines, 0.5–0.75; solid thin line, 0.25–0.5; dotted thin lines, 0–0.25. Activity for saccades toward the receptive field increased, and that for saccades away decreased as function of local fractional income, resulting in more reliable spatial selectivity (difference between the two saccade directions) with increasing reward probability. (B) LIP neurons are modulated by limb motor planning. Monkeys viewed a display containing a cue (a letter “E”) and several distracters. Without moving gaze from straight ahead, they reported the orientation of the cue by releasing one of two bars grasped with their hands. The neuron illustrated here responded much more strongly when the cue rather than a distracter appeared in its receptive field (left versus right panels). This cue-related response was modulated by the manual release: the neuron responded much more when the monkey released the left than when she released the right bar (blue versus red traces). Limb modulations did not always accompany a bar release, but were found only when the attended cue was in the receptive field. Bar-release latencies were on the order of 400–500ms.

the higher probability of reward. LIP responses to the saccade target (blue traces) increased as a function of reward probability. Note that reward probability modulated the LIP response but did not fundamentally change the neurons' spatial selectivity: neurons always responded more before a saccade to the receptive field than before a saccade away even if the reward expected for the former was less than for the latter.

Behavior related modulations of LIP also include effects related to limb rather than eye movements. In one experiment monkeys were trained to discriminate the orientation of a cue presented in the peripheral visual field and, without making a saccade to the cue, to report the *orientation* of the cue by releasing a bar grasped with either the right or left hands. LIP neurons generated the expected spatial salience signal, responding much more strongly if the cue than if a distracter

appeared in their receptive fields (Figure 48.4B, left versus right panels). However, this response was modulated by the monkey's choice of limb. The neuron illustrated in Figure 48.4B responded more strongly to the cue in the receptive field if the monkey released the left than if he released the right bar, while other neurons showed the opposite preference, responding more for right than for left bar release.

These findings suggest that salience maps integrate information about a wide variety of behavioral cues relevant for directing attention, whether these cues are from the visual, cognitive, motor or motivational domains (Fig. 48.5). Although the output of these maps has an invariant meaning—a selected location—this output is constructed from a wide variety of sources of information that are relevant to a current behavior. By virtue of these integrative properties salience maps

**FIGURE 48.5** A salience representation can be viewed as an intermediate representation that interacts with multiple behavioral systems (visual, motor, cognitive, and motivational) and fashions a unified signal of “salience” based on multiple task demands. By virtue of feedback connections to these systems the salience map can help coordinate output processing in multiple “task-relevant areas”.

have the potential to coordinate perceptual selection with ongoing action for a wide variety of behaviors.

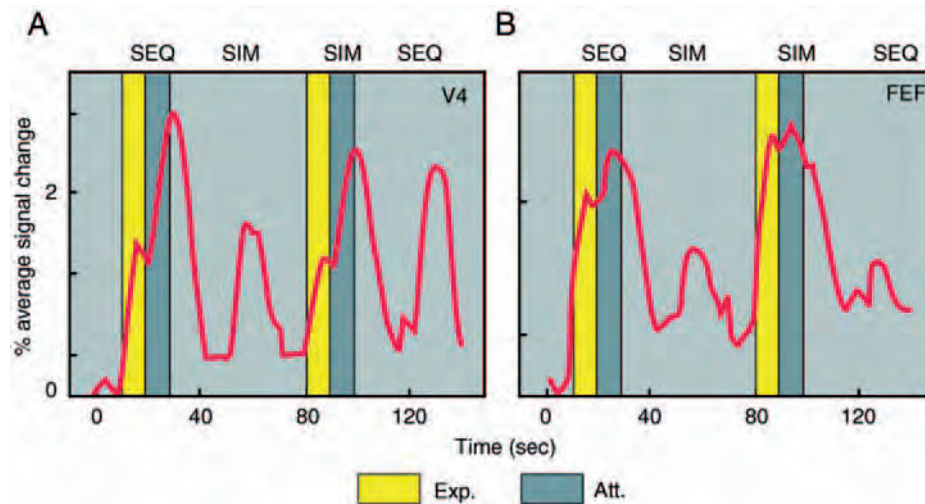

Human functional brain imaging studies are in agreement with both single-cell physiology and neuropsychological studies in identifying areas in the parietal, frontal, and cingulate cortices as being especially active in relation to spatially directed attention. When observers attend to a location in space in anticipation of the appearance of a stimulus, this is accompanied by elevated levels of activity in a fronto-parietal network consisting of the superior parietal lobe

(SPL), the frontal eye field (FEF), and the supplementary eye field (SEF) extending into the anterior cingulate cortex (Fig. 48.6; for review, see Kastner and Ungerleider, 2000). This elevation in activity persists throughout the expectation period and when stimuli later appear at the attended location (Fig. 48.7B). It is important to note that the fronto-parietal attentional control network is not limited to controlling spatial attention. It is also activated when subjects select non-spatial information. Object- or feature-based attention engages the fronto-parietal attention network as well

**FIGURE 48.6** Regions in human brain activated by attention and regions associated with neglect. (A) Visual stimulation did not activate the frontal or parietal cortex reliably when attention was directed elsewhere in the visual field. (B) When the subject directed attention to a peripheral target location and performed an object discrimination task, a distributed fronto-parietal network was activated, including the SEF, the FEF, and the SPL. (C) The same network of frontal and parietal areas was activated when the subject directed attention to the peripheral target location in the expectation of the stimulus onset—in the absence of any visual input whatsoever. This activity therefore may not reflect attentional modulation of visually evoked responses, but rather attentional control operations themselves. (D) Meta-analysis of studies investigating the spatial attention network. Axial slices at different Talairach planes are indicated. Talairach (peak) coordinates of activated areas in the parietal and frontal cortex from several studies are indicated (for references, see Kastner and Ungerleider, 2000). R, right hemisphere; L, left hemisphere.

**FIGURE 48.7** Directed attention in humans with and without visual stimulation. (A) Time series of fMRI signals in V4. Directing attention to a peripheral target location in the absence of visual stimulation led to an increase of baseline activity (textured blocks), which was followed by a further increase after the onset of stimuli (gray-shaded blocks). Baseline increases were found in both the striate and the extrastriate visual cortex. (B) Time series of fMRI signals in FEF. Directing attention to the peripheral target location in the absence of visual stimulation led to a stronger increase in baseline activity than in the visual cortex; the further increase of activity after the onset of stimuli was not significant. Sustained activity was seen in a distributed network of areas outside the visual cortex, including SPL, FEF, and SEF, suggesting that these areas may provide the source for the attentional top-down signals seen in visual cortex. Adapted from Kastner *et al.* (1999).

indicating a general domain-independent mechanism of attentional control (Yantis and Serences, 2003).

### ATTENTION AFFECTS NEURAL ACTIVITY IN THE HUMAN VISUAL CORTEX IN THE PRESENCE AND ABSENCE OF VISUAL STIMULATION

Frontal and parietal areas have been associated with the control of spatial attention, but they are not usually considered crucial for visual processing or object recognition. There is converging evidence from event-related potential (ERP) and functional imaging studies that feedback signals from the fronto-parietal areas that control the allocation of attention can affect the neural processing of visual information in the human visual cortex. In a typical experiment, identical visual stimuli are presented simultaneously to corresponding peripheral field locations to the right and to the left of a central fixation point. Subjects are instructed to direct attention covertly to the right or the left by a symbolic cue presented at the fixation point and to detect the occurrence of a visual stimulus or, in some cases, discriminate a feature of the attended stimulus. Directing attention to the left hemifield increases stimulus-evoked activity in the extrastriate visual cortex of

the right hemisphere, whereas directing attention to the right hemifield increases activity in the extrastriate visual cortex of the left hemisphere (Heinze *et al.*, 1994) (Fig. 48.8). Thus, responses to stimuli are enhanced on the side of the extrastriate cortex that contains representations of the attended hemifield. As is the case in the fronto-parietal areas, this increase in response is observed during the period prior to appearance of a stimulus, reflecting the effects of feedback signals from the attentional control areas.

In one imaging study (Kastner *et al.*, 1999), subjects were cued to direct attention covertly to a target location in the periphery of the visual field and to anticipate the onset of visual stimuli. Visual stimuli occurred with a delay of several seconds. Neural activity associated with spatially directed attention in the absence and in the presence of visual stimulation could therefore be distinguished. As was the case in the fronto-parietal control network, fMRI signals increased when attention was directed to the target location and before any visual stimulus was present on the screen. This increase in baseline activity was followed by an additional increase when stimuli appeared at the attended location (Fig. 48.7A), reflecting attention-dependent increases in the stimulus evoked response itself. These studies and related single-unit studies in the monkey show that spatial attention effects are topographically organized and retinotopically specific, resulting in increased

**FIGURE 48.8** Attentional modulation of event related potentials (ERPs). In a typical experiment, subjects fixate a central cross and attend either to the left or right visual field. Stimuli are then presented to the left and right visual fields in a rapid sequence. This idealized example illustrated the common finding that the average ERP elicited by an attended visual field stimulus contains larger P1 and N1 components.

activity among neurons coding the attended location. Taken together, these findings suggest that spatial attention modulates visual processing by amplifying the neural signals for stimuli at an attended location.

Earlier we noted that the attentional control network is activated during nonspatial attention. Functional brain imaging studies and single-unit recording studies in nonhuman primates have found evidence that nonspatial attention also modulates sensory cortices. One such study found that selective attention to shape, color, or speed enhanced activity in the regions of the extrastriate visual cortex that selectively process these same attributes. Attention to shape and color led to response enhancement in regions of the posterior portion of the fusiform gyrus, including area V4. Attention to speed led to response enhancement in areas MT/MST (Corbetta *et al.*, 1991). In other studies, attention to faces or houses led to response enhancement in areas of the midanterior portion of the fusiform gyrus, areas responsive to the processing of faces and objects. Taken together, these results support the idea that selective attention to a particular stimulus attribute modulates neural activity in those extrastriate areas that preferentially process the selected attribute.

### **ATTENTION INCREASES SENSITIVITY AND BOOSTS THE CLARITY OF SIGNALS GENERATED BY NEURONS IN PARTS OF THE VISUAL SYSTEM DEVOTED TO PROCESSING INFORMATION ABOUT OBJECTS**

Consistent with the previously mentioned functional imaging studies, single-unit recording studies in the visual cortices have found that when attention is

directed to a single stimulus in the receptive field, there is often an increase in the firing rates of neurons that respond to the attended stimulus (Reynolds and Chelazzi, 2004). How could such a change in firing rate improve an observer's ability to identify properties of stimuli that appear at an attended location? A likely answer is that by increasing neuronal responses, attention enables neurons to send signals that better differentiate between stimuli with different physical characteristics (McAdams and Maunsell, 1999). Why would an increase in firing rate enable the neuron to more reliably signal the identity of the attended stimulus? The reason is that neuronal signals are noisy. Consider a neuron that responds poorly to a grating oriented 45° from vertical, and responds strongly to a 90° grating. Response variability will likely cause some presentations of the poorer 45° orientation stimulus to elicit responses that are higher than responses observed on some presentations of the 90° orientation stimulus. This is illustrated in Figure 48.9, which shows the distribution of responses of a hypothetical neuron, elicited by two different stimuli. The two curves in the upper part of Figure 48.9 indicate the distributions of responses elicited by the two stimuli, without attention. Although the distributions are not identical, they overlap a great deal. Responses within this area of overlap cannot be uniquely associated with either stimulus. The lower part of Figure 48.9 illustrates the effect of attention: to shift response distributions of both stimuli to the right. This shift is larger for the 90° orientation stimulus, and so with attention, the two distributions overlap less. As a result, the neuron can more reliably signal which of the two stimuli is present.

Microstimulation studies support the conclusion that attention-dependent changes in firing rate within the visual cortices result from feedback signals that are

Attention-dependent increases in firing rate improve the quality of visual information

**FIGURE 48.9** Attention-dependent increases in firing rate can improve the ability of a neuron to signal stimulus properties. Response distributions of a hypothetical neuron to a 45 and 90° oriented grating. With attention directed away from the receptive field (top), there is substantial overlap between the distributions; consequently, the response on a given trial does not reliably indicate which stimulus is present. Attention boosts responses elicited by the preferred stimulus by more than it boosts responses to the poor stimulus, reducing the ambiguity in the signal.

generated in the fronto-parietal attentional control network. Moore and Armstrong (2003) measured the locations in FEF where stimulating current would move the eyes, the “movement field” of the stimulation site. They then reduced the stimulating current to a level too low to evoke an eye movement, and observed the effect of this stimulation on the responses of neurons in visual area V4. They found that FEF stimulation caused V4 neurons to respond more robustly to a stimulus that appeared at the movement field within the V4 neuron’s receptive field (Fig. 48.10A). Figure 48.10B shows responses of a single V4 neuron with and without stimulation. The time course of stimulus presentation (RF stim) and current injection (FEF stim) are illustrated at the top of the panel. The neuronal responses in the two conditions are indicated at the bottom of the figure. Stimulation was injected 500 ms after the appearance of the stimulus, at which point the stimulus-evoked response had begun to diminish in strength. The average response on microstimulation trials (gray) was elevated following electrical stimulation, relative to nonstimulation trials.

### ATTENTION MODULATES NEURAL RESPONSES IN THE HUMAN LATERAL GENICULATE NUCLEUS

The lateral geniculate nucleus (LGN) is the thalamic station in the retinocortical projection and traditionally has been viewed as the gateway to the visual cortex. In addition to retinal afferents, the LGN receives input from multiple sources including striate cortex, the thalamic reticular nucleus (TRN), and the brain stem. The LGN therefore represents the first stage in the visual pathway at which cortical top-down feedback signals could affect information processing.

It has proven difficult to study attentional response modulation in the LGN using single-cell physiology due to the small RF sizes of LGN neurons and the possible confound of small eye movements. Several single-cell physiology studies have failed to demonstrate attentional modulation in the LGN, supporting a notion that selective attention affects neural processing only at the cortical level. This notion was recently revisited using fMRI in humans (O’Connor *et al.*, 2002).

**FIGURE 48.10** Electrical stimulation of FEF increases neuronal responsiveness in V4. (A) Current was injected into FEF while neuronal activity was recorded from V4. (B) The visual stimulus appeared in the receptive field for one second (RF stim). 500 ms after the onset of the visual stimulus, a low level of current was applied to a site in FEF for 50 ms (FEF stim). The response of a single V4 neuron with (gray) and without (black) FEF microstimulation appears below. The apparent gap in response reflects the brief period during which V4 recording was paused while current was injected into FEF, when, for technical reasons, the stimulating current interfered with the ability to record action potentials. Following stimulation, the V4 neuron had elevated responses on trials when FEF was electrically stimulated, as compared to trials without FEF stimulation.

As in visual cortex, different modulatory effects of attention were found. Neural responses to attended visual stimuli were enhanced relative to the same stimuli when unattended. As in cortex, this effect of attentional response enhancement was shown to be spatially specific in the LGN. And directing attention to a location in the absence of visual stimulation and in anticipation of the stimulus onset increased neural baseline activity. Together, these studies indicate that the LGN appears to be the first stage in the processing of visual information that is modulated by attentional top-down signals.

These studies were suited to compare the magnitude of the attention effects across the visual system. The magnitude of all attention effects increased from early to more advanced processing levels along both the ventral and dorsal pathways of visual cortex. This is consistent with the idea that attention operates through top-down signals that are transmitted via

cortico-cortical feedback connections in a hierarchical fashion. This idea is supported by single-cell recording studies, which have shown that attention effects in area TE of inferior temporal cortex have a latency of approximately 150 ms, whereas attention effects in V1 have a longer latency of approximately 230 ms. According to this account, one would predict smaller attention effects in the LGN than in striate cortex. Surprisingly, it was found that all attention effects tended to be larger in the LGN than in striate cortex. This finding suggests that attentional response modulation in the LGN is unlikely to be due solely to corticothalamic feedback from striate cortex, but may be further influenced by additional sources of input. In addition to corticothalamic feedback projections from V1, which comprise about 30% of its modulatory input, the LGN receives another 30% of modulatory inputs each from the TRN and the parabrachial nucleus of the brain stem. Given its afferent input the LGN may be in an ideal strategic position to serve as an early gatekeeper in attentional gain control.

### **THE VISUAL SEARCH PARADIGM HAS BEEN USED TO STUDY THE ROLE OF ATTENTION IN SELECTING RELEVANT STIMULI FROM WITHIN A CLUTTERED VISUAL ENVIRONMENT**

So far this chapter has considered the situation when attention is cued to a location (or a feature) in the visual field. However, one is rarely told in advance to attend to a particular location. Normally, one needs to find a particular object in a complex world that is composed of a large number of stimuli. Psychologists have used a visual search paradigm to understand how attention selects behaviorally relevant stimuli out of a group of other stimuli.

In a typical task, observers are asked to search among an array of stimuli and indicate whether a particular target is present in the array. This task is easier under some conditions than others. For example, it is easy to determine whether a horizontal green bar is present in Figure 48.11A. It takes longer to make this judgment for stimuli in Figure 48.11B. Treisman and Gelade (1980) found that searches for a target with a unique feature, like the one illustrated in Figure 48.11A, can be completed quickly regardless of the number of elements in the search array—the target seems to “pop out” of the search array. Such searches often are referred to as efficient. In contrast, Treisman and Gelade (1980) found that the amount of time required to find a target that is defined by conjunctions of

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 48.11** Efficient and inefficient visual searches. (A) Pop-out search. The horizontal green bar differs from all other array elements in a single feature, color. As a result, it pops out immediately, regardless of how many elements are in the array. (B) The same target is difficult to find when it is embedded among elements that cannot be differentiated from it on the basis of a single feature (color or orientation). (C) The dark target pops out among squares and circles. (D) When the same target is perceived to be a square occluded behind a circle, it is difficult to find among squares and circles. Because this arrangement of the array interferes with visual search, this suggests that integration of objects into wholes occurs prior to the activation of attentional mechanisms used in visual search. Thus, these mechanisms are evidently not necessary for completion. Adapted from Rensink and Enns (1998).

elementary features (e.g., a horizontal green among horizontal reds and vertical greens, as in Fig. 48.11B) increases linearly with the number of elements in the array. Such searches often are referred to as inefficient. The amount of time added per item depends on stimulus conditions, but a rule of thumb is that each addi-

tional item in the array adds about 50 ms to the amount of time taken to locate the target. The fact that it takes time to locate the target in Figure 48.11B implies that the visual system is limited in capacity. If it were not, the target could be identified immediately by evaluating every element in the array simultaneously.

## WHERE IS THE COMPUTATIONAL BOTTLENECK AS REVEALED BY SEARCH TASKS?

Considerable debate exists regarding the locus and nature of the computational bottleneck that causes the capacity limitations that are revealed by visual search tasks. One influential theory, feature integration theory (FIT, Treisman and Gelade, 1980), proposes that capacity limitations occur at very early stages of cortical processing where “elementary” features are bound into coherent objects. This theory proposes that in the “pop-out” case, where the target differs from distracters in a single elemental feature, a search can be completed efficiently because there is no need to bind together different elementary features. Thus, a green target among red distracters (Fig. 48.11A) can be found in parallel by V1 neurons that respond to green but not red stimuli, without the need for visual attention. However, in a conjunction search, where each of the elementary target features (color and orientation) is shared with distracters, the observer must bind elementary features into coherent object representations before search can occur. According to this account, one cannot process multiple objects simultaneously because in order to avoid misconjoining features from different objects, attention selects features from one location at a time. Consistent with this idea, patient RM, who suffered damage to his parietal attentional control system, often misconjoins the shape and color of letters, even after viewing them for up to 10 seconds; that is, he mixes up which letters are presented in which colors.

However, the idea that limited capacity occurs at early stages of processing has been challenged. For example, some studies suggest that parts of objects are integrated into wholes prior to the application of attention. Consider the task of searching for the oddly shaped object appearing at the bottom of Figure 48.11 (adapted from Rensink and Enns, 1998). This odd shape pops out from among the squares and circles in Figure 48.11C, but it is harder to find the same shape in Figure 48.11D. The difference is that in Figure 48.11D, the oddly shaped part appears to be a square that is occluded by a superimposed circle; that is, the visual system completes the shape of the occluded square, hiding it among the other squares. Because this completion stops the square from popping out, the completion operation must occur prior to visual search.

Further evidence that features can be integrated preattentively into objects comes from the finding that when an observer attends to one feature of an object

(e.g., its orientation), other features of the object are selected automatically as well. In a now classic study, Duncan (1984) found that observers could easily make simultaneous judgments about two features of the same object (e.g., its orientation and whether or not it contained a gap). Making the second judgment did not interfere with the first judgment. However, observers were severely impaired when they simultaneously judged the same two features, one on each of two different stimuli. This finding suggests that when attention is directed to one feature of an object, all the features that make up the object can automatically be selected together because the features are already linked together into objects. These sorts of observations suggest that limited capacity results from information processing bottlenecks that occur relatively late in processing, after features are already integrated into wholes. One possibility is that the bottleneck occurs when objects enter a limited capacity working memory. Under this view, attention plays the role of selecting which objects pass through the bottleneck.

These two perspectives are not mutually exclusive. Some feature integration may occur preattentively (e.g., Rensink and Enns, 1998), but other types of stimulus integration might require spatial selection. As described earlier, attention has been found to modulate neural activity at all stages of visual processing including early stages (Motter, 1993; O'Connor *et al.*, 2002), where neuronal responses first show signs of grouping the features and parts of objects into wholes, as well as late stages, which are likely involved in selecting stimuli for storage in working memory. Thus, both early and late stages of processing may act as limited capacity bottlenecks.

## NEURONAL RECEPTIVE FIELDS ARE A POSSIBLE NEURAL CORRELATE OF LIMITED CAPACITY

Extracellular recording studies of attention in awake, behaving monkeys have revealed that the receptive fields of individual neurons might contribute to the limitation in visual capacity. As visual information traverses the successive cortical areas of the ventral stream that underlie object recognition (Ungerleider and Mishkin, 1982), the sizes of receptive fields increase from less than a degree of visual arc in primary visual cortex (area V1) to about 20° of visual arc in area TE, the last purely visual area in the ventral visual processing stream (Chapter 46). Similar increases in receptive field size are observed in the dorsal visual processing stream. In a typical scene, such large receptive fields

will contain many different objects. Therefore, a likely explanation for why one cannot process many different objects in a scene simultaneously is that neurons, whose signals are limited in bandwidth, cannot simultaneously send signals about all the stimuli inside their receptive fields. This idea implies that processing limitations exist at all levels of processing but that they become more pronounced in higher order visual areas, where receptive field sizes are larger. How then do neurons transmit signals about behaviorally relevant stimuli in their receptive fields?

One proposal is that the selective processing of behaviorally relevant stimuli is accomplished by two interacting mechanisms: competition among potentially relevant stimuli and biases that determine the outcome of this competition. For example, when an observer is asked to detect the appearance of a target at a particular location, this task is thought to activate spatially selective feedback signals in cortical areas, such as parts of the parietal and frontal cortex discussed earlier. These cortical areas provide a task-appropriate spatial reference frame and transmit signals to the extrastriate cortex, where they bias competition in favor of stimuli that appear at the attended location. Similarly, when an observer searches for an object in a cluttered scene, feature-selective feedback is thought to bias competition in favor of stimuli that share features in common with the searched-for object. When competition is resolved, the winning stimulus controls neuronal responses, and other stimuli are effectively filtered out of the visual stream.

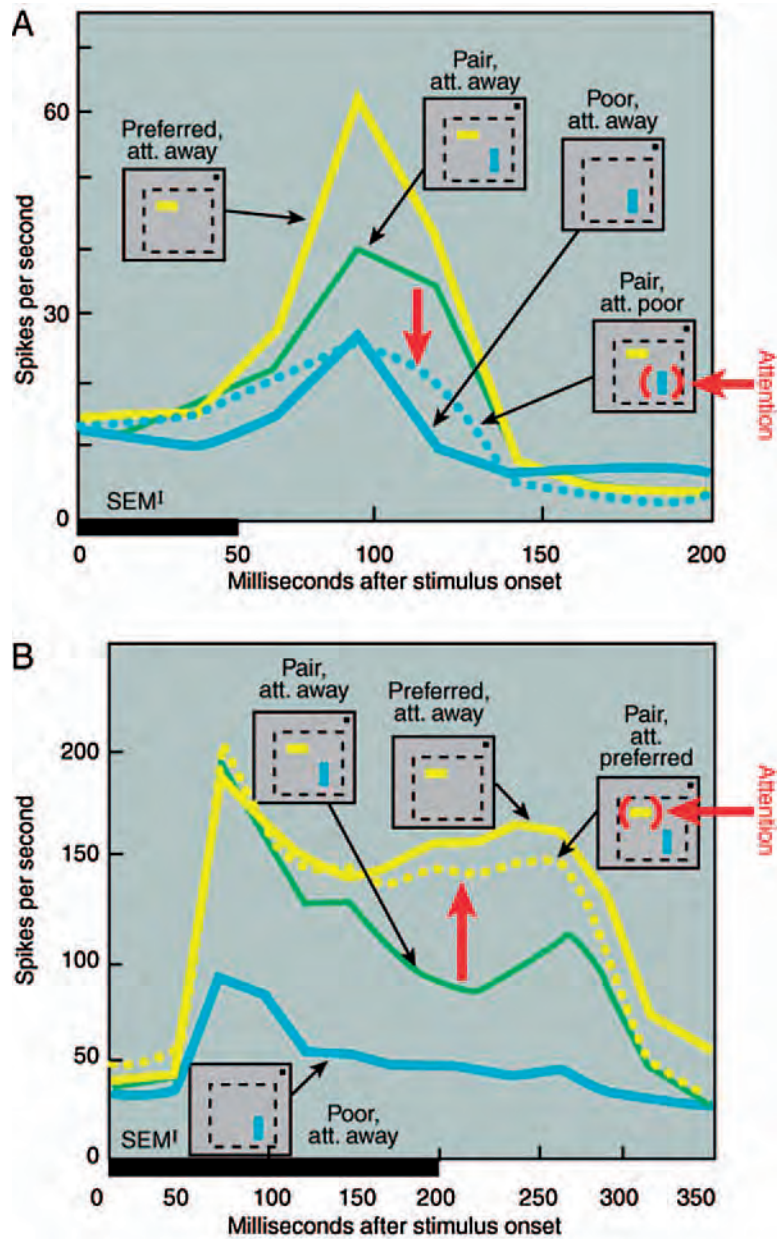

Studies in monkeys have compared the effect of attention on neuronal responses with single and multiple stimuli in the receptive field. Consistent with the proposal just outlined, larger changes in firing rate occur when multiple stimuli appear within the receptive field (and one stimulus must be attended), as compared to when the attended stimulus appears alone and there is no competition to be resolved (Moran and Desimone, 1985). According to the biased competition model just described, neurons that respond to a stimulus should be suppressed when a second stimulus is added that activates a competing population of neurons. To test this idea, pairs of stimuli were presented that activated two nearby populations of neurons (Reynolds *et al.*, 1999). Monkeys attended away from the receptive fields of the neurons. The first stimulus was chosen to be of a color and orientation that would strongly activate the recorded neuron. Then, a second stimulus, which elicited a response in a nearby population of neurons, was added. As predicted, the addition of this second stimulus partially suppressed the responses of many neurons to the first stimulus. To test whether attentional feedback would

resolve competition in favor of the neurons that responded to the attended stimulus, attention was then directed to the poor stimulus. As predicted, this often magnified the suppressive influence of the poor stimulus, further reducing the firing rates of many neurons (Fig. 48.12A). In a final experiment, attention was directed to the preferred stimulus. Consistent with the resolution of competition in favor of the neurons that responded to the preferred stimulus, directing attention to the preferred stimulus strongly reduced the suppressive effect of the poor stimulus (Fig. 48.12B).

Similar results have been reported in the dorsal stream of visual processing (Recanzone and Wurtz, 2000; Treue and Maunsell, 1999). Thus, when multiple stimuli appear together within the receptive fields of neurons in the later stages of the ventral visual processing stream and in motion-sensitive areas MT and MST of the dorsal stream, the neuronal response is driven preferentially by the attended stimulus. In this way, attention helps determine which stimuli are selected for processing in these areas.

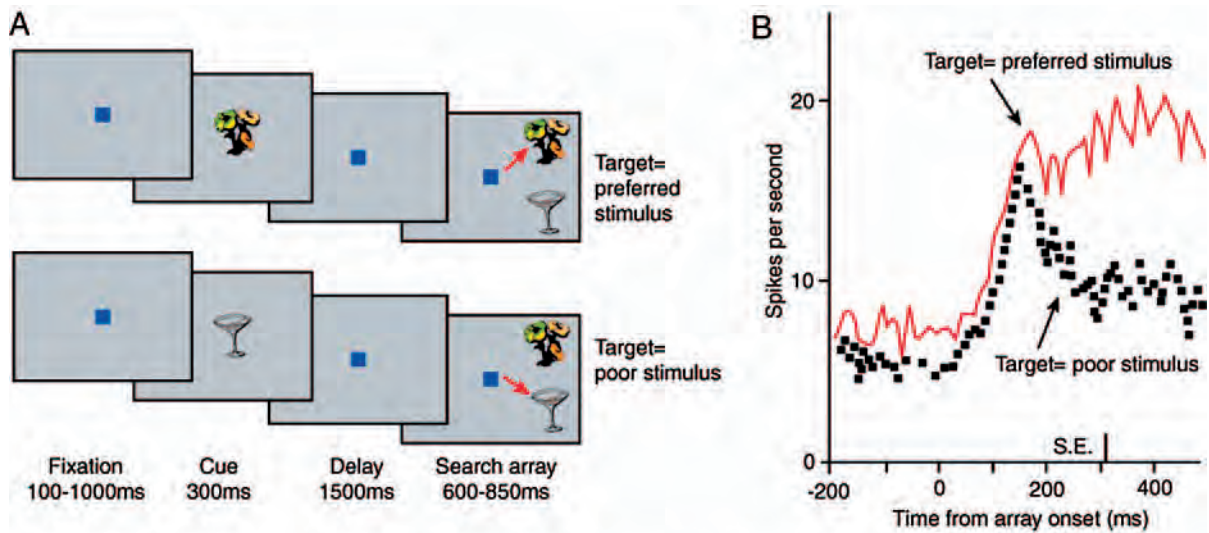

### COMPETITION CAN BE BIASED BY NONSPATIAL FEEDBACK

The findings just summarized support the proposal that competitive neural circuits can be biased by spatially selective feedback signals. As illustrated in Figure 48.13, feature-selective feedback can also bias competition. Responses of neurons in area TE were recorded as monkeys searched for a target (Chelazzi *et al.*, 1998). On each trial, the monkey viewed a cue stimulus that appeared at the fixation point. After a delay, an array of stimuli (the search array) appeared within the receptive fields of neurons in area TE. The monkey's task was to indicate whether a target matching the cue stimulus was present in the array, by making a saccade to the target. Locations of the stimuli were selected at random so that the monkey could not know where the target would appear, if it appeared at all. During the delay period, many TE neurons had a higher baseline firing rate when the cue stimulus was a preferred stimulus for the cell than when it was a poor stimulus; that is, neurons that were tuned to respond to the target were activated while the monkey prepared to search for the target. An interesting possibility is that this activation might bias the visual system toward detecting the target object, just as spatially specific feedback is thought to bias the system toward a particular location. Consistent with this, within 150 to 200 ms after the search array appeared, the response of the neuron

**FIGURE 48.12** Attention to one stimulus of a pair filters out the effect of the ignored stimulus. (A) The x-axis shows time (in milliseconds) from stimulus onset, and the thick horizontal bar indicates stimulus duration. Small iconic figures illustrate sensory conditions. Within each icon, the dotted line indicates the receptive field, and the small dot represents the fixation point. The location of attention inside the receptive field is indicated in red. Attention was directed away from the receptive field in all but one condition. The preferred stimulus is indicated by a horizontal yellow bar and the poor stimulus by a vertical blue bar. In fact, the identity of both stimuli varied from cell to cell. The yellow line shows the response of a V2 neuron to the preferred stimulus. The solid blue line shows the response to the poor stimulus. The green line shows the response to the pair. The addition of the poor stimulus suppressed the response to the preferred stimulus. Attention to the poor stimulus (red arrow) magnified its suppressive effect and drove the response down to a level (dotted blue line) that was similar to the response elicited by the poor stimulus alone. (B) Response of a second V2 neuron. The format is the same as in A. As in the neuron above, the response to the preferred stimulus was suppressed by the addition of the poor stimulus. Attention directed to the preferred stimulus filtered out this suppression, returning the neuron to a response (dotted yellow line) similar to the response that was elicited when the preferred stimulus appeared alone inside the RF. Adapted from Reynolds *et al.* (1999).

**FIGURE 48.13** Responses of inferior temporal (IT) neurons during a memory-guided visual search. (A) Task. Monkeys fixated a spot on a computer screen and were shown a central cue (here, either the flower or the cup). After a delay, two (or more) stimuli appeared within the receptive field and the monkey had to saccade to the stimulus that had appeared earlier as the cue. Sometimes (top four images), the cue was a preferred stimulus for the cell (the flower) and the monkey had to saccade to the preferred stimulus. On separate trials (lower four images), the cue was a poor stimulus (the cup) and the monkey had to saccade to the poor stimulus. (B) Neuronal responses. During the delay period, IT neurons showed an elevated baseline activity that reflected the cue stored in memory. The spontaneous firing rate was higher on trials in which the cue was a preferred stimulus for the cell, relative to trials when the cue was a poor stimulus. After the search array appeared, the responses separated, increasing or decreasing depending on whether the cue was, respectively, a preferred or poor stimulus for the cell. This separation occurred well before the onset of the saccade, which is indicated by the vertical bar on the horizontal axis.

increased or decreased, depending on whether the target was, respectively, a preferred or a poor stimulus for the cell. That is, shortly after the appearance of the search array, the activity of the cell reflected the identity of the target stimulus and was no longer influenced by the nontarget stimulus, even though the nontarget stimulus was still present physically within its receptive field.

### FILTERING OF UNWANTED INFORMATION IN HUMANS

Functional brain imaging studies suggest that in the human visual cortex, just as in the monkey cortex, mechanisms exist such that multiple stimuli compete for neural representation and unwanted information can be filtered out (Kastner *et al.*, 1998, 2001). In one fMRI study, subjects maintained fixation while they were presented with colorful visual stimuli in four nearby locations in the periphery of the visual field (Kastner *et al.*, 1998). Stimuli were presented under two different conditions. In a sequential condition, a single stimulus appeared in one of the four peripheral

locations, then another appeared in a different location, and so on, until each of the four stimuli had been presented in the four different locations. In a simultaneous condition, the same four stimuli appeared in the same four locations, but they were presented at the same time. Thus, physical stimuli were identical in the two conditions except that in the second case, all four stimuli appeared simultaneously, which should encourage competitive interactions among the stimuli. The subjects' task was to count letters at fixation, thereby ignoring the peripheral stimulus presentations. Activation of V1 and ventral stream extrastriate areas V2 to TEO was found under both presentation conditions. Although the fMRI signal was similar in the two presentation conditions in V1, activation was reduced in the simultaneous condition compared to the sequential condition in V2. This reduction in activity was especially pronounced in V4 and TEO. The most straightforward interpretation of this result is that simultaneously presented stimuli interacted in a mutually suppressive way. This sensory suppression effect may be a neural correlate of competition in the human visual cortex. Importantly, the suppression effects appeared to be scaled to the receptive field size of neurons within visual cortical areas; that is, the

effects were larger in areas with larger receptive fields. This observation suggests that, as in the monkey visual cortex, competitive interactions occur most strongly at the level of the receptive field (Kastner *et al.*, 1998).

The effects of spatially directed attention on multiple, competing visual stimuli have been studied in a variation of the same paradigm (Kastner *et al.*, 1998). In addition to the two different visual presentation conditions, sequential and simultaneous, two different attentional conditions were tested, unattended and attended. During the unattended condition, attention was directed away from the visual display by having subjects count the occurrences of letters at the fixation point. In the attended condition, subjects were instructed to attend covertly to the stimulus location that was closest to the fixation point and to count the occurrences of one of the four stimuli. The attended condition led to greater increases in fMRI signals to simultaneously presented stimuli than to sequentially presented stimuli. Thus, in this case, attention partially cancelled out the suppressive interactions among competing stimuli. The magnitude of the attentional effect was greater where the suppressive interactions among stimuli had been strongest, such that the strongest reduction of suppression occurred in areas V4 and TEO. These findings support the idea that directed attention enhances information processing of stimuli at attended locations by counteracting the suppression induced by nearby stimuli that are competing for limited processing resources. In this way, unwanted distracting information is filtered out effectively.

Unwanted information can not only be filtered out effectively by top-down mechanisms that resolve competitive interactions among multiple objects, but also by bottom-up mechanisms that are defined by the context of the stimuli. As we have seen earlier, if a salient stimulus is present in a cluttered scene, it will be effortlessly and quickly detected regardless of the number of distracters, suggesting that competition is biased in favor of the salient stimulus. Bottom-up influences related to stimulus context of a visual display, in which a single, salient stimulus pops out from a homogeneous background were examined using the same design of sequentially and simultaneously presented stimuli described earlier (Beck and Kastner, 2005). The pop-out display condition, in which a single item differed from the others, was compared to a heterogeneous display, in which all four stimuli were different. Subjects were engaged in a difficult letter detection task at fixation and never attended to the pop-out or heterogeneous displays that were shown in the periphery of the visual field. Competitive

interactions among multiple stimuli were eliminated in area V4 when the stimuli were presented in the context of pop-out displays relative to heterogeneous displays, indicating that competition was biased in favor of the salient stimulus in a bottom-up stimulus context-dependent fashion. These pop-out effects appeared to originate from area V1, where the strongest responses to pop-out displays were found. The effects of pop-out on competitive interactions among multiple stimuli appeared to operate in an automatic fashion, thus independently of attentional top-down control. Taken together, the studies reviewed in this section indicate that both top-down attention and bottom-up stimulus-driven mechanisms are critical in resolving competitive interactions among multiple stimuli at intermediate processing levels of visual cortex, thereby filtering out unwanted information from cluttered visual scenes.

---

## CONCLUSIONS

---

“Everyone knows what attention is. It is the taking possession of the mind in clear and vivid form of one out of what seem several simultaneous objects or trains of thought.” Thus did William James define the elusive entity commonly known as “attention.” A century later, experimental neuroscience and cognitive psychology afford a closer look at the neural mechanisms enabling this “taking possession” to occur.

The behavioral manifestations of attention are clearly not the result of operations in any one dedicated neural center. Selective attention affects neural activity at all levels of the visual system and other sensory systems, with the possible exception of neurons in the sensory periphery. A few structures located at the top of the visual system hierarchy in the parietal, frontal, and cingulate cortices are thought to be relatively more specialized for generating the signals that guide selective attention, and these are among the areas that are thought to provide feedback signals that influence sensory processing in areas that are specialized for analyzing the physical properties of the sensory environment.

Answers are beginning to be available to the question of why attention is necessary in the first place. A possible computational bottleneck may be built into all levels of the visual system in the form of spatial receptive fields. The fact that several objects within a certain spatial region can activate the same neuron reduces the ability of such neurons to transmit accurate information about each one of these objects. Mechanisms therefore are required to shrink the functional recep-

tive field around the object(s) that needs greater scrutiny in a particular situation. Other bottlenecks will doubtlessly be revealed in future research.

# Learning and Memory: Basic Mechanisms

Significant advances have been made in understanding the ways in which the nervous system encodes and retrieves information. One focus of current research is on the understanding of learning and memory at the cellular level, where the information-encoding process can be traced to changes in neuronal properties such as membrane excitability and synaptic strength. One emerging principle is that no single universal mechanism for learning and memory exists. Instead, different memory systems (Chapter 50) can use different mechanisms. Therefore, a comprehensive understanding of memory mechanisms requires an understanding of the general ways in which neurons are changed by learning and the ways in which those changes are maintained and expressed at the cellular level.

Research during the past several decades on several vertebrate and invertebrate model systems has led to the development of several general principles. A list of these principles (Byrne, 1987) might include the following:

1. Multiple memory systems are present in the brain (Chapter 50).
2. Short-term and long-term forms of learning and memory involve changes in existing neural circuits.
3. These changes may involve multiple cellular mechanisms within individual neurons.
4. Second-messenger systems play a role in mediating cellular changes.
5. Changes in membrane channels often are correlated with learning and memory.
6. Long-term memory requires new protein synthesis, whereas short-term memory does not.

This chapter describes several of the types of neural and molecular mechanisms implicated in learning

and memory. The chapter first considers some of the paradigms that have been used to study simple forms of nonassociative and associative learning and provides an example of mechanistic analyses that have been performed in a selected invertebrate model system. The later sections of the chapter describe the mechanisms of two phenomena, which are known as long-term potentiation (LTP) and long-term depression (LTD). Both LTP and LTD occur in forebrain structures, and LTP and LTD are thought to be mechanisms for memory storage in the central nervous system.

## PARADIGMS HAVE BEEN DEVELOPED TO STUDY ASSOCIATIVE AND NONASSOCIATIVE LEARNING

### Associative Learning

Associative learning is a broad category that includes many of our daily learning activities that involve formation of associations among stimuli and/or responses. It usually is subdivided into classical conditioning and instrumental conditioning. Classical (or Pavlovian) conditioning is induced by a procedure in which a generally neutral stimulus, termed a *conditioned stimulus* (CS), is paired with a stimulus that generally elicits a response, termed an *unconditioned stimulus* (US). Two examples of unconditioned stimuli are food, which elicits salivation, or a shock to the foot, which elicits limb withdrawal. Instrumental (or operant) conditioning is a process by which an organism learns to associate consequences with its own behavior. In an operant conditioning paradigm, the delivery of a reinforcing stimulus is contingent upon the

expression of a designated behavior. The probability that this behavior will be expressed is then altered. This chapter focuses on classical conditioning, as it is mechanistically the best understood type of associative conditioning.

An astute observation by Ivan Pavlov, a Russian physiologist who had been studying digestion in dogs, led to his discovery of classical conditioning. He first noticed that the mere sight of the food dish caused dogs to salivate. He continued the experiments to see if dogs would also salivate in response to a bell rung at feeding time. Pavlov trained dogs to stand in a harness and, after the sound of a bell, fed them meat powder (Fig. 49.1). At first, the bell by itself did not elicit any response, but the meat powder elicited reflex salivation, which was termed the *unconditioned response* (UR). He noted that after a few pairings of the bell and meat powder the dogs began to salivate when the bell rang, before they received the meat powder. This response is termed the *conditioned response* (CR). This type of conditioning came to be called reward or appetitive *classical conditioning*. If the bell or another stimulus was followed by an unpleasant event, such as an electric shock, then a variety of autonomic

responses became conditioned. This type of conditioning is termed aversive conditioning.

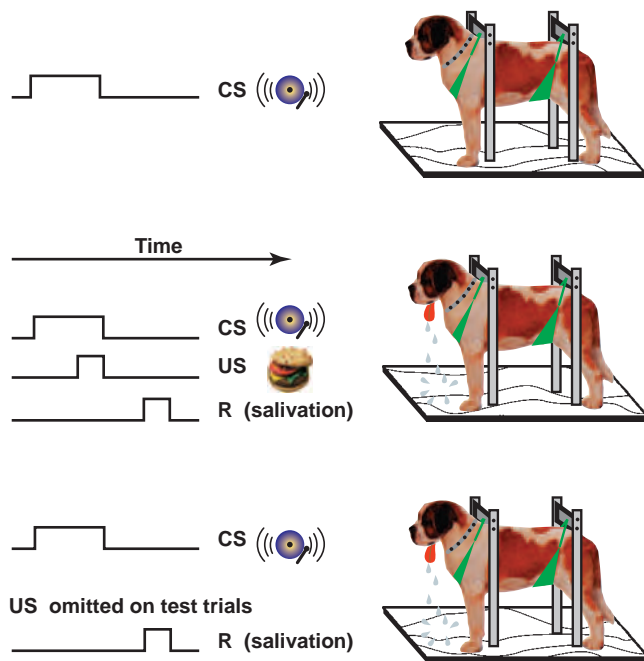

## Nonassociative Learning

Three examples of nonassociative learning have received the most experimental attention: habituation, dishabituation, and sensitization. *Habituation* is defined as a reduction in the response to a stimulus that is delivered repeatedly. *Dishabituation* refers to the restoration or recovery of a habituated response due to the presentation of another, typically strong, stimulus to the animal. *Sensitization* is an enhancement or augmentation of a response produced by the presentation of a strong stimulus. The following sections introduce the *Aplysia* and focus on the neural and molecular mechanisms of sensitization.

## INVERTEBRATE STUDIES: KEY INSIGHTS FROM APLYSIA INTO BASIC MECHANISMS OF LEARNING

Since the mid-1960s, the marine mollusk *Aplysia* has proven to be an extremely useful model system to gain insights into the neural and molecular mechanisms of simple forms of memory. Indeed, the pioneering discoveries of Eric Kandel using this animal were recognized by his receipt of the Nobel Prize in Physiology or Medicine in 2000. A number of characteristics make *Aplysia* well suited for the examination of the molecular, cellular, morphological, and network mechanisms underlying neuronal modifications (plasticity) and learning and memory. The animal has a relatively simple nervous system with large, individually identifiable neurons that are accessible for detailed anatomical, biophysical, biochemical, and molecular studies. Neurons and neural circuits that mediate many behaviors in *Aplysia* have been identified. In several cases, these behaviors have been shown to be modifiable by learning. Moreover, specific loci within neural circuits at which modifications occur during learning have been identified, and aspects of the cellular mechanisms underlying these modifications have been analyzed (Byrne *et al.*, 1993; Byrne and Kandel, 1996; Hawkins *et al.*, 1993).

A single sensitizing stimulus, such as a brief several second-duration electric shock, can produce a reflex enhancement that lasts minutes (short-term sensitization), whereas prolonged training (e.g., multiple stimuli over an hour or more) produces an enhancement that lasts from days to weeks (long-term sensitization).

**FIGURE 49.1** Classical conditioning. In the procedure introduced by Pavlov, the production of saliva is monitored continuously. Presentation of meat powder reliably leads to salivation, whereas some “neutral” stimulus such as a bell initially does not. With repeated pairings of the bell and meat powder, the animal learns that the bell predicts the food and salivates in response to the bell alone. Modified from Rachlin (1991).

## Multiple Cellular Processes Mediate Short- and Long-Term Sensitization in Aplysia

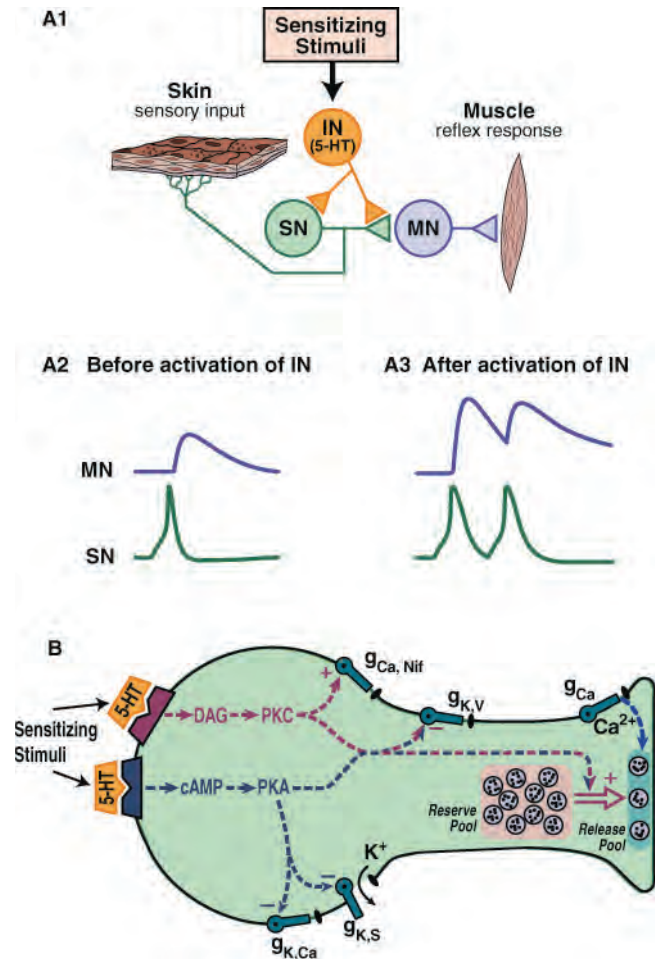

A discussion of memory mechanisms can be divided into three parts: induction, expression, and maintenance. *Induction* refers to the initial events that trigger or initiate the modification process; *expression* concerns how the modification process ultimately is expressed; and *maintenance* addresses the manner in which the modification is made to endure over time.

### Short-Term Sensitization

Short-term (minutes) sensitization is induced when a single brief train of shocks to the body wall results in the release of modulatory transmitters, such as serotonin (5-HT), from a separate class of interneurons (IN) referred to as facilitatory neurons (Fig. 49.2A1). These facilitatory neurons regulate the properties of the sensory neurons and the strength of their connections with postsynaptic interneurons and motor neurons (MN) through a process called *heterosynaptic facilitation* (Byrne and Kandel, 1996; Figs. 49.2A2 and 49.2A3). The molecular mechanisms contributing to short-term heterosynaptic facilitation are illustrated in Figure 49.2B. The first step is the binding of 5-HT to one class of receptors on the outer surface of the membrane of the sensory neurons. This leads to the activation of adenylyl cyclase, which in turn leads to an elevation of the intracellular level of the second messenger cyclic adenosine 3',5'-monophosphate [cyclic AMP (cAMP)] in sensory neurons. When cAMP binds to the regulatory subunit of cAMP-dependent protein kinase [protein kinase A (PKA)], the catalytic subunit is released and can now add phosphate groups to specific substrate proteins and therefore alter their functional properties.

One consequence of this protein phosphorylation is an alteration in the properties of membrane channels. Specifically, the increased levels of cAMP lead to a decrease in the serotonin-sensitive potassium current [ $S\text{-K}^+$  current ( $I_{K,S}$ )], a component of the calcium-activated  $K^+$  current ( $I_{K,Ca}$ ) and the delayed  $K^+$  current ( $I_{K,V}$ ). (See Chapter 6 for more information on these channel types.) These changes in membrane currents lead to depolarization of the membrane potential, enhanced excitability, and an increase in the duration of the action potential (i.e., spike broadening). Reflections of enhanced excitability include an increase in the number of action potentials elicited in a sensory neuron by a fixed extrinsic current injected into the cell or by a fixed stimulus to the skin (Fig. 49.2A3).

Cyclic AMP also appears to activate a facilitatory process that is independent of membrane potential and spike duration. This process is represented in

**FIGURE 49.2** Model of short-term heterosynaptic facilitation of the sensorimotor connection that contributes to short- and long-term sensitization in *Aplysia*. (A1) Sensitizing stimuli activate facilitatory interneurons (IN) that release modulatory transmitters, one of which is 5-HT. The modulator leads to an alteration of the properties of the sensory neuron (SN). (A2 and A3) An action potential in SN after the sensitizing stimulus results in greater transmitter release and hence a larger postsynaptic potential in the motor neuron (MN, A3) than an action potential before the sensitizing stimulus (A2). For short-term sensitization, the enhancement of transmitter release is due, at least in part, to broadening of the action potential and an enhanced flow of  $Ca^{2+}$  into the sensory neuron. (B) Model of a sensory neuron that depicts the multiple processes for short-term facilitation that contribute to short-term sensitization. 5-HT released from facilitatory neurons binds to at least two distinct classes of receptors on the outer surface of the membrane and leads to the transient activation of two intracellular second messengers, DAG and cAMP, and their respective kinases (PKC and PKA). These kinases affect multiple cellular processes, the combined effects of which lead to enhanced transmitter release when subsequent action potentials are fired in the sensory neuron (see text for additional details). Modified from Byrne and Kandel (1996).

Figure 49.2B (large open arrow) as the translocation or mobilization of transmitter vesicles from a reserve pool to a releasable pool. The translocation makes more transmitter-containing vesicles available for release with subsequent action potentials in the sensory neuron. The overall effect is a short-term, cAMP-dependent enhancement of transmitter release. One substrate for cAMP/PKA-dependent phosphorylation is synapsin (Angers *et al.*, 2002). Synapsin is a synaptic vesicle-associated protein that tethers synaptic vesicles to cytoskeletal elements and thus helps control the reserve pool of vesicles in synaptic terminals (Chapter 8). Phosphorylation of synapsin would allow vesicles in the reserve pool to migrate to the releasable pool and thus contribute to enhanced transmitter release.

Serotonin also acts through another class of receptors to increase the level of the second messenger diacylglycerol (DAG). DAG activates protein kinase C (PKC), which, like PKA, contributes to facilitation that is independent of spike duration (e.g., mobilization of vesicles). In addition, PKC regulates a nifedipine-sensitive  $\text{Ca}^{2+}$  channel ( $I_{\text{Ca,Nif}}$ ) and the delayed  $\text{K}^+$  channel ( $I_{\text{K,V}}$ ). Thus, the delayed  $\text{K}^+$  channel ( $I_{\text{K,V}}$ ) is dually regulated by PKC and PKA. The modulation of  $I_{\text{K,V}}$  contributes importantly to the increase in duration of the action potential (Fig. 49.2A3). Due to its small magnitude, the modulation of  $I_{\text{Ca,Nif}}$  appears to play a minor role in the facilitatory process.

Prolonged treatments of 5-HT (1.5h) also activates mitogen-activated protein kinase (MAPK) (Martin *et al.*, 1997). However, this pathway appears to be important only for the induction of longer-term processes (see later). Of general significance is the observation that a single modulatory transmitter (i.e., 5-HT) activates multiple kinase systems. The involvement of multiple second messenger systems in synaptic plasticity also appears to be a theme emerging from mammalian studies. For example, as discussed in a later section of the chapter, the induction of LTP in the CA1 area of the hippocampus appears to involve MAPK, PKC, calcium/calmodulin-dependent protein kinase (CaM kinase II), and tyrosine kinase (reviewed in Dineley *et al.*, 2001).

The consequences of activating these multiple second-messenger systems and modulating these various cellular processes are expressed when test stimuli elicit action potentials in the sensory neuron at various times after the presentation of the sensitizing stimuli (Fig. 49.2A3). More transmitter is available for release as a result of the mobilization process and each action potential is broader, allowing a larger influx of  $\text{Ca}^{2+}$  to trigger release of the available transmitter. The combined effects of mobilization and spike broaden-

ing lead to the facilitation of transmitter release from the sensory neuron and consequently a larger postsynaptic potential in the motor neuron. Larger postsynaptic potentials lead to enhanced activation of interneurons and motor neurons and thus to an enhanced behavioral response.

The maintenance of short-term sensitization is dependent on the persistence of the PKA- and PKC-induced phosphorylations of the various substrate proteins.

### Long-Term Sensitization

Sensitization also exists in a long-term form, which persists for at least 24h. Whereas short-term sensitization can be produced by a single brief stimulus, the induction of long-term sensitization requires a more extensive training period over an hour or more.

Both short- and long-term sensitization share some common cellular pathways during their *induction*. For example, both forms activate the cAMP/PKA cascade (Fig. 49.3). However, in the long-term form, unlike the short-term form, activation of the cAMP/PKA cascade induces gene transcription and new protein synthesis (Byrne *et al.*, 1993; Hawkins *et al.*, 1993). Repeated training leads to a translocation of PKA to the nucleus where it phosphorylates the transcriptional activator CREB1 (cAMP responsive element binding protein). CREB1 binds to a regulatory region of genes known as CRE (cAMP responsive element). Next, this bound and phosphorylated form of CREB1 leads to increased transcription. Serotonin, either by acting through cAMP or through activation of a tyrosine receptor kinase-like molecule (ApTrk) also leads to the activation of MAPK, which phosphorylates the transcriptional repressor CREB2. Phosphorylation of CREB2 by MAPK leads to a derepression of CREB2 and therefore promotes CREB1-mediated transcriptional activation (Bartsch *et al.*, 1995).

The role of transcription factors in long-term memory formation is not limited to the induction phase but may also extend to the consolidation phase, where consolidation is defined as the time window during which RNA and protein synthesis are required for converting short- to long-term memory. For example, treatment of ganglia with 5 pulses of 5-HT over a 1.5 h period to mimic sensitization training leads to the binding of CREB1 to the promoter of its own gene and induces CREB1 synthesis (Mohamed *et al.*, 2005). This observation agrees well with earlier findings that the requirement for gene expression is not limited to the induction phase. The necessity of prolonged transcription and translation for LTF observed at 24 h persists for at least 7-9 h after induction. These results suggest that CREB1 can regulate its own level of expression, giving rise to a

**FIGURE 49.3** Simplified scheme of the mechanisms in sensory neurons that contribute to long-term sensitization. Sensitization training leads to the release of 5-HT and the cAMP-dependent phosphorylation of CREB1. 5-HT, either by acting through cAMP or through activation of a tyrosine receptor kinase-like molecule (ApTrk), also leads to the activation of MAPK, which regulates the repressor CREB2. The combined effects of activation of CREB1 and derepression of CREB2 lead to regulation of the synthesis of at least 10 proteins, only 3 of which (ApTBL, ApCAM, and ApUch) are shown. Two of these proteins (ApTBL and ApUch) appear to be components of positive feedback cycles. ApTBL is believed to activate latent forms of TGF- $\beta$ , which can then bind to receptors on the sensory neuron. TGF- $\beta$  activates MAPK, which may act by initiating a second round of gene regulation by affecting CREB2-dependent pathways. Increased synthesis of ApUch leads to enhanced degradation of the regulatory subunit of PKA, leading to enhanced activation of the catalytic subunit and increased phosphorylation of CREB1. The third protein ApCAM is downregulated. Downregulation of ApCAM is involved in regulating growth processes associated with long-term facilitation.

CREB1 positive feedback loop that supports memory consolidation.

The combined effects of activation of CREB1 and derepression of CREB2 lead to changes in the synthesis of specific proteins. So far, more than 10 gene products that are regulated by sensitization training have been identified, and others are likely to be found in the future. These results indicate that there is not a single memory gene or protein, but that multiple genes are regulated, and they act in a coordinated way to alter neuronal properties and synaptic strength. The following section discusses three regulated proteins of particular significance.

The down-regulation of a homologue of a neuronal cell adhesion molecule (NCAM), ApCAM plays a key role in long-term facilitation. This down-regulation has two components. First, the synthesis of ApCAM is reduced. Second, preexisting ApCAM is internalized via increased endocytosis. The internalization and degradation of ApCAM allow for the restructuring of the axon arbor (Bailey *et al.*, 1992). The sensory neuron can now form additional connections with the same postsynaptic target or make new connections with other cells. Another protein whose synthesis is regulated by long-term facilitation is *Aplysia* tolloid/BMP-like protein (ApTBL-1). Tolloid and the related molecule BMP-1 appear to function as secreted Zn<sup>2+</sup> proteases. In some preparations, they activate members

of the transforming growth factor  $\beta$  (TGF- $\beta$ ) family. Indeed, in sensory neurons, TGF- $\beta$  mimics the effects of 5-HT in that it produces long-term increases in the synaptic strength of the sensory neurons (Zhang *et al.*, 1997). Interestingly, TGF- $\beta$  activates MAPK in the sensory neurons and induces its translocation to the nucleus. Thus, TGF- $\beta$  could be part of an *extracellular* positive feedback loop, possibly leading to another round of protein synthesis (Fig. 49.3) to further consolidate the memory (Zhang *et al.*, 1997). A third important protein, *Aplysia* ubiquitin hydrolase (ApUch), appears to be involved in an *intracellular* positive feedback loop. During the induction of long-term facilitation, ApUch levels in sensory neurons are increased, possibly via CREB phosphorylation and a consequent increase in *ApUch* transcription. The increased levels of ApUch increase the rate of degradation, via the ubiquitin-proteasome pathway, of proteins including the regulatory subunit of PKA (Chain *et al.*, 1999). The catalytic subunit of PKA, when freed from the regulatory subunit, is highly active. Thus, increased ApUch will lead to an increase in PKA activity and a more protracted phosphorylation of CREB1. This phosphorylated CREB may act to further prolong *ApUch* expression, thus closing a positive feedback loop.

One simplifying hypothesis is that the mechanisms underlying the *expression* of short- and long-term

sensitization are the same, but extended in time for long-term sensitization. Some evidence supports this hypothesis. For example, long-term sensitization, like short-term sensitization, is associated with an enhancement of sensorimotor connections. In addition,  $K^+$  currents and the excitability of sensory neurons are modified by long-term sensitization (Cleary *et al.*, 1998). However, the mechanisms underlying the *expression* of short- and long-term sensitization differ in four fundamental ways. First, long-term sensitization training leads to a *decrease* in the duration of the sensory neuron action potential (Antzoulatos and Byrne, 2007). Second, structural changes such as neurite outgrowth and active zone remodeling are associated with the expression of long-term but not with short-term sensitization (Bailey and Kandel, 1993). Interestingly, the structural changes take time to develop. Long-term synaptic facilitation measured one day after four days of training is associated with structural changes, whereas long-term facilitation measured one day after a single training session is not (Wainwright *et al.*, 2004). Third, long-term sensitization is associated with an increase in high-affinity glutamate uptake (Levenson *et al.*, 2000). A change in glutamate uptake could potentially exert a significant effect on synaptic efficacy by regulating the amount of transmitter available for release, the rate of clearance from the cleft, and thereby the duration of the EPSP and the degree of receptor desensitization. Finally, long-term sensitization has been correlated with changes in the postsynaptic cell (i.e., the motor neuron; Cleary *et al.*, 1998). Thus, as with other examples of memory, multiple sites of plasticity exist even within this simple reflex system.

### Other Temporal Domains for the Memory of Sensitization

Historically, memory has been divided into two temporal domains, short term and long term. It has become increasingly clear from studies of a number of memory systems that this distinction is overly simplistic. For example, in *Aplysia*, Carew and colleagues (Sutton *et al.*, 2001) and Kandel and colleagues (Ghirardi *et al.*, 1995) have discovered an intermediate phase of memory that has distinctive temporal characteristics and a unique molecular signature. The intermediate-phase memory for sensitization is expressed at times approximately 30 min to 3 h after the beginning of training. Like long-term sensitization, its induction requires protein synthesis, but unlike long-term memory it does not require mRNA synthesis. The expression of the intermediate-phase memory requires the persistent activation of PKA.

In addition to intermediate-phase memory, it is likely that *Aplysia* has different phases of long-term memory. For example, at 24 h after sensitization training there is increased synthesis of a number of proteins, some of which are different from those whose synthesis is increased during and immediately after training. These results suggest that the memory for sensitization that persists for times greater than 24 h may be dependent on the synthesis of proteins occurring at 24 h and may have a different molecular signature than the 24-h memory.

### Mechanisms Underlying Associative Learning of Withdrawal Reflexes in *Aplysia*

The withdrawal reflexes of *Aplysia* are subject to classical conditioning (Byrne *et al.*, 1993; Hawkins *et al.*, 1993). The short-term classical conditioning observed at the behavioral level reflects, at least in part, a cellular mechanism called *activity-dependent neuromodulation*. A diagram of the general scheme is presented in Figure 49.4. The US pathway is activated by a shock to the animal, which elicits a withdrawal response (the UR). When a CS is paired consistently with the US, the animal will develop a withdrawal response (CR) to the CS. Activity-dependent neuromodulation is proposed as the mechanism for this pairing-specific effect. The US activates both a motor neuron (UR) and a modulatory system. The modulatory system delivers the neurotransmitter serotonin to all the sensory neurons (parts of the various CS pathways), which leads to a nonspecific enhancement of transmitter release from the sensory neurons. This nonspecific enhancement contributes to short-term sensitization (see prior discussion). Sensory neurons whose activity is temporally contiguous with the US-mediated reinforcement are additionally modulated. Spiking in a sensory neuron during the presence of 5-HT leads to changes in that cell relative to other sensory neurons whose activity was not paired with the US. Thus, a subsequent CS will lead to an enhanced activation of the reflex (Fig. 49.4B). Figure 49.5 illustrates a more detailed model of the proposed cellular mechanisms responsible for this example of classical conditioning. The modulator (US) acts by increasing the activity of adenylyl cyclase (AC), which in turn increases the levels of cAMP. Spiking in the sensory neurons (CS) leads to increased levels of intracellular calcium, which greatly enhances the action of the modulator to increase the cAMP cascade. This system determines CS-US contiguity by a method of coincidence detection at the presynaptic terminal.

Now, consider the postsynaptic side of the synapse. The postsynaptic region contains NMDA-type

**FIGURE 49.4** Model of classical conditioning of a withdrawal reflex in *Aplysia*. (A) Activity in a sensory neuron (SN1) along the CS+ (paired) pathway is coincident with activity in neurons along the reinforcement pathway (US). However, activity in the sensory neuron (SN2) along the CS− (unpaired) pathway is not coincident with activity in neurons along the US pathway. The US directly activates the motor neuron, producing the UR. The US also activates a modulatory system in the form of the facilitatory neuron, resulting in the delivery of a neuromodulatory transmitter to the two sensory neurons. The pairing of activity in SN1 with the delivery of the neuromodulator yields the associative modifications. (B) After the paired activity in A, the synapse from SN1 to the motor neuron is selectively enhanced. Thus, it is more likely to activate the motor neuron and produce the conditioned response (CR) in the absence of US input. Modified from Lechner and Byrne (1998).

**FIGURE 49.5** Model of associative facilitation at the *Aplysia* sensorimotor synapse. This model has both a presynaptic and a postsynaptic detector for the coincidence of the CS and the US. Furthermore, a putative retrograde signal allows for the integration of these two detection systems at the presynaptic level. The CS leads to activity in the sensory neuron, yielding presynaptic calcium influx, which enhances the US-induced cAMP cascade. The CS also induces glutamate release, which results in postsynaptic calcium influx through NMDA receptors if paired with the US-induced depolarization of the postsynaptic neuron. The postsynaptic calcium influx putatively induces a retrograde signal, which further enhances the presynaptic cAMP cascade. The end result of the cAMP cascade is to modulate transmitter release and enhance the strength of the synapse. Modified from Lechner and Byrne (1998).

receptors (Chapters 9 and 11). These receptors need concurrent delivery of glutamate and depolarization in order to allow calcium to enter. The glutamate is provided by the activated sensory neuron (CS), and the depolarization is provided by the US (Antonov *et al.*, 2003; Roberts and Glanzman, 2003). Thus, the postsynaptic neuron provides another example of coincidence detection. The increase in intracellular calcium putatively causes a retrograde signal to be released from the postsynaptic to the presynaptic terminal, ultimately acting to further enhance the cAMP cascade in the sensory neuron. The overall amplification of the cAMP cascade acts to raise the level of PKA, which in turn leads to the modulation of transmitter release. These activity-dependent changes enhance synaptic efficacy between the specific sensory neuron of the CS pathway and the motor neuron. Thus, the sensory neuron along the CS pathway will be better able to activate the motor neuron and produce the CR.

## Summary

Certain invertebrates display an enormous capacity for learning and offer particular experimental advantages for analyzing the cellular and molecular mechanisms of learning. For example, behaviors in *Aplysia* are mediated by relatively simple neural circuits, which can be analyzed with conventional anatomical and electrophysiological approaches. Once the circuit is specified, the neural locus for the particular example of learning can be found, and biophysical, biochemical, and molecular approaches can then be used to identify mechanisms underlying the change. The relatively large size of some of these cells allows these analyses to take place at the level of individually identified neurons. Individual neurons can be removed surgically and assayed for changes in the levels of second messengers, protein phosphorylation, RNA, and protein syntheses. Moreover, peptides and nucleotides can be injected into individual neurons.

This chapter has focused exclusively on *Aplysia*, but many other invertebrates have proven to be valuable model systems for the cellular and molecular analysis of learning and memory. Each has its own unique advantages. For example, *Aplysia* is excellent for applying cell biological approaches to the analysis of learning and memory mechanisms. Other invertebrate model systems such as *Drosophila*, although not well suited for cell biological approaches because of their small neurons, offer tremendous advantages for obtaining insights into mechanisms of learning and memory through the application of genetic approaches. A frequently used protocol in *Drosophila* employs a two-stage differential odor-shock avoidance procedure,

in which animals learn to avoid odors paired (CS+) with shock but not odors explicitly unpaired (CS-). This learning is typically retained for 4–6 h, but retention for 24 h to 1 week can be produced by a spaced training procedure. Several mutants deficient in learning have been identified. Analysis of the affected genes has revealed elements of the cAMP signaling pathway as key in learning and memory. It is now known that the formation of long-term memory requires activation of the cAMP signaling pathway, which, in turn, activates members of the CREB transcription family. These proteins appear to be the key molecular switch that enables expression of genes necessary for the formation of long-term memories. These transcription factors are also important for long-term memory in *Aplysia* as described above and in vertebrates (see below). See Byrne (1987) and Carew (2000) for a review of other selected invertebrate model systems that have contributed importantly to the understanding of memory mechanisms.

## VERTEBRATE STUDIES: LONG-TERM POTENTIATION

In contrast to the studies on invertebrates like *Aplysia* described earlier, in vertebrates it has been more difficult to link synaptic plasticity with specific examples of learning. However, one exciting and extensively studied candidate memory mechanism is the synaptic phenomenon termed long-term potentiation (LTP). This phenomenon is defined as a persistent increase in synaptic strength (as measured by the amplitude of the EPSP in a follower neuron) that can be induced rapidly by a brief burst of spike activity in the presynaptic afferents. The intense experimental interest in LTP is driven by the working hypothesis that this form of synaptic plasticity may participate in information storage in several brain regions. This section describes the properties of LTP and how it is studied, reviews its underlying mechanisms, and explores the possibility of linkages between LTP and learning and memory.

### Long-Term Potentiation Occurs in a Variety of Neural Synapses

The first evidence that long-term modification of mammalian synapses could be induced by experimental means appeared in 1973, when Timothy Bliss and Terje Lomo demonstrated LTP in the hippocampus of the anesthetized rabbit. Brief, high-frequency stimulation of the perforant-pathway input to the dentate

gyrus produced a long-lasting enhancement of the extracellularly recorded field potential. Subsequent studies of nonanesthetized animals have shown that LTP can last for weeks or months. Originally thought to be unique to the mammalian hippocampal formation, LTP is now known to occur in the cerebellum, neocortical regions, subcortical regions such as the amygdala, mammalian peripheral nervous system, the arthropod neuromuscular junction, and the *Aplysia* sensorimotor synapse. It is important to bear in mind that no universal mechanism exists for inducing LTP. Indeed, different mechanisms may be used at the same synapse, depending on the experimental conditions. This chapter focuses primarily on the LTP at the synapse made by a pyramidal neuron in the CA3 region of the hippocampus to a pyramidal neuron in the CA1 region of the hippocampus.

**Long-Term Potentiation at the CA3–CA1 Synapse**

Within the hippocampus proper, by far the best studied synapse is that from the Schaffer collateral/commissural (Sch/com) fibers of the CA3 pyramidal cells to the CA1 pyramidal cells (Fig. 49.6). In fact, this

**FIGURE 49.6** Schematic of a transverse hippocampal brain slice preparation from the rat. Two extracellular stimulating electrodes are used to activate two nonoverlapping inputs to pyramidal neurons of the CA1 region of the hippocampus. By suitably adjusting the current intensity delivered to the stimulating electrodes, different numbers of Schaffer collateral/commissural (Sch/com) axons can be activated. In this way, one stimulating electrode was made to produce a weak postsynaptic response and the other to produce a strong postsynaptic response. Also illustrated is an extracellular recording electrode placed in the stratum radiatum (the projection zone of the Sch/com inputs) and an intracellular recording electrode in the stratum pyramidale (the cell body layer). Also indicated is the mossy fiber projection from granule cells of the dentate gyrus (DG) to the pyramidal neurons of the CA3 region. Adapted from Barrionuevo and Brown (1983).

is probably the most commonly studied synapse in the mammalian brain, due in part to its relatively simple circuitry and its laminar organization. These features make it possible to extract useful data from extracellular recordings, which are easier to perform than intracellular recordings and preferable for some purposes. Examples of LTP induction are illustrated in Figure 49.7B. The lower waveforms are extracellularly recorded field EPSPs recorded in the CA1 region in response to a single weak stimulation of the Sch/com pathway. Brief electric stimuli delivered to this pathway lead to the initiation of action potentials in the individual axons in the pathway. These action potentials then propagate to the synaptic terminals. The release of transmitter from the multiple afferent terminals produces a summated EPSP in the postsynaptic cell, which can be detected with an extracellular electrode. Test stimuli are delivered repeatedly at a low rate that produces stable EPSPs in the postsynaptic cell (Figs. 49.7A and B1). After a baseline period, a brief high-frequency tetanus is delivered. Subsequent test stimuli produce enhanced EPSPs (Fig. 49.7B2). The enhancement persists for many hours. Although the synaptic enhancement is stable after the tetanus, LTP, like heterosynaptic facilitation of the sensori-motor

**FIGURE 49.7** LTP at the CA3–CA1 synapse in the hippocampus. (A) Test stimuli are delivered repeatedly once every 10 s while the strength of the synaptic connection is monitored. Strength can be assessed by the *amplitude* of the extracellularly recorded EPSP or, as was done in this example, as the *slope* of the rising phase of the EPSP, which provides an accurate reflection of its strength. To induce LTP, two 1 s, 100 Hz tetani were delivered with a 20 interval. Subsequent test stimuli produce enhanced EPSPs. The enhancement is stable and persists for at least 2 h. Examples of extracellularly recorded field EPSPs before (B1) and 90 min after the induction of LTP (B2). In B3 the traces from B1 and B2 are superimposed. Modified from Nicoll *et al.* (1998).

synapse in *Aplysia*, has multiple temporal domains. One domain is associated with an enhancement of the EPSP that persists for about 90 min. This form of LTP is referred to as early LTP (E-LTP). A second domain referred to as late LTP (L-LTP) is associated with synaptic enhancement that persists for periods of time greater than about 90 min. As described later, different mechanisms underlie the induction and maintenance of E- and L-LTP.

### *Properties of Long-Term Potentiation at the CA3–CA1 Synapse Include Cooperativity, Associativity, and Input Specificity*

The CA3–CA1 synapses exhibit a form of LTP characterized by “classical” properties that have been termed “cooperativity,” “associativity,” and “input specificity” (Fig. 49.8) (Brown *et al.*, 1990; Bliss and Collingridge, 1993). These “classical properties” are actually different manifestations of the same underlying mechanism that is responsible for this type of LTP. Other less commonly studied types of LTP have different signatures.

*Cooperativity* refers to the fact that the probability of inducing LTP, or the magnitude of the resulting change, increases with the number of stimulated afferents. Weak high-frequency stimulation, which activates fewer afferents, often fails to induce LTP (Fig. 49.8A). In contrast, strong stimulation, which activates more afferents, produces LTP more reliably (Fig. 49.8B). Thus, the additional axons recruited by higher stimulation intensities “cooperate” to trigger LTP.

*Associativity* was shown in preparations in which two distinct axonal inputs converged onto the same postsynaptic target. Consider the interactions between

two stimulus pathways, one termed the *weak* pathway with a small number of stimulated afferents, and the other, termed the *strong* pathway, with a large number of stimulated afferents (Fig. 49.8C). Tetanic (high-frequency) stimulation of the *weak* input by itself failed to produce LTP in that pathway unless this stimulation was paired with tetanic stimulation of the *strong* input. Thus, LTP was induced in a *weak* input only when its activity was associated with activity in the *strong* input.

*Input specificity* means that LTP is restricted to only the inputs that received the tetanic stimulation. The unstimulated *weak* pathway was not facilitated after the tetanus to the *strong* pathway (Fig. 49.8B).

### *A Hebbian Mechanism Explains the Properties of Long-Term Potentiation at the CA3–CA1 Synapse in the Hippocampus*

How can these classical properties of LTP in the CA1 region of the hippocampus be explained? In the late 1940s, the Canadian psychologist Donald Hebb (1949) formulated a postulate regarding the conditions that cause synapses to change. His thinking proved to be influential and guided later experiments that probed the mechanisms behind LTP. According to Hebb’s postulate:

*When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A’s efficiency, as one of the cells firing B, is increased. (Hebb, 1949, p. 62)*

In short, coincident activity in two synaptically coupled neurons was proposed to cause increases in

**FIGURE 49.8** Features of LTP at CA3–CA1 synapses in the hippocampus. A single hippocampal pyramidal cell is shown receiving a weak and strong synaptic input. (A) Tetanic stimulation of the weak input alone does not cause LTP in that pathway (compare the EPSP before and after the tetanus). (B) Tetanic stimulus of the strong input alone causes LTP in the strong pathway, but not in the weak pathway. (C) Tetanic stimulation of both the weak and the strong pathway together causes LTP in both the weak and the strong pathway. Modified from Nicoll *et al.* (1998).

the synaptic strength between them. Numerous modern interpretations of Hebb's postulate exist, but most are captured by the mnemonic: "Cells that fire together, wire together."

Could the classical properties of LTP all be consequences of synapses that obey a Hebbian rule? Possibly so if a critical amount of postsynaptic depolarization were a necessary condition for inducing LTP in active synapses. In this case, cooperativity would result when enough input fibers were stimulated to produce the critical amount of postsynaptic depolarization. Associativity would emerge from the fact that the strong input caused sufficient depolarization of the postsynaptic membrane during the presynaptic activity in the weak input. Input specificity would occur because LTP was induced only in those inputs to a neuron that were active at the same time that the cell was sufficiently depolarized by the strong input to that neuron. In other words, these classical phenomena could all be manifestations of a single underlying Hebbian mechanism at the CA3–CA1 synapse.

Not all forms of LTP are Hebbian, however. Examples of non-Hebbian LTP can be found at the mossy fiber–CA3 synapse in the hippocampus and at the parallel fiber–Purkinje cell synapse in the cerebellum. These results indicate that the classical properties of cooperativity, associativity, and input specificity are not universal.

## Mechanisms for Induction, Expression, and Maintenance of Long-Term Potentiation

### LTP Induction

It is currently thought that there are multiple mechanisms or at least multiple second-messenger pathways that can lead to persistent synaptic enhancement. Multiple mechanisms may also contribute to expression and maintenance.

**Calcium Ions and LTP.** It is generally agreed that the induction of LTP depends on an increase in the intracellular concentration of calcium ions ( $[Ca^{2+}]_i$ ) in some key compartment of pre- and/or postsynaptic cells (Bliss and Collingridge, 1993; Johnston *et al.*, 1992; Nicoll and Malenka, 1995). The exact role of calcium in the induction process depends on the particular form of LTP and the synaptic system. In the CA1 region of the hippocampus, LTP induction in the Sch/com synapse depends on changes in postsynaptic  $[Ca^{2+}]_i$ .

It is currently thought that many different pathways modulate or control  $[Ca^{2+}]_i$  in the critical subcellular

compartment(s) (Bliss and Collingridge, 1993; Nicoll and Malenka, 1995; Teyler *et al.*, 1994) (Fig. 49.9). Two major pathways that have been studied extensively are implicated in some aspect of LTP induction: calcium influx through ionotropic GluRs, especially the *N*-methyl-*D*-aspartate receptor (NMDAR); and calcium influx through voltage-gated calcium channels (VGCCs).

**NMDAR-dependent LTP.** Recall that the classical form of LTP in the CA1 region of the hippocampus has properties that can be explained in terms of a Hebbian mechanism. For this form of LTP, considerable evidence shows a role for the NMDAR (Bliss and Collingridge, 1993). Numerous pharmacological studies have shown that competitive antagonists of NMDA, such as D-2-amino-5-phosphonopentenoic acid (D-AP5, also termed AP5 or APV) or NMDA ion channel blockers, such as the noncompetitive antagonist (+)-5-methyl-10, 11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5,10-imine (MK-801), can prevent the induction of LTP.

**FIGURE 49.9** Events leading to some forms of LTP and LTD. The schematic depicts a postsynaptic spine with various sources of Ca<sup>2+</sup>. The NMDA receptor channel complex admits Ca<sup>2+</sup> only after depolarization removes the Mg<sup>2+</sup> block in the presence of bound glutamate. Calcium may also enter through the ligand-gated AMPA receptor channel or voltage-gated calcium channels (VGCC), which may be located on the spine head or dendritic shaft. Calcium pumps (P), located on the spine head, neck, and dendritic shaft, are hypothesized to help isolate Ca<sup>2+</sup> concentration changes in the spine head from those in the dendritic shaft.

The NMDAR has two properties that immediately suggest the nature of its role in LTP induction at Hebbian synapses (Gustafsson and Wigstrom, 1988; Brown *et al.*, 1990; Bliss and Collingridge, 1993). First, NMDARs are permeable to  $\text{Ca}^{2+}$  (in addition to  $\text{Na}^+$  and  $\text{K}^+$ ). This property is significant because postsynaptic  $[\text{Ca}^{2+}]_i$  plays a critical role in inducing NMDAR-dependent LTP. Second, the channel permeability is a function of both pre- and postsynaptic factors. Channel opening requires the neurotransmitter glutamate (or some related agonist) to bind to the NMDA site. This in turn requires presynaptic activity for glutamate release. At the usual resting membrane potential, the ionic channels of NMDARs normally are blocked by magnesium ions ( $\text{Mg}^{2+}$ ), but this channel block is relieved by sufficient depolarization of the postsynaptic membrane. Thus, the NMDAR-mediated conductance is voltage dependent, allowing  $\text{Ca}^{2+}$  entry only when presynaptic release is combined with postsynaptic depolarization.

At this point, you should recall the distinction between the properties of the NMDAR and those of the AMPAR ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor) (see Chapters 9 and 11 for details), which also are found in the postsynaptic membrane. The AMPAR does not exhibit voltage-dependent  $\text{Mg}^{2+}$  block, has relatively lower  $\text{Ca}^{2+}$  permeability, and the AMPAR-mediated conductance is essentially voltage independent. Released glutamate can potentially act on both the AMPARs and the NMDARs associated with the membrane on the dendritic spine (Fig. 49.9). With this knowledge, one can easily envision a possible role for the AMPAR and NMDAR in a Hebbian modification. Nearly concurrent presynaptic activity (producing glutamate release and binding) and postsynaptic depolarization (relieving the  $\text{Mg}^{2+}$  block) allow  $\text{Ca}^{2+}$  influx into the dendritic spine of the postsynaptic neuron. The increased  $[\text{Ca}^{2+}]_i$  in some critical region of the dendritic spine, presumably very close to the NMDAR, is thought to activate  $\text{Ca}^{2+}$ -dependent enzymes, such as calmodulin-dependent kinase II (CaM kinase II), which play a key role in LTP induction (Fig. 49.9).

In qualitative terms, one can understand how these molecular events could help account for the properties of cooperativity, associativity, and spatiotemporal specificity. Active synapses release glutamate, which can bind to the NMDAR, causing  $\text{Ca}^{2+}$  influx into dendritic spines on the postsynaptic cell. This  $\text{Ca}^{2+}$  influx acts locally and results in input-specific LTP. However, the  $\text{Ca}^{2+}$  influx occurs only when the synaptic input is strong enough to depolarize the postsynaptic membrane sufficiently to relieve the  $\text{Mg}^{2+}$  block, giving rise

to cooperativity (see Fig. 49.8). The depolarization itself is mediated in large part by the (voltage-independent) AMPARs, which are also colocalized on the dendritic spine (Fig. 49.9). Note that activity in a weak input by itself would not depolarize the postsynaptic cell sufficiently to relieve the  $\text{Mg}^{2+}$  block unless this activity were properly timed in relationship to activity in a strong input to the same cell. The combined depolarization of the two inputs gives rise to associativity and input specificity (Fig. 49.8).

**NMDAR-independent LTP.** Most of the preceding accounts of the Hebbian, NMDAR-dependent form of LTP apply only to certain synapses under some conditions, and even then it may be only one aspect of the story (Johnston *et al.*, 1992; Nicoll and Malenka, 1995). In many synapses, LTP induction does not appear to require the NMDA receptor (Johnston *et al.*, 1992; Teyler *et al.*, 1994). Even within the hippocampus, some synapses exhibit NMDAR-independent forms of LTP. For example, in the presence of the competitive antagonist APV, even the Sch/com inputs to CA1 pyramidal neurons, which are known to exhibit the classical Hebbian form of LTP that relies on the NMDAR, can exhibit an NMDAR-independent type of LTP. The onset of NMDAR-independent LTP is relatively slow (20–30 min), exhibits input specificity, and is prevented by a blocker of voltage-gated calcium channels (VGCCs). Thus, a distinction exists between “NMDA LTP” and “VGCC LTP.” Other work has suggested that VGCCs are likely to be responsible for certain types of LTP in the CA3 region of the hippocampus and in the visual cortex.

The general case may be that both NMDAR-dependent and NMDAR-independent forms of LTP may coexist in the same brain region, among different classes of synaptic inputs onto the same postsynaptic neuron, and even among the same class of synaptic inputs to the same postsynaptic neuron.

**Induction of late LTP.** A common requirement for the induction of both early LTP and late LTP at the CA3–CA1 synapse is the elevation of levels of intracellular calcium in the postsynaptic (i.e., CA1) neuron. Additional steps are involved in the induction of L-LTP, however. As was the case for the induction of long-term facilitation of the sensorimotor synapse in *Aplysia*, activation of PKA appears to be necessary for the induction of L-LTP (Huang *et al.*, 1996). However, in the CA1 neuron the cAMP pathway is engaged directly by the activation of a calcium-sensitive adeny-

yl cyclase rather than being activated by 5-HT as in *Aplysia*. (Transmitters that regulate cAMP in CA1 neurons can profoundly modulate LTP, however.) Thus, at the CA1 neuron elevated levels of calcium lead to activation of adenylyl cyclase, increased synthesis of cAMP, and activation of PKA. Also, like long-term facilitation in *Aplysia*, MAPK kinase is necessary for the induction of L-LTP (Dineley *et al.*, 2001). The mechanisms of activation of MAPK in CA1 neurons have not been elucidated in detail, but may involve PKA, PKC, or both acting together. The final steps in the induction of L-LTP involve a PKA- and MAPK-dependent phosphorylation of CREB and induction of CREB responsive genes. These genes would encode the proteins underlying changes at the synapse (but see Box 49.1).

The mechanisms underlying the induction of long-term neuronal plasticity and memory seem to be highly conserved across species. NMDAR-dependent LTP has been characterized at the sensorimotor synapse of *Aplysia* (Lin and Glanzman, 1994). Formation of some long-term memories in *Drosophila* depends on both an increase in the activity of a transcriptional activator of the bZip family, dCREB2a, and a decrease in the activity of a related repressor, dCREB2b. Establishment of LTM in *Drosophila* therefore appears analogous to induction of *Aplysia* LTF, involving transcriptional activation by one bZip family member (CREB1 in *Aplysia*) and relief of repression by another member

(CREB2 in *Aplysia*). CREB activation also correlates with mammalian long-term memories. Interference with CREB function can inhibit long-term memories whereas overexpression of CREB can facilitate them.

### LTP Expression

Up to this point, evidence related to early events in the causal chain that triggers the induction process has been emphasized. Another question follows naturally: What biochemical and biophysical changes incorporate this modification once it has been triggered? Most of the ideas about enhanced synaptic transmission concern either increased transmitter release or increased receptivity to released transmitter. The former entails presynaptic changes, and the latter, postsynaptic. Although some of the induction mechanisms discussed previously implicated a postsynaptic increase in  $[Ca^{2+}]_i$ , this does not necessarily imply that expression must also be postsynaptic. Ample evidence is available for ongoing two-way communication across the synaptic cleft, so a postsynaptic trigger could, in principle, give rise to a pre- and/or postsynaptic modification (see also Fig. 49.5). There are extensive and seemingly conflicting accounts in the literature regarding the nature of the changes responsible for the observed increase in synaptic efficacy following LTP induction. Some of the possibilities are illustrated schematically in Figure 49.10. However, regarding LTP at the CA3–CA1 synapse, expression of LTP is

#### BOX 49.1

### IS MEMORY MORE THAN CHANGES IN SYNAPTIC STRENGTH?

The search for the biological basis of learning and memory has led many of the leading neuroscientists of the twentieth century to direct their efforts to investigating the synapse. The focus of most recent work on LTP (and indeed the bulk of this chapter) has been to elucidate the mechanisms underlying changes in synaptic strength. Although changes in synaptic strength are certainly ubiquitous, they are not the exclusive means for the expression of neuronal plasticity associated with learning and memory. Both short-term and long-term sensitization and classical conditioning of defensive reflexes in *Aplysia* are associated with an enhancement of excitability of the sensory neurons in addition to changes in synaptic strength. Classical and operant conditioning of feeding behavior in *Aplysia* also leads to changes in excitability of

neuron B51. Interestingly, in this case there is a bidirectional control. The excitability of B51 is increased by operant conditioning, whereas it is decreased by classical conditioning. Changes in excitability of sensory neurons in the mollusc *Hermisenda* are produced by classical conditioning. In vertebrates, classical conditioning of eye-blink reflexes produces changes in the excitability of cortical neurons. Eye-blink conditioning also produces changes in the spike afterpotential of hippocampal pyramidal neurons. Finally, as described in their original report on LTP, Bliss and Lomo found that the expression of LTP was also associated with an apparent enhanced excitability.

John H. Byrne

**FIGURE 49.10** Schematic representation of possible loci for cellular changes involved in the enhancement of synaptic efficacy. The efficacy of a synapse can be potentiated through at least six mechanisms. First, there could be an increase in the fraction (release probability) of available presynaptic vesicles that undergo exocytosis. For example, in *mechanism 1*, two out of four available vesicles are released (i.e., 50% release probability), in contrast to the *normal synapse*, where only one out of four vesicles is released (i.e., 25% release probability). Second, there could be an increase in the number of release sites at the presynaptic neuron (*mechanism 2*). Third, the synapse could be potentiated through an increase in the number of vesicles available for release. For example, at a release site with eight vesicles, two of them will be exocytosed (instead of one) (*mechanism 3*), even if the release probability (25%) is the same as at the normal synapse. Fourth, there could be an increase in the sensitivity of the preexisting receptors to presynaptically released neurotransmitter or a greater conductance of the channel (*mechanism 4*). Fifth, there could be an increase in the number of functional receptors (illustrated as an increase from two active receptors at the normal synapse to four at the potentiated synapse; *mechanism 5*). Finally, the synapse could also be potentiated through coordinated presynaptic and postsynaptic morphological changes, such as the growth of new synaptic contacts between the same pair of neurons (*mechanism 6*). Adapted from Wang *et al.* (1997).

associated with an increase in the number of functional AMPA receptors in the postsynaptic neuron (*mechanism No. 5* in Fig. 49.10; for review see Malinow and Malenka, 2002). LTP at this synapse also involves phosphorylation of the AMPA receptor, which leads to an increased conductance that contributes to enhanced synaptic efficacy (*mechanism No. 4* in Fig. 49.10). Recent results indicate that a family of small transmembrane AMPA receptor regulatory proteins (TARPs) controls both AMPA receptor trafficking and channel gating (for review see Nicoll *et al.*, 2006). In contrast to the postsynaptic expression of LTP at the CA3-CA1 synapse, LTP at the mossy fiber-CA3 synapse appears to involve an increase in transmitter release.

#### LTP Maintenance

Regardless of the ultimate nature and locus of the modification that gives rise to LTP expression, the more general problem remains of how a synaptic change can endure over long periods of time in the face of constant molecular turnover.

**Maintenance of Early LTP.** The maintenance of E-LTP is due to the persistence of phosphorylation of substrate proteins involved in expression mechanisms (see earlier discussion). This phosphorylation, in turn, is regulated by the engagement of protein kinases and phosphatases. For E-LTP, autonomously active forms of PKC and CaM kinase II appear to be particularly important.

**Maintenance of Late LTP.** The maintenance of persistent forms of LTP ultimately involves alterations in gene expression and changes in protein synthesis. High-frequency electrical stimulation in the rat hippocampus raises levels of specific mRNAs that encode transcription factors (e.g., *fos*, *zif268*), cytoskeletal proteins (e.g., *arc*), and signal transduction molecules such as CaM kinase II. Moreover, protein synthesis inhibitors block the late phase of LTP but not earlier phases. One interesting observation is that brain slices that received protein synthesis inhibitors just 2h after high-frequency stimulation showed no decline in late LTP, indicating that there is a critical

time window during which protein synthesis might be necessary to maintain long-term plasticity. One new protein that is synthesized is protein kinase Mzeta (PKM $\zeta$ ). PKM $\zeta$  is necessary for maintenance of L-LTP and seems necessary for maintaining the increase in postsynaptic AMPA receptors (Ling *et al.*, 2006; Pastalkova *et al.*, 2006). Other work conducted *in vivo* has pointed to a still later stage of LTP that lasts for weeks and that is blocked by treatment with protein synthesis inhibitors during the tetanus (Krug *et al.*, 1984). As indicated earlier, similar multiple stages of long-term synaptic plasticity have been identified in *Aplysia*. They also are found in bees, *Drosophila*, and *Hermisenda*.

Although the involvement of new protein synthesis is consistent with the data, it immediately raises the problem of synaptic input specificity. If neural activity ultimately affects gene expression in the nucleus, then the mRNAs and proteins produced in the somatic compartment could, in principle, travel to any synapse within the cell. The problem is how to modify only the appropriate synapses and maintain synapse specificity. One solution is for the specific kinase(s) activated locally during a tetanus to phosphorylate one or more substrates and that these substrates act to “tag” the synapse as one that has been potentiated. For example, a stimulus that activates one CA1 synaptic input sufficiently to induce L-LTP can lead to the induction of L-LTP by a weaker stimulus to a second synaptic input even when that second input is by itself sufficient to only induce E-LTP. This effect is limited to a time window where the second weaker stimulus occurs within an hour or so of the stronger one. These results indicate that the second stimulus can lead to the transient (~1h) activation of a “tag” that can specifically “capture” “plasticity factors” induced by the strong stimulus (Frey and Morris, 1997; Martin *et al.*, 1997). A major goal of current LTP research is to identify the nature of the tag and the plasticity factors.

Support of a more permanent synaptic modification might require a self-perpetuating tag and/or a biochemical positive feedback loop that maintains synaptic strength (Hayer and Bhalla, 2005). Positive feedback based on network activity may also be important. Periodic reactivation of strengthened synapses may be necessary to re-activate mechanisms of L-LTP, maintaining synaptic strength for months or longer (Wang *et al.*, 2006; Smolen, 2007).

### Links between Long-Term Potentiation and Learning

Long-term potentiation has properties that have long been considered necessary for the encoding and

retrieval of information. Hebbian forms of LTP exhibit associativity, which appears to be a desirable property, and all forms of LTP appear to be well suited to rapid learning. One of the more important challenges entails linking LTP (and LTD, see later) to learning and memory (Martin *et al.*, 2000). This task has proven rather difficult to achieve, although evidence is accumulating for a causal link between LTP and memory.

Several different experimental strategies have been used to search for links between LTP and learning. These include correlating changes in synaptic efficacy with learning and blocking or saturating LTP mechanisms to show that learning has been blocked. Correlating synaptic enhancement with memory has been possible in several systems such as in amygdala circuits that mediate fear conditioning (see Chapter 50). However, there has been only limited success so far. The first obstacle to surmount is the “needle in the haystack” problem. The synaptic changes underlying learning are presumably rather specific and localized. Consequently, it is difficult to place a recording electrode in the correct anatomical location. Moreover, as described later, learning may involve decreases as well as increases in synaptic strength. Coarse recording techniques might see no net change. Saturation of LTP by the massive stimulation of afferents has blocked learning, but the concern here is that the saturation may affect the basic operation of the circuit. The most widely used approach has been to block LTP with pharmacological or gene knockout techniques. This approach has generated many successes but also some striking dissociations, as blocking experiments have two problems. First, it is difficult to be sure that the agent used to block LTP does not cause some secondary effect. Thus, if memory is blocked successfully, it may be because of a block of some other process critical for memory and not the block of LTP. Second, if, for example, an agent that blocks NMDAR-dependent LTP fails to block learning, it may not necessarily imply that LTP does not mediate learning, but rather that the animal simply has used another non-NMDAR-independent memory mechanism to solve the problem.

Some of the more promising work in this area has come from studies of genetically engineered knockout mice. The first generation of knockouts prevented the expression of some factor that was thought to be necessary for LTP, such as CaM kinase-II. Although these studies were intriguing, they suffered from the fact that the consequences of a gene knockout might alter brain development and might not be confined to a specific part of the brain under study. Some of these problems have been overcome

in a second generation of knockouts that have temporal as well as spatial specificity. For example, temporal and spatial control of gene expression can now be achieved using binary transgene systems such as tetracycline transactivating systems and Cre/LoxP recombination systems. The NMDAR gene in only CA1 pyramidal cells of the hippocampus has been knocked out using the Cre/LoxP system (Tsien *et al.*, 1996). The results provide strong evidence in favor of the notion that NMDA receptor-dependent synaptic plasticity at CA1 synapses is required for the acquisition of spatial memory. This general approach holds tremendous promise for testing hypotheses about the functional role of various forms of LTP in specific brain regions.

Recently, learning in rats was verified to induce hippocampal LTP (Whitlock *et al.*, 2006). Also, inhibition of PKM $\zeta$  in the hippocampus *in vivo* was demonstrated to disrupt LTP maintenance and eliminate spatial learning (Pastalkova *et al.*, 2006). These results have strengthened the link between LTP and learning.

## LONG-TERM DEPRESSION

LTD is believed by many to be the mechanism by which learning is encoded in the cerebellum (Ito, 2001), as well as a process whereby LTP could be reversed in the hippocampus and neocortex (Bear and Malenka, 1994). In the hippocampus, brief, high-frequency stimulation (HFS) (e.g., four trains of 10 shocks at 100 Hz) can induce classical LTP, whereas low-frequency stimulation (LFS) over longer periods (1 Hz for 10 min) can induce LTD.

Some forms of LTD appear to be mediated by the NMDAR and these forms appear to be due to dephosphorylation of AMPAR subunits, which decreases their conductance and hence the synaptic efficacy, as well as endocytosis of AMPARs, which decreases their surface number and hence the synaptic efficacy. In addition, NMDAR-independent forms of LTD exist. These often depend on activation of metabotropic glutamate receptors. For example, NMDAR-independent LTD in the parallel fiber input to Purkinje cells in the cerebellum is induced by the combined increase in intracellular levels of Ca<sup>2+</sup> (by activity) in postsynaptic Purkinje cells and activation of metabotropic glutamate receptors produced by the release of glutamate from parallel fibers.

The form of LTD may vary in different brain regions and sometimes among different inputs to the same brain region. Even within the CA1 region, the Sch/

com input may exhibit both NMDAR-dependent and NMDAR-independent forms of LTD.

Calcium levels in the dendritic spines appear to be a common locus for the induction of NMDAR-dependent LTP and LTD. For example, at the Sch/com input to CA1, both LTP and LTD can be blocked by injecting Ca<sup>2+</sup> chelators into the postsynaptic cell. If both LTP and LTD are triggered by Ca<sup>2+</sup> entry, then how are their induction processes different? Presumably, more Ca<sup>2+</sup> influx occurs during an LTP-inducing HFS than during an LTD-inducing LFS. One formal molecular model developed by John Lisman incorporates this Ca<sup>2+</sup>-dependent, bidirectional control of synaptic strength. In this model, high [Ca<sup>2+</sup>]<sub>i</sub> activates a protein kinase that phosphorylates a protein causing LTP induction, whereas low [Ca<sup>2+</sup>]<sub>i</sub> activates a protein phosphatase that dephosphorylates this protein and causes LTD. The synaptic strength thus depends on which of these competing processes is most active, which in turn will be a function of the pattern of activity experienced by the cell (Fig. 49.9).

LTP and LTD can be readily reversed. If low frequency stimulation (LFS) is applied after a synapse is potentiated by high frequency stimulation (HFS), the synaptic strength decreases. This phenomenon is called depotentiation. In contrast, if HFS is applied after a synapse is depressed by LFS, the synaptic strength increases. This phenomenon is called dedepression. Accumulating evidence indicates that the mechanisms of depotentiation differ from that of LTD, and the mechanisms of dedepression differ from that of LTP.

## Summary

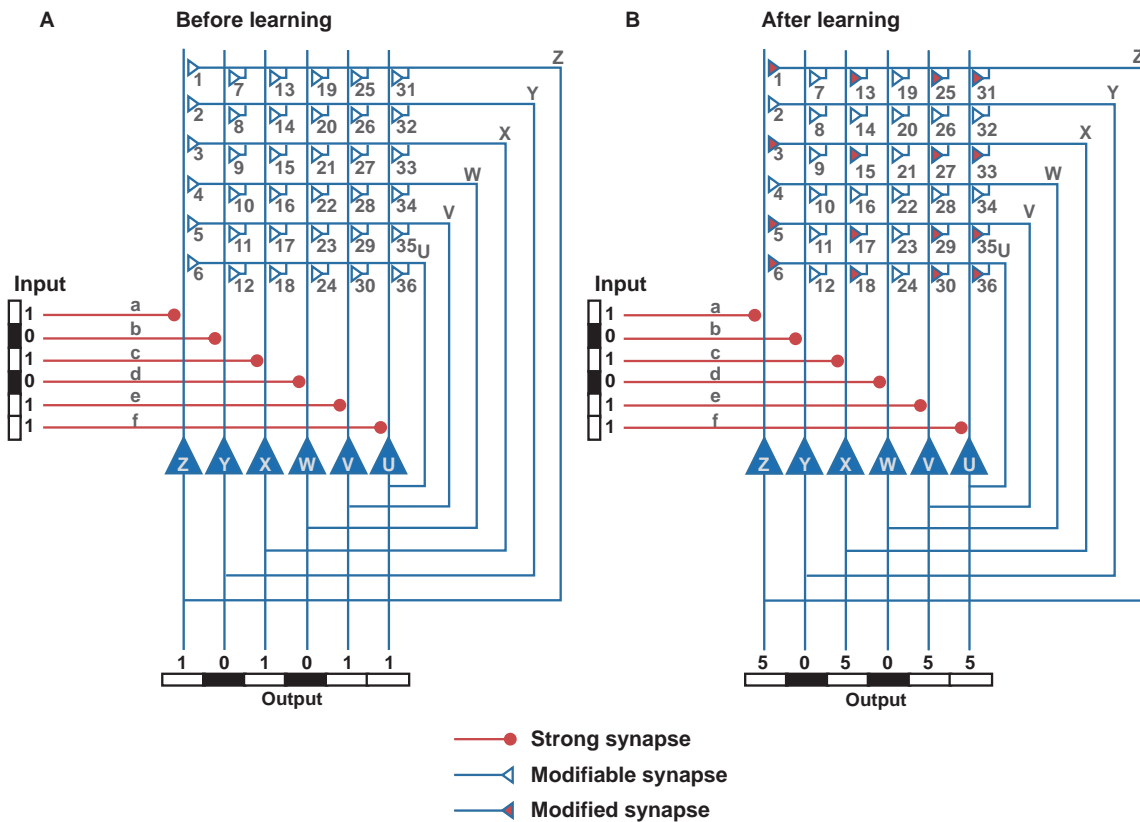

The understanding of LTP and LTD is evolving rapidly (Malenka and Nicoll, 1999). For example, whereas the N-methyl-D-aspartate receptor was once the pivotal focus of long-term potentiation research, it is now clear that other mechanisms should be considered. It has also become evident that high-frequency stimulation is but one end of a spectrum of stimulations that can induce synaptic changes. Lower stimulation frequencies can induce long-term depression, which may share some common molecular mechanisms with LTP. Finally, several stages in the maintenance of LTP have been identified, and probably more will be found. A remaining challenge is to clarify the varieties of LTP and LTD mechanisms and to demonstrate their functional significance by establishing convincing links to the encoding and retrieval of information.

## HOW DOES A CHANGE IN SYNAPTIC STRENGTH STORE A COMPLEX MEMORY?

The relationship between the synaptic changes and the behavior of conditioned reflexes can be straightforward because the locus for the plastic change is part of the mediating circuit. Thus, the change in the strength of the sensorimotor synapse in *Aplysia* can be related to the memory for sensitization (e.g., Fig. 49.2A1). However, the idea that an increase in synaptic strength leads to an enhanced behavioral response, and a decrease in synaptic strength leads to a decreased behavioral response, can be misleading. For example, a decrease in synaptic strength in a postsynaptic neuron that exerts an inhibitory action can be translated into an enhanced behavioral response. Indeed, in

the parallel fiber-to-Purkinje cell connection in the cerebellum, such a disinhibition is precisely the mechanism that has been proposed to contribute to classical conditioning of the eye-blink reflex (see Chapter 50 for a discussion of this form of conditioning). Nevertheless, for relatively simple reflex systems in which the circuit is well understood, it is possible to directly relate a change in synaptic strength to learning. However, in most other examples of memory, it is considerably less clear how the synaptic changes are induced and, once induced, how the information is retrieved. This is especially true in memory systems that involve the storage of information for patterns, facts, and events. Neurobiologists have turned to artificial neural circuits to gain insights into these issues.

A simple network that can store and “recognize” patterns is illustrated in Figure 49.11. The network is artificial, but nevertheless is inspired by actual cir-

**FIGURE 49.11** Autoassociation network for recognition memory. The artificial circuit consists of six input pathways that make strong connections to each of six output neurons. The output neurons have axon collaterals that make synaptic connections (numbered 1–36) with each of the output cells. (A) A pattern represented by activity in the input lines or axons (a, b, c, d, e, f) is presented to the network. A 1 represents an active axon (e.g., a spike), whereas a 0 represents an inactive axon. The input pathways make strong synapses (●) with the postsynaptic output cells. Thus, output cells (u, v, w, x, y, z) generate a pattern that is a replica of the input pattern. The collateral synapses were initially weak and do not contribute to the output. Nevertheless, the activity in the collaterals that occurred in conjunction (assume minimal delays within the circuit) with the input pattern led to a strengthening of a subset of the 36 synapses. (B) A second presentation of the input produces an output pattern that is an amplified, but an otherwise intact, replica of the input. An incomplete input pattern can be used as a cue to retrieve the complete pattern.

cuitry in the CA3 region of the hippocampus. In this example, six different input projections make synaptic connections with the dendrites of each of six postsynaptic neurons (Fig. 49.11A). The postsynaptic neurons serve as the output of the network. Input projections can carry multiple types of patterned information, and these patterns can be complex. In order to simplify the present discussion, consider that the particular input pathway in Figure 49.11A carries information regarding the pattern of neural activity induced by a single brief flash of a spatial pattern of light. For example, activity in the top pathway (line *a*) might represent light falling on the temporal region of the retina, whereas activity in the pathway on the bottom (line *f*) might represent light falling on the nasal region of the retina. Thus, the spatial pattern of an image falling upon the retina could be reconstructed from the pattern of neuronal activity over the  $n$  (in this case 6) input projections to the network.

Three aspects of the circuit endow it with the ability to store and retrieve patterns. First, each of the input lines makes a sufficiently strong connection with its corresponding postsynaptic cell to activate it reliably. Second, each output cell ( $z$  to  $u$ ) sends an axon collateral that makes an excitatory connection with itself as well as the other five output cells. This pattern of synaptic connectivity leads to a network of 36 synapses (42, including the 6 input synapses). Third, each of the 36 synaptic connections are modifiable through an LTP-like mechanism (see earlier discussion). Specifically, the strength of a particular synaptic connection is initially weak, but it will increase if the presynaptic and postsynaptic neurons are active at the same time. The circuit configuration with the embedded synaptic “learning rule” leads to an autoassociation or autocorrelation matrix. The autoassociation is derived from the fact that the output is fed back to the input where it associates with itself.

Now consider the consequences of presenting the patterned input to the network of Figure 49.11A. The input pattern will activate the six postsynaptic cells in such a way as to produce an output pattern that will be a replica of the input pattern. In addition, the pattern will induce changes in the synaptic strength of the active synapses in the network. For example, synapse 3 will be strengthened because the postsynaptic cell, cell  $z$ , and the presynaptic cell, cell  $x$ , will be active at the same time. Note also that synapses 1, 5, and 6 will be strengthened as well. This occurs because these input pathways to cell  $z$  are also active. Thus, all synapses that are active at the same time as cell  $z$  will be strengthened. When the pattern is presented again as in Figure 49.11B, the output of the cell will not only be governed by the input, but also by the feedback con-

nections, a subset of which were strengthened (Fig. 49.11B, filled synapses) by the initial presentation of the stimulus. Thus, for output cell  $z$ , a component of its activity will be derived from input  $a$ , but components will also come from synapses 1, 3, 5, and 6. If each of the initially strong and newly modified synapses is assumed to contribute equally to the firing of output cell  $z$ , the activity would be five times greater than the activity produced by input  $a$  before the learning. After learning, the output is an amplified version of the input but the basic features of the pattern are preserved.

Note that the “memory” for the pattern does not reside in any one synapse or in any one cell. Rather, it is *distributed* throughout the network at multiple sites. The properties of these types of autoassociation networks have been examined by James Anderson, Teuvo Kohonen, David Marr, Edmond Rolls, David Wilshaw, and their colleagues and found to exhibit a number of phenomena that would be desirable for a biological recognition memory system. For example, such networks exhibit pattern completion. If a partial input pattern is presented, the autoassociation network can complete the pattern in the sense that it can produce an output that is approximately what is expected for the full input pattern. Thus, any part of the stored pattern can be used as a cue to retrieve the complete pattern. For the example of Figure 49.11, the input pattern was {101011}. This pattern led to an output pattern of {505055}. If the input pattern were degraded to {101000}, the output pattern would be {303022}. Some change in the strength of firing occurs, but the basic pattern is preserved. This preservation is a simple example of the phenomenon known as graceful degradation, which is exhibited by autoassociative networks. With graceful degradation the network can still function if some of the input connections or postsynaptic cells are lost. This property arises from the distributed representation of the memory within the circuit.

## Summary

The concept of distributed representation of memory crosses multiple levels of organization of memory systems. Multiple brain systems are involved in memory, and memory is distributed among synapses in a particular memory circuit (Fig. 49.11). Also, memory at any one synapse is represented by multiple cellular changes (Figs. 49.2, 49.3, and 49.9). The reductionist approaches described in this chapter have provided key insights into cellular memory mechanisms. In the near future, a major experimental question to be answered is the extent to which the mechanisms for learning are common both within any one animal and

between different species. Although many common features are emerging, there seem to be some differences. Thus, it will be important to understand the extent to which specific mechanisms are used selectively for one type of learning and not another. Irrespective of the particular example of learning and memory that is analyzed, whether it be simple or complex, it will be important to pay attention to three major details: details of the circuit interactions, details of the learning rule, and details of the intrinsic biophysical properties of the neurons within the circuit.

# Learning and Memory: Brain Systems

## INTRODUCTION

The previous chapter summarized the cellular and molecular mechanisms of memory and explained that individual neurons contain complex machinery capable of altering membrane excitability and synaptic strength. These neuronal building blocks are the fundamental basis of plasticity, and this plasticity supports behavior through memory systems, complex circuits involving a large number of interconnected neurons. The present chapter focuses on the major memory systems of the brain and considers how each system supports learning. The chapter begins with a brief history of the concept of multiple forms of memory, followed by a summary of each of the major memory systems of the mammalian brain (Fig. 50.1). The final section considers how these systems might collaborate, compete, or operate in parallel to support learned behaviors.

## HISTORY OF MEMORY SYSTEMS

The history of memory systems can be usefully framed by the early question of whether a specific memory could be localized or whether it would be distributed throughout the brain. Even early on there was evidence that the answer might lie somewhere between the extremes. In the 1920s, the psychologist Karl Lashley conducted a series of experiments in which he carefully damaged various areas in the cerebral cortex of rats who had learned a route through a simple maze. He found that the specific location of the brain damage did not relate to memory performance as well as the total amount of cortex damaged and concluded that memory was distributed through-

out the brain. Yet a short time later, the neurosurgeon Wilder Penfield found that when he stimulated various areas of the brains of awake epileptic patients (in order to identify functional areas deemed too important to be removed during surgery to treat the epilepsy), stimulation in some brain regions, particularly in the temporal lobe, led the patient to experience specific memories. He reasoned that, if focal stimulations bring specific memories to mind, then individual brain regions might contain individual memories. The psychologist Donald Hebb offered a reconciliation for these diverse findings by suggesting that thoughts and memories were supported by "cell assemblies," networks of neurons, and that learning experiences resulted in changes in the connections between cells (Hebb, 1949). Thus, to the extent that a change at an individual juncture between cells (i.e., a synapse) recorded experience, memory was localized. Yet to the extent that full memories resulted from a reactivation of an entire cell assembly, memory was distributed.

Although it was not appreciated at this time that different networks, or "cell assemblies," might support different forms of memory, several philosophers and psychologists had already suggested that an important difference existed between the type of everyday memory that one brings to mind in the form of words, pictures, or sounds and the type of memory that accrues with our actions as habits and dispositions. For example, in the early nineteenth century the philosopher Maine de Biran distinguished between *representative memory*, which he imagined as the recollection of ideas and events, *mechanical memory*, which he described as the acquisition of habits and skills, and *sensitive memory*, which he described as the acquisition of affective values for otherwise neutral stimuli. In the

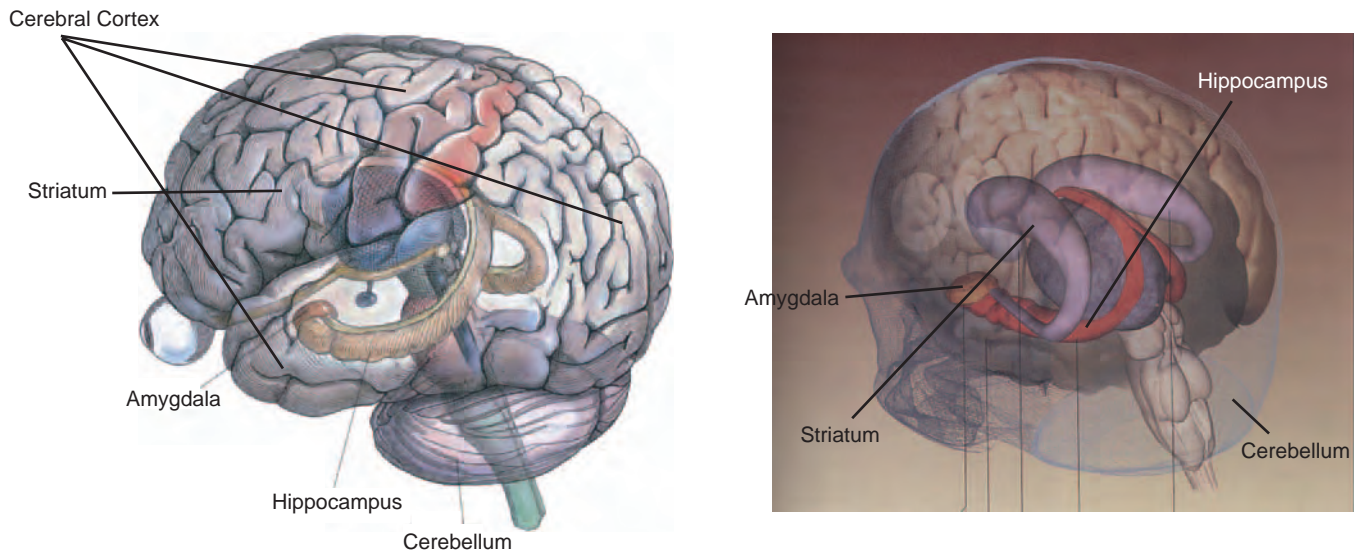

FIGURE 50.1 Drawing of the human brain showing components of the major memory systems.

late nineteenth century, the philosopher and psychologist William James similarly envisioned walking, writing, fencing, singing, and other habitual routines as being fundamentally different from memories produced by conscious recollection.

Thus, by the mid-twentieth century, the work of philosophers, psychologists, and neurosurgeons would have seemed to create an intellectual readiness for the idea of multiple memory systems in the brain. However, at this time the study of memory was guided not by the pursuit of brain systems but by behavioral psychology, a field based on the principle that the opaque details of brain and consciousness were best set aside as more productive research was accomplished by focusing on observable behavior. Despite this principled disregard of the brain, a distinction emerged between a learning based on stimulus-response habit-like learning, such as that described by Clark Hull, and a more cognitive stimulus-stimulus form of learning, such as that described by Edward Tolman. Nevertheless, both ideas were strongly entrenched in a behaviorist tradition and were based on the idea that memory was a single capacity—they disagreed on only how to best depict that capacity. Although behavioral psychology did not actually argue against the idea that particular brain areas might be specialized for particular kinds of memory, its steadfast insistence that the details of the brain be ignored created a vacuum of relevant data. Thus, despite the contributions of earlier work, there was no

clear evidence that brain areas are specialized to support different forms of memory.

Incontrovertible evidence that at least one brain region was specialized to support everyday memory came from a man who underwent brain surgery to treat severe epilepsy and who became perhaps the most famous patient in neuroscience (Scoville and Milner, 1957). This man, known as H.M., began experiencing seizures at the age of 10. It was unclear what caused the seizures, but it was very clear that something drastic had to be done. Heavy doses of anticonvulsant medications did not stop the seizures from worsening to a point at which they were debilitating. Acting on the idea that dysfunctional brain tissue might be causing the seizures, on September 1, 1953 the neurosurgeon William Scoville removed substantial tissue from the medial aspect of H.M.'s temporal lobes (Fig. 50.2).

In one sense, the surgery was a success. The frequency and severity of the seizures were reduced. In another sense, the outcome was tragic. On April 26, 1955, Brenda Milner, a colleague of both Penfield and Hebb, conducted a neuropsychological examination of patient H.M. The profound memory impairment was immediately obvious. H.M. gave the date as March, 1953 and his age as 27 (2 years younger than his actual age). He performed poorly on memory for short stories, word lists, pictures, and a wide range of other materials. Remarkably, it was unclear that he even remembered that he had undergone brain surgery.

**FIGURE 50.2** Magnetic resonance images showing the brains of amnesic patients H.M. and E.P. The images show axial sections through the medial temporal lobes and reveal damaged tissue as a bright signal. H.M.'s damage resulted from surgery, and E.P.'s damage was caused by viral encephalitis. Nevertheless, the resulting lesion was similar for the two patients. Both patients sustained extensive damage to the medial temporal lobes and are profoundly amnesic. From Stefanacci *et al.* (2000).

The severity of H.M.'s amnesia was shocking—he showed almost no capacity for new learning. Also, the fact that the brain damage was known to be confined to a particular region (the medial temporal lobes) added to the intrigue. Yet the observation that a major neurological deficit followed resection of a substantial amount of brain tissue was perhaps not surprising. Indeed, earlier reports already had described brain damaged individuals with memory impairments. Instead, the reason that H.M.'s case ushered in the modern era of research on memory systems came from the four aspects of his mental capacity that remained intact.

First, formal testing identified that cognitive abilities other than memory were intact. H.M.'s IQ score generally was unaffected by the surgery, and a battery of tests found no deficits in perception, abstract thinking, or reasoning ability. These intact abilities indicated that memory could be separated from perception and intelligence. Second, H.M. could hold on to small amounts of information as long as he was actively rehearsing the information. This finding suggested that the ability to maintain information online (now usually referred to as working memory) was distinct from the ability to make a lasting record in the brain (Chapter 51). Third, H.M.'s childhood memories were relatively intact. This finding suggested that, although the medial temporal lobes might be important for

forming new memories, this region was unlikely to be the final storage site for memory. Fourth, H.M. had an intact ability to acquire new motor skill learning (Milner, 1962). Over several days of practice, H.M. gradually improved at tracing the outline of a star when viewing the paper only through a mirror (a task that initially is challenging even for healthy individuals) despite never forming a memory for the testing experience. Thus, the contrast between H.M.'s profound memory loss and intact cognitive abilities outside the ability to form new memory set the stage for the work that has led to our current understanding of memory systems in the brain. H.M.'s case showed that memory is a dissociable cognitive capacity and that day to day memory was supported by brain structures that differed from those that supported the acquisition of motor skills.

H.M. has participated in numerous studies in the decades since his surgery and has provided invaluable insights into the organization of memory systems in the brain. However, studies of other amnesic patients have also been crucial to the emergence of the current understanding of memory and the brain. For example, a later study by Neal Cohen and Larry Squire (1980) suggested that the domain of preserved memory in amnesia was much larger than just motor skill learning. They asked a group of amnesic patients to practice reading words that had been reversed to appear as if

they were being viewed in a mirror. Similar to H.M.'s improvement in mirror tracing, the group of amnesic patients steadily improved in the speed with which they could read the mirror-reversed words despite having great trouble remembering the practice sessions. The study helped to show that a great deal of learning can occur outside the scope of conscious recollection and that this nonconscious learning is not limited to motor skill learning. Cohen and Squire borrowed terminology from work in artificial intelligence (Winograd, 1975) and suggested that amnesia was characterized by an impairment in *declarative memory* and that *procedural memory* was left intact.

Another amnesic patient, patient R.B., helped to show that damage limited to the hippocampus could result in substantial memory impairment (Zola-Morgan *et al.*, 1986). Like H.M., R.B. performed poorly on a range of declarative memory tests, although his deficit was not nearly as severe as H.M.'s. Detailed histological analysis of R.B.'s brain indicated that his memory impairment resulted from damage to a specific subregion (region CA1) in his hippocampus. Thus, patient R.B.'s case showed that damage limited to the hippocampus was sufficient to produce amnesia.

Soon after the report on patient H.M., researchers began work in experimental animals, such as rats and monkeys, in an attempt to create a model of human amnesia. Initially, the separate lines of investigation on humans and animals were divergent and suggested to some that the functions of the hippocampus might differ between species. However, subsequent findings from these two areas converged, both in their characterizations of the kind of memory that is dependent on the hippocampal region and in their identification of functional domains and anatomical pathways associated with other types of memory. In early studies, this line of work focused particularly on the hippocampus. In one proposal, O'Keefe and Nadel (1978) summarized a large body of literature on the effects of hippocampal damage on different behavioral tasks and concluded that animals with damage to the hippocampus are severely impaired at many forms of spatial learning. It is now generally believed that the hippocampus is important for nonspatial as well as spatial memory, yet this early proposal added to ongoing work in humans and monkeys by identifying several key properties of hippocampus-dependent memory in experimental animals. In particular, they characterized this kind of memory as rapidly acquired and driven by curiosity rather than by rewards and punishments, properties that are consistent with characterizations of hippocampus-dependent memory in humans.

Our understanding of memory systems has advanced greatly since H.M.'s surgery and it is still

unfolding. The study of amnesia has provided insights not only about the role of the hippocampal memory system in declarative memory but also about the ability of other memory systems to support learning in the absence of conscious recollection. A large body of work, including research on humans and on experimental animals, has allowed researchers to understand better the unique contributions of the striatum, cerebellum, amygdala, and cerebral cortex to different forms of memory. Thus, we now know that the hippocampus anchors only one of several memory systems in the brain and that each of these brain structures are components of other memory systems that contribute to our ability to benefit from experience. The following sections provide an overview of these systems.

## MAJOR MEMORY SYSTEMS OF THE MAMMALIAN BRAIN

### Overview

The following sections consider the best understood memory systems of the brain. The discussion focuses on individual structures that play central roles in each of the different systems and presents separate sections on the hippocampus, striatum, cerebellum, amygdala, and cerebral cortex (Fig. 50.1). However, each of these regions anchors a much larger network of distributed brain areas that work in concert to support particular forms of memory. For example, the hippocampal memory system includes not only the hippocampus but also areas in the adjacent parahippocampal region as well as many distributed unimodal and polymodal neocortical areas. These areas normally work together to support conscious recollection of facts and events, a capacity termed declarative memory. Even though declarative memory depends on very specialized information processing and plasticity within the hippocampus, a complicated and distributed circuitry outside the hippocampus is also required for these alterations to emerge as the experience of remembering. Most importantly, the cerebral cortex plays a role in many types of memory, and the present chapter will discuss both its specific role as a part of multiple memory systems and the memory functions it supports outside of those systems.

A memory system is most usefully defined in psychological terms as well as anatomical terms. That is, a memory system is most clearly identified by both a distinct circuitry and a unique set of operating characteristics. Memory systems are not separated according to stimulus modality (e.g., auditory vs. visual modality) or between response modalities (e.g., manual vs.

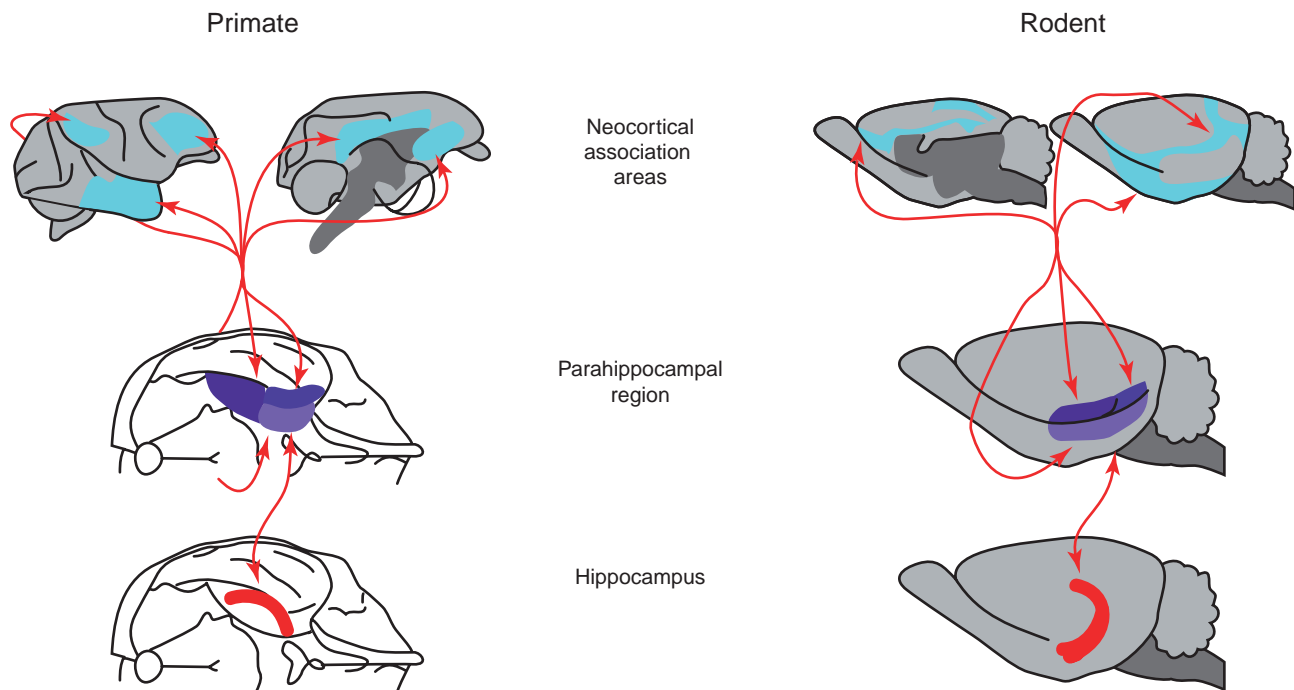

verbal responses). Instead, the critical distinctions involve how each system's anatomy and physiology support a particular type of memory representation in terms of its organization and psychological characteristics. Finally, memory systems collaborate, compete, or operate in parallel to support behavior in the course of one's day-to-day activities, and this issue will be considered in the final section of the chapter.

## Hippocampus

### Anatomy

The hippocampal memory system includes the hippocampus (defined here as the CA fields, dentate gyrus, and subiculum) and the entorhinal, perirhinal, and postrhinal cortices in the adjacent parahippocampal region (the postrhinal cortex is referred to as the parahippocampal cortex in primates; Fig. 50.3; Burwell *et al.*, 1995; Suzuki, 1996). The anatomy and circuitry of these regions, especially the hippocampus, are largely conserved across mammalian species (Manns and Eichenbaum, 2007). The hippocampal memory

system also depends on diverse and widespread higher order regions in the cortex that are both the source of information to the parahippocampal region and hippocampus and the targets of projections originating from these regions. The parahippocampal region serves as a convergence site for input from these cortical association areas and mediates the distribution of cortical afferents to the hippocampus. These parahippocampal cortical areas are interconnected and send major efferents to multiple subdivisions of the hippocampus. Within the hippocampus, an intricate pattern of connectivity mediates a large network of associations (Amaral and Witter, 2004), and these connections support forms of long term potentiation that could participate in the rapid coding of novel conjunctions of information (Chapter 49). The outcomes of hippocampal processing are directed back to the adjacent cortical areas in the parahippocampal region, and the outputs of that region are directed in turn back to the same areas of the cerebral cortex that were the source of its inputs. Additional structures also have been included as components of this system, including midline diencephalic structures.

**FIGURE 50.3** The anatomy of the hippocampal memory system in monkeys and rats. The hippocampal memory system includes the hippocampus (CA fields, dentate gyrus, and subiculum) and the parahippocampal region, which includes the entorhinal cortex, the perirhinal cortex, and the parahippocampal cortex. The hippocampal memory system also includes midline diencephalic nuclei. Multiple association areas in the cerebral cortex send outputs that converge on cortical areas in the parahippocampal region, which in turn sends its outputs to the hippocampus. The output path involves return projections from the hippocampus to the surrounding parahippocampal region, which in turn projects back to the same cortical association areas. From Eichenbaum (2001).

### *Amnesia and Declarative Memory*

Damage to the hippocampus and parahippocampal region produces anterograde amnesia, a memory deficit characterized by an inability to make lasting memories of one's daily experiences. That is, the hippocampal memory system ordinarily supports remembering of new facts and events and makes this information subsequently available for conscious recollection. This capacity is called declarative memory. In most amnesic patients, the deficit in declarative memory extends to both remembering specific personal events (*episodic memory*) and learning new facts (*semantic memory*). Their deficit encompasses all stimulus modalities and impacts nonverbal expression as well as verbal report. Moreover, amnesic patients are impaired whenever the memory task requires the explicit expression of memory, as in tests of free recall or recognition memory. Further, damage to the hippocampus and parahippocampal region results in loss of memory acquired for some period before the damage. This memory impairment is referred to as retrograde amnesia.

Amnesia resulting from damage restricted to the hippocampus and parahippocampal region is highly selective in four important ways, the same four ways discussed earlier with regard to the intact abilities of patient H.M. First, perceptual, motor, and intellectual functions are intact. Across a broad range of neuropsychological tests, amnesic patients perform well on assessments of sensory capacities, motor coordination, intelligence, and language performance. Second, memory acquired long before the onset of amnesia is typically intact. The preservation of these remotely acquired memories generally is thought to be the consequence of a consolidation process in which the hippocampus plays a critical role for a prolonged period, after which retrieval of memories can be supported by other areas, including the neocortex. Thus, the impact of retrograde amnesia is typically time limited. The process of consolidation is discussed in more detail later. Third, the capacity for immediate memory is typically intact in amnesic patients, and, just as in the case for healthy individuals, they can extend the contents of immediate memory in time through rehearsal or elaboration, a capacity often referred to as working memory (Chapter 52). Amnesic patients can immediately reproduce a list of six or seven numbers as well as healthy individuals, but the memory deficit becomes evident as soon as immediate memory span is exceeded or after a delay is interposed that includes some distraction to interrupt rehearsal.

Fourth, the various forms of memory that are supported by brain systems outside the hippocampal

memory system are intact in amnesic patients. For example, amnesic patients demonstrate normal acquisition of a broad variety of tasks in which memory is expressed through behavioral performance such as in the mirror-guided tracing task and the mirror-reversed word reading task described earlier in the chapter. Other examples include artificial grammar learning and improving reaction times on a repetitive sequence of finger taps. One profoundly amnesic patient, patient E.P., has a memory impairment and brain damage very similar to that of patient H.M. (Fig. 50.2). Patient E.P. has shown normal performance on a broad variety of non-conscious memory tasks, despite the fact that his nearly complete anterograde amnesia has kept him from forming conscious memories of the testing situations themselves. In some of these examples, the learning was simple and reflexive, such as in the case of standard eyeblink classical conditioning (discussed in more detail later in the chapter in the section on the cerebellum).

In other examples, performance on more complicated tasks came to resemble that of healthy individuals despite the fact that the learning was supported by a type of nonconscious and relatively inflexible type of learning. For example, in one study E.P. was shown eight pairs of objects one at a time, each pair containing a correct object and an incorrect object. He slowly learned to pick up the correct object in each pair and after 18 weeks was able to select the correct object almost every time (Bayley *et al.*, 2005). When he was asked how he knew which object to pick up he pointed to his head and replied, "It's here somehow or another and the hand goes for it." Yet, in addition to being unavailable to awareness and being very slowly acquired, E.P.'s memory for the objects also appeared to lack the flexibility of that shown by healthy individuals, who had learned the task after only three sessions. When the task was changed by presenting all 16 objects together and by asking E.P. to sort them into correct and incorrect piles, his performance deteriorated precipitously. In contrast, healthy individuals performed nearly perfectly on the sorting task. In another study, over the course of 12 weeks E.P. came to learn a list of 60 three-word nonsense sentences (e.g., "speech caused laughter"), such that he eventually was able to respond correctly some of the time when asked to fill in the missing third word (e.g., "speech caused ???"; Bayley and Squire, 2002). Yet E.P. continually expressed surprise when informed that he had seen the sentences previously. In addition, his memory also differed from control subjects in that it appeared to be somewhat rigid. When the middle word of each sentence was replaced by a synonym, E.P. was able to answer correctly for only one sentence. His performance contrasted with that of healthy individuals, who learned the sen-

tences after only two weeks and who had no trouble adapting to the new testing format.

These studies with patient E.P. illustrate that although some examples of memory supported by structures outside the hippocampal memory system can be simple and reflexive, other examples can be more complex and can include acquisition of new verbal information and biases for one of the response choices that is readily available. These studies also highlight by contrast the characteristics of memory supported by the hippocampal memory system. Memories formed via the hippocampal system typically are acquired rapidly, flexible, and available to conscious recollection.

### ***Functional Brain Imaging and the Hippocampal Memory System***

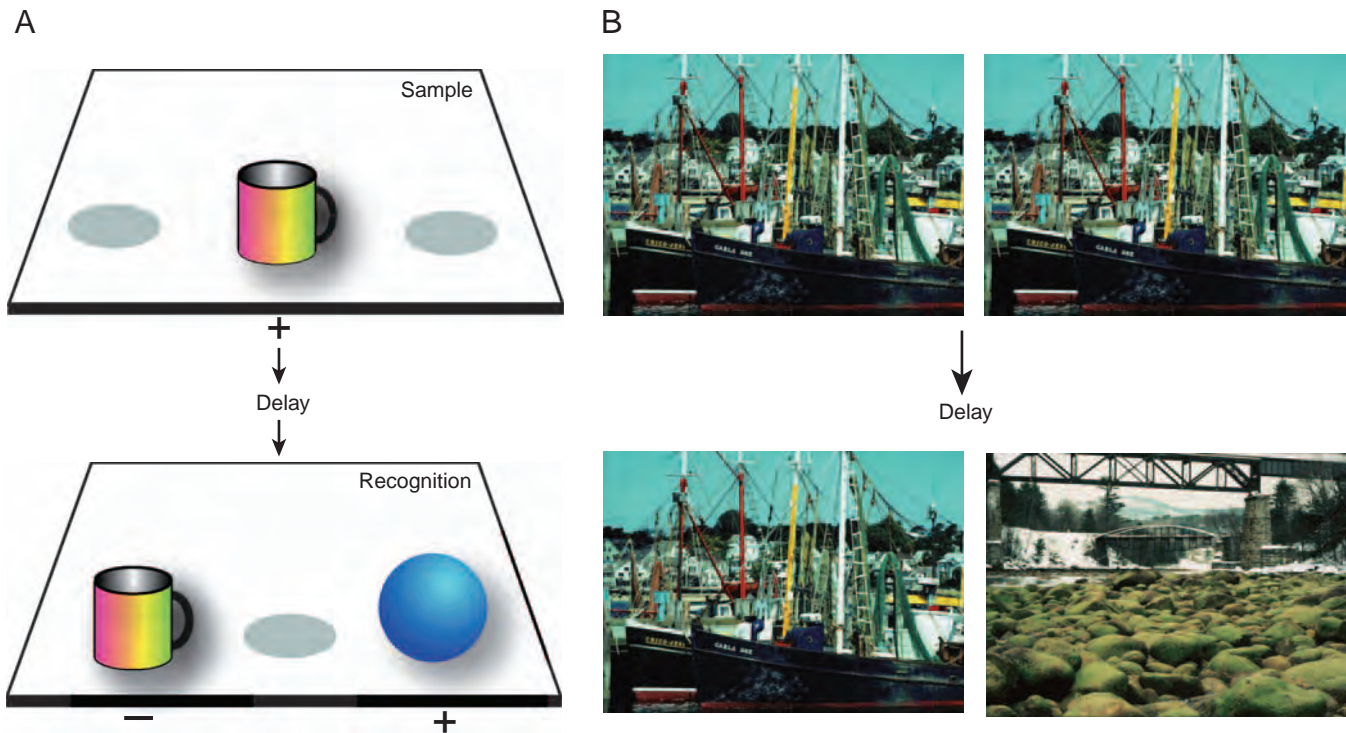

Functional brain imaging studies in humans, including functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), have shown that the hippocampal memory system is engaged in a variety of declarative memory tasks. For example, in one of the earliest studies, increased activity was observed in the hippocampus and parahippocampal region when participants viewed previously unseen photographs as compared to when participants viewed photographs that they had already seen on multiple occasions (Stern *et al.*, 1996). Subsequent studies have also found that activity in the hippocampal memory system often is related to the success of memory encoding or retrieval. For example, in one study, participants saw a list of words one at a time while being scanned (Wagner *et al.*, 1998). After the scanning session, participants were given a test to assess which words were remembered and which words were forgotten. The results indicated that activity in the hippocampal memory system during encoding (in this case, in the parahippocampal region) was greater for words that were subsequently remembered as compared to words that were forgotten. Many subsequent functional brain imaging studies have also identified memory-related activity in the hippocampus itself. Activity in the hippocampus is particularly strong in tasks that demand memory for associations that compose specific experiences (Eichenbaum *et al.*, 2007). Moreover, functional brain imaging has become a key tool for understanding how the hippocampal memory system, as well as other memory systems, ordinarily operate in the intact human brain.

### ***Models of Anterograde Amnesia in Experimental Animals***

Neuroscientists have used a specific, carefully selected set of behavioral tests in developing a nonhu-

man primate model of human amnesia to identify the particular medial temporal lobe structures that support declarative memory. The tasks involve learning about three-dimensional objects or complex pictures. In one task, delayed nonmatching to sample, subjects are shown an object once and then, after a delay, are shown two objects (the original object and a new one). The task of the monkeys is to select the new object (Fig. 50.4A). When the delay is only a few seconds, monkeys with experimental lesions that include the same medial temporal lobe structures damaged in H.M. (including the hippocampus and adjacent cortices) performed as well as normal monkeys (Mishkin, 1978). As the delay was increased, the monkeys became progressively more impaired. Thus, monkeys with medial temporal damage, like humans with amnesia, have intact immediate memory but perform poorly when the memory demand increases over time. Monkeys with medial temporal lobe damage also perform poorly when they must retain rapidly acquired object discriminations for a prolonged period. In contrast to these impairments in object memory, monkeys with medial temporal lobe damage have intact capacities for skill acquisition as measured in a task that involves learning to retrieve a candy by manipulating it along a bent rod. Thus, the pattern of both preserved and impaired memory in human amnesic patients is closely modeled by the performance of monkeys with similar brain damage (Zola-Morgan and Squire, 1985).

Using this animal model, investigators were able to identify the structures of the medial temporal lobe critical to supporting declarative memory. In H.M. the damage included the amygdala, the hippocampus, and the surrounding parahippocampal region. However, studies with monkeys have shown that the amygdala is not a part of the declarative memory system. In addition, the severity of memory impairment depends on the extent and locus of damage within the medial temporal lobe. Damage limited to the hippocampus, or to its major connections through the fornix, produces only a modest impairment. In contrast, damage that includes the adjacent cortices produces severe amnesia. Thus, the perirhinal and parahippocampal cortical regions themselves make major contributions to memory, and the hippocampus itself is a critical component of the system. Particularly compelling evidence about the role of the hippocampus in recognition memory has come from studies using a test known as the visual paired-comparison task (Zola *et al.*, 2000; Fig. 50.4B). In this task, the monkey initially is shown a pair of duplicate pictures. Then, following a variable delay, two pictures again are shown. One picture is identical to the initial sample and the other is a novel picture. Memory for the sample

**FIGURE 50.4** Recognition memory tasks used for studies of memory in nonhuman primates. Both tasks are easily adapted for human participants as well. (A) The delayed nonmatching-to-sample task using unique objects as stimuli. The subject initially is presented with a single novel object as the sample and must displace the object. This is followed by a variable delay during which the subject cannot see any objects. In the subsequent recognition test, two objects are presented, one of which is the same as the sample and the other of which is novel. Correct performance requires the subject to recognize and avoid the sample object and instead choose the novel one to receive a food reward. (B) Visual paired comparison task. During the sample phase the monkey looks at two identical pictures. In the test phase, one of the sample pictures is represented along with a novel picture. Memory for the repeated picture is inferred by measuring the subject's tendency to look away from the repeated picture and toward the new picture.

picture is measured in normal monkeys (and humans) by a lesser amount of time looking at the familiar picture than the novel one. On this test, damage limited to the hippocampus results in a rapid loss of memory such that, at a brief interval after presentation of the sample picture memory is intact, but after around 10 seconds memory is severely impaired. The overall pattern of findings supports the view that both the hippocampus as well as the adjacent cortical areas support performance on these and other tests of recognition memory.

Studies with rodents have also offered insights into the nature of memory representations in networks of hippocampal neurons. Many studies in rats have demonstrated that damage to the hippocampus results in deficits in a variety of spatial learning and memory tasks. A particularly useful example is place learning in the Morris water maze task (Morris *et al.*, 1982; Fig. 50.5). In this task, rats are trained to find a hidden escape platform submerged just below the surface in

a pool of cloudy water. Because there is no specific cue at the escape site, the rat must learn the location of the platform on the basis of spatial relationships among the cues that are visible in the room. Rats with hippocampal damage are severely impaired at this task. Additional evidence for the importance of the hippocampus in spatial memory comes from recordings of the firing patterns of hippocampal neurons in behaving rats. A major early finding in studies of hippocampal cells was that many of these neurons fire when the rat is in a particular location in its environment. This activity was shown to reflect an encoding of the spatial relationships among physical stimuli in the environment, leading experimenters to call these neurons "place cells" (O'Keefe, 1976).

Although these data indicate an essential role for the hippocampus in spatial learning, all forms of spatial learning are not dependent on the hippocampus. For example, rats with hippocampal damage can learn simple spatial discriminations, such as whether

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 50.5** The Morris water maze task. Early in training, rats search for the submerged platform for extended periods. After training the rat swims directly to the platform.

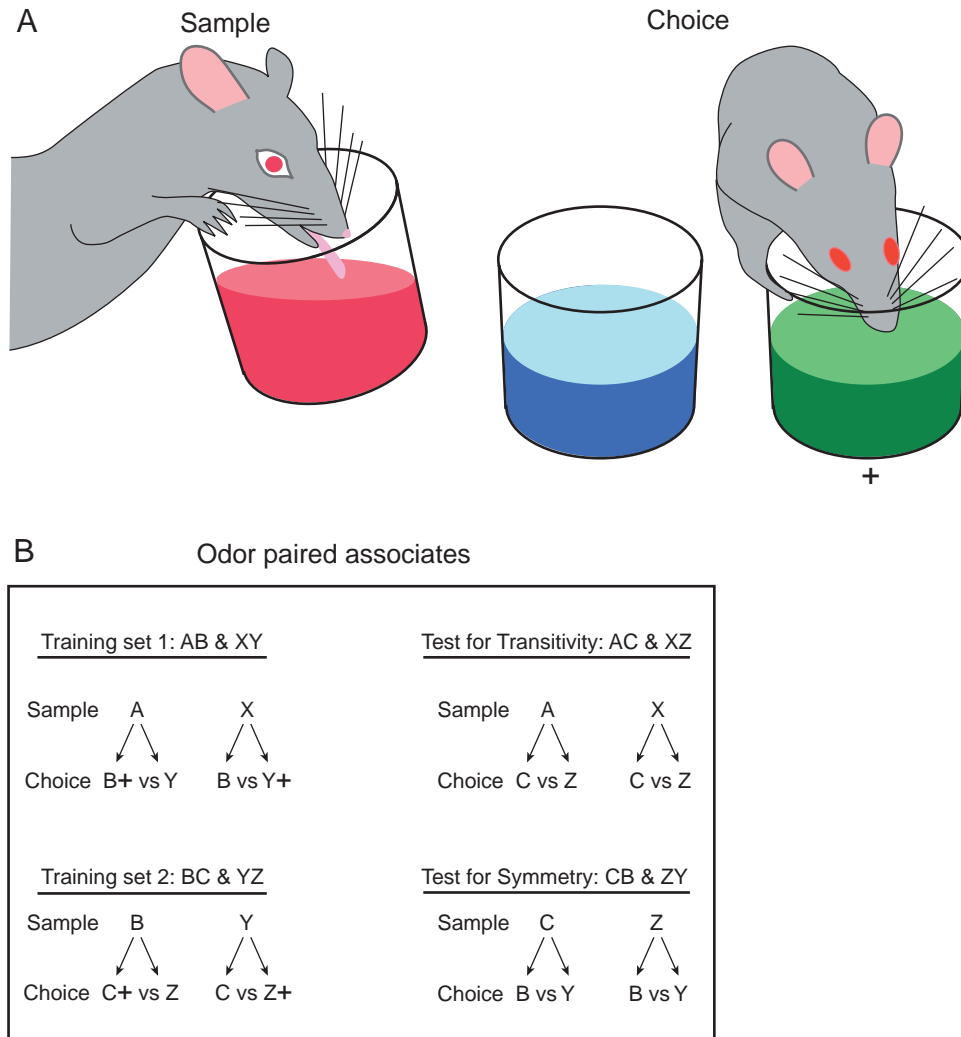

to turn left rather than right in a T-shaped maze. However they are impaired if they are forced initially to visit either the left or the right arm of the maze, and then asked to remember that experience and choose to visit the opposite arm. Rats with hippocampal damage can also learn to locate the escape platform in the Morris water maze when they are trained to find the platform from a single starting point. However, they

cannot learn if trials from different starting points are intermixed. These studies show that rats with hippocampal damage can sometimes use spatial memory to guide performance, but they cannot organize spatial information gained from different episodes to express memory flexibly according to the demands on a particular trial.

Other experimental evidence indicates that the hippocampus is also critically involved in the organization and flexible expression of nonspatial memories. For example, in one experiment intact rats and rats with damage to the hippocampus were trained to dig through sand mixed with one of a list of odors to obtain a cereal reward (Bunsey and Eichenbaum, 1996; Fig. 50.6). Initially, both healthy rats and rats with hippocampal lesions learned a set of simple associations between pairs of odors. For example, rats learned to dig in odor B when presented with odor A and to dig in odor C when presented with odor B. Subsequently, the rats were given probe tests to determine the extent to which learned representations supported two forms of flexible memory expression. One of these tests, a test for transitivity, measured the ability to infer an association between two odors that shared a common associate. For example, having learned that odor A is associated with odor B and that odor B is associated with odor C, could they infer that A is associated indirectly with C?

The other test, a test for symmetry, measured the ability to recognize associated odors when they were presented in the reverse of their training order. For example, if B is associated with C, is C associated with B? Intact rats showed strong transitivity and successfully inferred an association between A and C that had been learned only indirectly. In contrast, rats with selective hippocampal damage were severely impaired in that they showed no evidence of transitivity. In the symmetry test, healthy rats showed their associations were indeed symmetrical. In contrast, rats with hippocampal damage again were severely impaired, showing no detectable capacity for symmetry. Correspondingly, in humans the hippocampus is activated during retrieval of indirect associations during the same transitive inference judgment (Preston *et al.*, 2004; Fig. 50.7). These findings show that the role of the hippocampus in rats extends beyond spatial memory and suggest that the hippocampus encodes and retrieves nonspatial as well as spatial memories in both animals and humans.

Consistent with this view, numerous recording studies in rats, monkeys, and humans have shown that hippocampal cells also fire in association with visual, auditory, and olfactory stimuli, as well as combinations of these stimuli and the places where they occur,

**FIGURE 50.6** Associative transitivity and symmetry in paired associate learning. (A) On each training trial, one of two odors is presented as the sample. On the subsequent choice trial the animal must select the assigned associate, indicated by a “+”. (B) Outline of odor pairings used in training on two sequential sets of paired associates, plus stimuli used in tests for transitivity (C for A; Z for X) and symmetry (B for C; Y for Z). From Bunsey and Eichenbaum (1996).

suggesting that hippocampal neurons represent important stimuli in the context in which they are remembered (Ekstrom *et al.*, 2003; Wirth *et al.*, 2003; Wood *et al.*, 1999). For example, in one experiment, rats performed a variant of the delayed nonmatching to sample task that was guided by olfactory cues that were presented at several locations in an open field (Fig. 50.8A; Wood *et al.*, 1999). The activity of some hippocampal cells correlated with spatial features of the task (i.e., the rat’s location when it encountered odors), and the activity of other cells correlated with nonspatial features of the task (e.g., the identity of odors). However, a substantial number of hippocampal cells fired only when the animal encountered a particular combina-

tion of task features. For example, some cells fired when the rat sniffed a particular odor at a particular place but did so only when the odor represented the correct (i.e., nonmatch) choice. Thus, the hippocampus appeared to represent not only the locations that were common across trials but also the unique combinations of nonspatial and spatial features that may have helped the rat perform the task.

Observations also suggest that hippocampal neurons can represent sequences of events and places that compose episodic memories. For example, evidence of episodic-like coding was found in a study when rats performed a spatial alternation task on a T maze (Wood *et al.*, 2000; Fig. 50.9). Each trial began when the rat

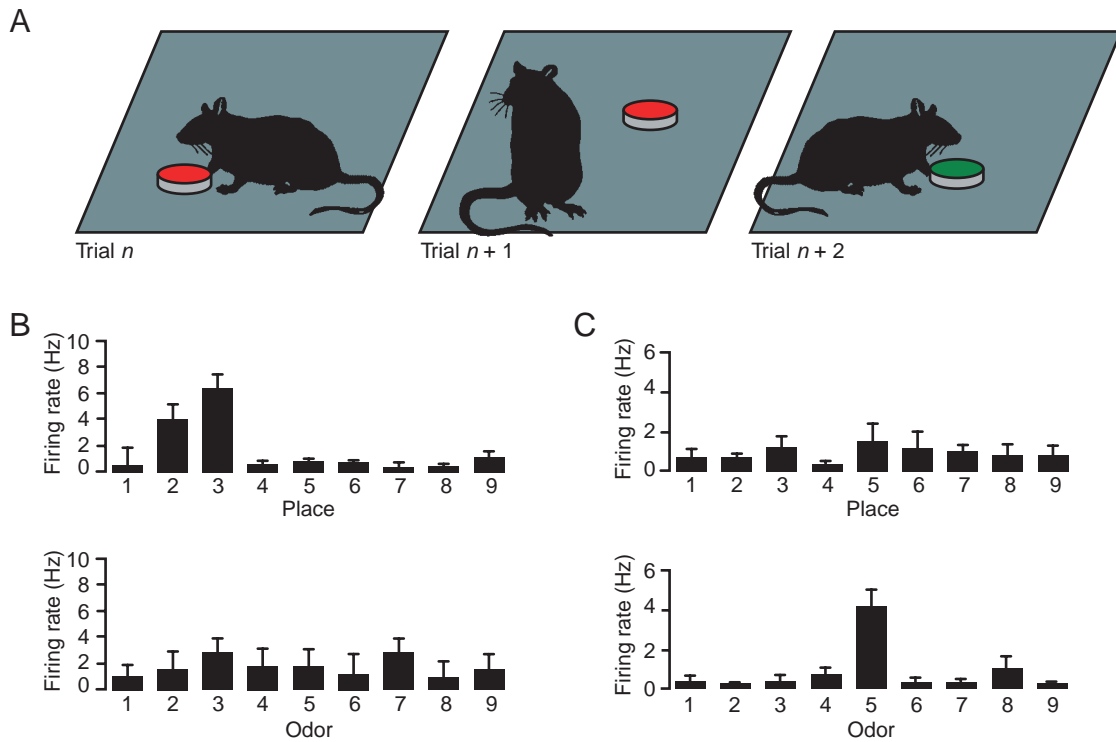

FIGURE 50.7 fMRI activity in the human hippocampus during judgments of associative transitivity. Bilateral regions in the hippocampus (indicated by yellow areas) were more active when participants used memory of face-house pairs (A-B and B-C) to infer face-face pairings (A-C) as compared to when participants simply memorized face-face pairings. **FIGURE 50.9** Selective firing during different types of memory episodes in rats performing a T maze alternation task. On left turn trials, different cells fire as the rat runs forward through a series of locations on the maze. On right turn trials, a different set of cells fire, even when the overt behavior and places are the same. From Eichenbaum (2000).

traversed the stem of the “T” and then selected either the left- or the right-choice arm. To alternate successfully, the rats were required to distinguish between their left-turn and right-turn experiences and to use the memory for their most recent previous experience so they could turn in the opposite direction on the next trial. Different hippocampal cells fired as the rats passed through the sequence of locations within the maze during each trial. These cells could be considered canonical place cells. However, in addition, the firing patterns of many of the cells depended on whether the rat was in the midst of a left- or right-turn episode, even when the rat was in the stem of the T and running similarly on both types of trials. Although the majority of the cells strongly preferred one trial type, most of the cells fired at least to some extent when the rat was at the same point in the stem on either trial type. Thus, the hippocampus encoded the left-turn and right-turn experiences using distinct representations, and these representations included information that could link them by their common features. These results suggest that the representations of event sequences, linked by codings of their common events and places, could constitute the substrate of a network of episodic memories, consistent with the idea that the hippocampus has a broad role in declarative memory.

### **Retrograde Amnesia and Consolidation**

Patients with amnesia due to medial temporal lobe damage suffer not only a deficit in learning new material (anterograde amnesia), but also loss of memories that were acquired before the brain damage (retro-

grade amnesia). Importantly, the retrograde deficit is time-limited, and material acquired shortly before the damage is affected most severely, whereas items learned earlier in life are relatively spared. For example, the profoundly amnesic patient E.P. (Fig. 50.2) has almost no capacity for new declarative learning but shows good memory from his childhood. In one study, E.P. was asked to think back to his childhood neighborhood and describe routes he would take from one location to another (e.g., grade school to the town theater; Teng and Squire, 1999). In some instances, he was asked to imagine that a main street was blocked and to describe an alternate route. E.P. performed as well as a group of healthy individuals who had lived in the neighborhood at the same time but who had moved from the area long before the study, indicating that his memory for the spatial layout of his childhood neighborhood had escaped the damage to his medial temporal lobes. By contrast, E.P. has been unable to learn the layout of the neighborhood he moved to subsequent to the onset of amnesia.

Retrograde amnesia is another aspect of the amnesic syndrome that has been studied extensively in experimental animals. For example, studies have also shown that simple object discriminations that were learned by monkeys shortly before medial temporal lobe damage are poorly retained, but discriminations learned remotely are spared. This pattern of memory impairment has been replicated in a variety of tasks in humans, monkeys, rabbits, rats, and mice and is thought to reflect a process of memory consolidation (Squire *et al.*, 2001).

The term consolidation has been used to characterize two kinds of brain events that affect the stability of memory after learning. One event involves the fixation of plasticity within synapses over a period of minutes or hours through a sequence of protein synthesis and morphological changes at synapses (Chapter 49). The other event involves a reorganization of memories, which occurs over weeks to years following new learning. This prolonged consolidation occurs in the hippocampal memory system and is thought to involve interactions between the hippocampus, parahippocampal region, and the cerebral cortex. Several models have been proposed to account for how the hippocampus might interact with other brain regions over a prolonged period in memory consolidation (Alvarez and Squire, 1995; McClelland *et al.*, 1995). These models assume that widespread areas of the neocortex contain the details of the information that is to be remembered and that areas in the hippocampal memory system support the capacity to retrieve the memory during the period shortly after learning. Over time, areas in the hippocampus are thought to reactivate the cortical rep-

representations through repetition, rehearsal, or spontaneous activity. The reactivation is then thought to induce plasticity in cortical–cortical connections, and these connections are viewed as a possible network structure for the permanent storage and organization of the memory.

Recent studies using molecular markers of neuronal activity and synaptic change have reported evidence consistent with this idea. For example, one study of maze learning in mice observed that these markers were found in high numbers in the hippocampus one day after learning but their numbers were much lower 30 days later (Maviel *et al.*, 2004). In contrast, the same markers were found to be at low levels in the cerebral cortex initially after learning but were observed to be high in various cortical areas 30 days after learning, areas including prefrontal, anterior cingulate, and retrosplenial cortices. These results suggested that plasticity in the hippocampus was initially important for the spatial memories but that over time plasticity in neocortical areas became more important.

There has long been interest in the role of sleep and dreaming in memory, and one idea has been that processes might occur during sleep that promotes the consolidation of hippocampus-dependent memories. Although the benefit of sleep to nonconscious examples of learning is generally accepted, the status of hippocampus-dependent memory is less certain (Stickgold, 2005). Nevertheless, there are several results that indicate that processes during sleep might contribute to consolidation of hippocampus-dependent memory. For example, specific patterns of activity observed in the hippocampus while rats were awake were observed to “replay” during both REM sleep and slow wave sleep (Sutherland and McNaughton, 2000). These results suggest that reactivation of memories during sleep may participate in the process of consolidation. In another study, induction of slow-wave like oscillations in the brains of human participants while they slept led to slightly improved recall upon waking (Marshall *et al.*, 2006). Thus, there is accumulating evidence regarding the role of sleep in the consolidation of hippocampus-dependent memory, but further work is needed to fully understand this process.

### Summary of Hippocampus

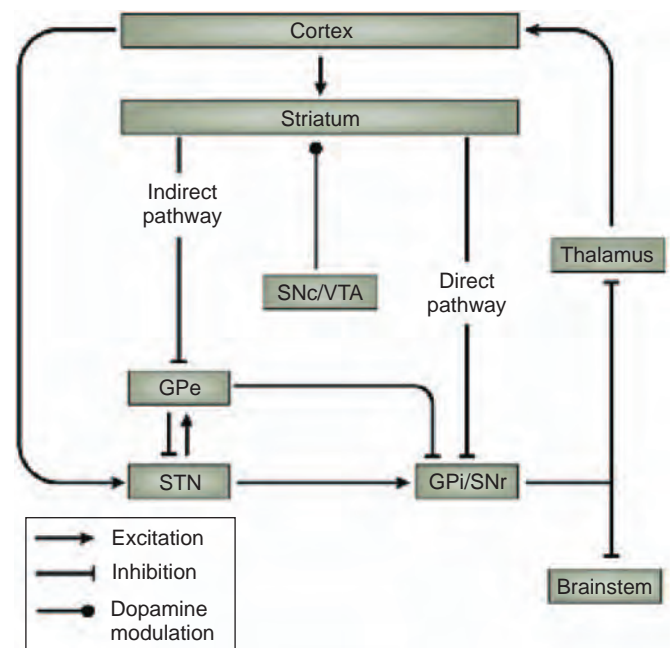

Amnesia associated with damage to the hippocampal memory system in humans is characterized by an inability to retain and consciously recollect memories of facts and events. Studies with animal models of amnesia memory provide a framework for thinking about hippocampal function in terms of memories that are represented as sequences of events remembered in the context in which they occurred and that are orga-

nized according to relations among distinct experiences. Furthermore, hippocampus-dependent memory is accessible through a variety of routes and forms of behavioral expression and supports the capacity to make generalizations and inferences from memory.

## Striatum

### Anatomy

The striatum is a major component of the basal ganglia and is involved with reward and motivation (Chapter 43) as well as with motor control (Chapter 31). The focus of the present section is the role of the striatum, particularly the dorsal striatum, in memory. The striatum receives its cortical inputs from many areas of the cerebral cortex (Fig. 50.10). The projections are organized topographically such that divergent and convergent projections into modules within the striatum might sort and associate somatosensory and motor representations. The striatum projects to other components of the basal ganglia and to the thalamus, which project back to both the premotor and motor cortex and the prefrontal association cortex. Notably, there

are minimal projections from this system to the brain stem motor nuclei and none to the spinal motor apparatus, which suggests the system operates mainly to modify cortical motor representations rather than control behavior through direct motor outputs.

### *Memory for Habits, Actions, and Outcomes*

The idea that the striatum is critical for many forms of stimulus-response habit learning was introduced in studies in experimental animals that dissociated this system from other memory systems, such as the hippocampal memory system. For example, in one study the role of the striatum in learning specific behavioral responses was demonstrated using a simple T maze apparatus where two possible strategies in solving the maze were compared directly (Packard and McGaugh, 1996; Fig. 50.11). In this study, rats began each trial at the base of the T maze and were rewarded with food at the end of one choice arm (e.g., left). Accordingly, the rats could have acquired the task by learning to make a specific turning response (a “response” strategy, left in this example). Alternatively, rats could have remembered where the reward was located relative to the surrounding stimuli in the test room, independent of any particular behavioral response required to obtain it (a “place” strategy). The critical test to distinguish these two strategies was to rotate the maze by 180° in such a way that the start point was at the opposite end of the room. After training for a week on the T maze

task, most rats used a place strategy on the probe test. However, when they were trained for another week with the maze in its original orientation and were then presented with an additional probe trial, most rats adopted a response strategy. These results suggested that under these training circumstances, initial acquisition of the task was guided by memory of the reward locus, but subsequent overtraining led to development of a habitual turning response.

Packard and McGaugh (1996) also examined whether different brain systems supported these different strategies. All animals had been implanted with indwelling cannulae that allowed injection of a local anesthetic or saline directly and locally into one of two brain structures, the hippocampus or the striatum, prior to the probe tests. The effects of the anesthetic were striking. On the first probe trial, when the striatum was inactivated, animals behaved just as controls. That is, they were predominantly place learners and the place strategy did not depend on the striatum. In contrast, when the hippocampus was inactivated, the animals showed no preference on the first probe trial, indicating that the hippocampus was essential for the place strategy and that this was the only strategy available in the early stage of learning. On the second probe test conducted after additional training, control subjects had acquired the response strategy, and inactivation of the hippocampus had no effect. In contrast, animals with the striatum inactivated lost the turning

**FIGURE 50.11** “Place” versus “response” learning. The rat is trained initially to turn left in order to obtain a reward at a particular location. In a subsequent test, the maze is rotated and the rat is allowed to select whether it will perform the same left turning “response” or remember the “place” of the previous reward.

response and instead showed that they were relying on the place strategy. The results indicated that animals normally develop an initial place strategy that depends on the hippocampus and do so prior to acquiring a habit-like response strategy. With overtraining, a response habit mediated by the striatum is acquired, and it predominates over the hippocampal place strategy. Nevertheless, the place memory can be “uncovered” by inactivating the striatum and suppressing the turning response strategy. These results suggested that there are distinct types of memory that guide place and response strategies, that the response strategy tends to be acquired more slowly than place memory, and that the response strategy is supported by the striatum.

More recent research has suggested that the memory supported by the striatum is not necessarily acquired slowly. For example, one study that recorded from neurons in the striatum and prefrontal cortex in monkeys found that the striatal neurons led prefrontal neurons in tracking the reversal of action-outcome contingencies (Pasupathy and Miller, 2005). On each day of testing, monkeys were trained to move their eyes left after seeing one novel picture and to move their eyes right after seeing a second novel picture. Monkeys were rewarded with juice with each correct response. After the monkeys learned these associations, the picture-direction associations were reversed (e.g., the first picture then indicated that right was the appropriate response). During the trials when the monkeys were learning to reverse their responses to the pictures, neuronal activity related to viewing the pictures in both the striatum and prefrontal cortex mirrored the monkeys’ improvement in performance. However, the striatal activity led the prefrontal activity in two ways. First, on each trial the onset of activity in the striatal neurons tended to occur before the onset of the prefrontal neurons. Second, a relationship between the neuronal activity while viewing each picture and the subsequent correct eye movement emerged in fewer trials in the striatum as compared to the prefrontal cortex. The observation that activity in the striatum in this task reflected reversal of a learned association more quickly than the prefrontal cortex suggests that memory supported by the striatum may not necessarily be particularly slow and may be used to instruct the prefrontal cortex in mediating complex stimulus-response associations.

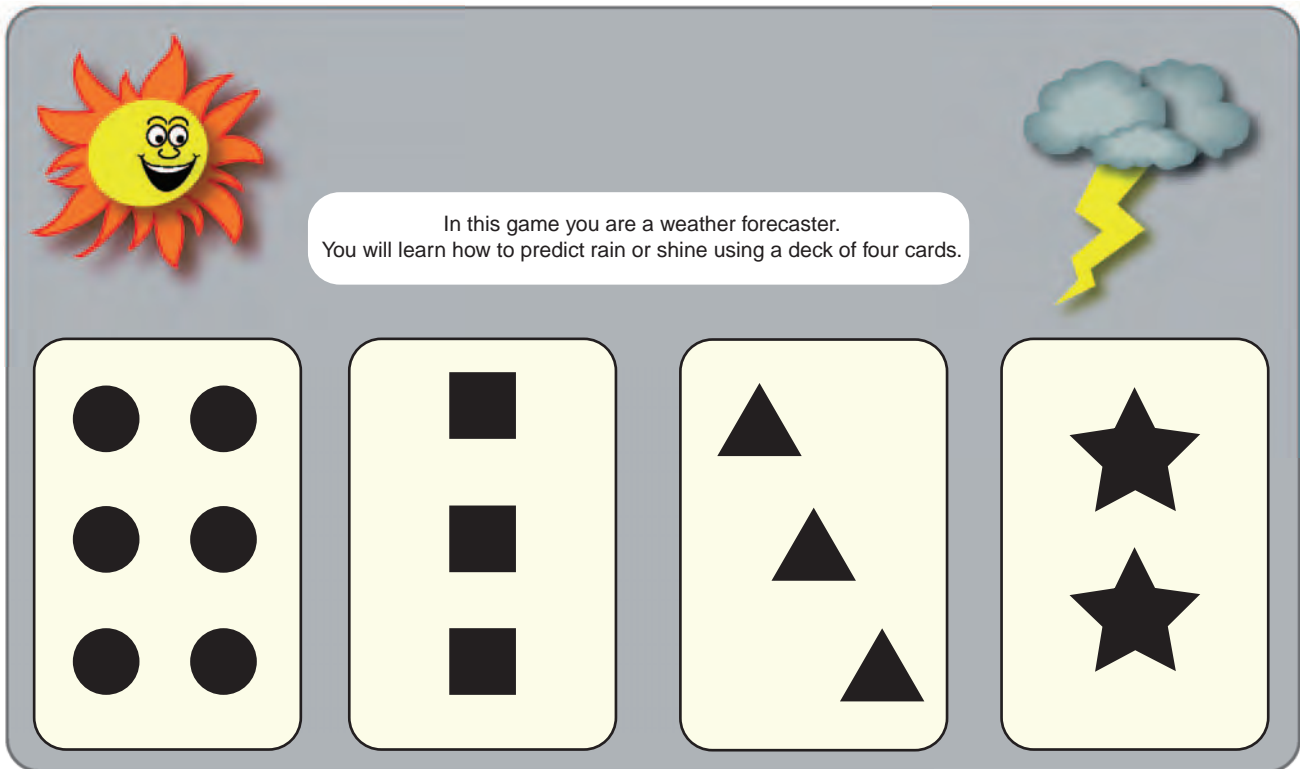

Research with human participants has also indicated that the striatal system may play a critical role in memory even for more complex forms of stimulus-response learning. For example, Knowlton and colleagues (1996) tested patients in the early stages of Parkinson’s disease on a probabilistic classification

learning task formatted as a weather prediction game (Fig. 50.12). Parkinson’s disease is associated with the degeneration of neurons in the substantia nigra and a resulting major loss of input to the striatum. Amnesic patients were also tested, and their results contrasted with that of the Parkinson’s patients. The task involved predicting on each trial one of two possible outcomes (“rain” or “sunshine”) based on cues that were presented to the subject. On each trial, one, two, or three cards from a deck of four were presented. Each card was associated with the sunshine outcome independently and probabilistically, 75%, 57%, 43%, or 25% of the time, and the outcome with multiple cards was determined by the conjoint probabilities. After the cards were presented on each trial, the subject was asked to choose between rain and shine and was then given feedback (correct or incorrect). The probabilistic nature of the task made it difficult for subjects to improve by recalling specific previous trials because the same configuration of cues could lead to different outcomes. The most useful information was the probability associated with particular cues and combinations of cues, which could be acquired gradually across trials much as habits and skills are acquired. Over a block of 50 trials, normal subjects gradually improved from pure guessing (50% correct) to about 70% correct. However, patients with Parkinson’s disease failed to show significant learning, and the failure was particularly evident in those patients with more severe parkinsonian symptoms. In contrast, amnesic patients were successful in learning the task, achieving levels of accuracy similar to the controls by the end of the 50-trial block.

Subsequent to training on the weather prediction task, these subjects were given a set of multiple-choice questions about the nature of the task and the kinds of stimulus materials they had encountered. Normal subjects and patients with Parkinson’s disease performed very well in recalling the task events. In contrast, the amnesic patients were severely impaired. Thus this example of probabilistic classification learning was disrupted by striatal damage, whereas declarative memory for the learning events was impaired by hippocampal or diencephalic damage.

### *Summary of Striatum*

The dorsal striatum supports learning that accrues over repeated trials and supports examples of stimulus-response, habit-like learning. However, the dorsal striatum also supports memory that goes beyond simple stimulus-response learning and includes probabilistic classification learning as well as examples in which subjects learn about reversals of outcomes of particular actions.

## Cerebellum

### Anatomy

The cerebellum consists of the cerebellar cortex, which has been divided into lobes and further into lobules, and several deep cerebellar nuclei (see Chapter 32 for more detailed anatomy). The cerebellum receives direct input from the spinal cord and brain stem as well as indirect input from a variety of sensory and motor areas in the cerebral cortex via pontine nuclei in the brain stem. The cerebellum projects directly to the spinal cord, brain stem, hypothalamus, and thalamus, and the thalamic targets in turn project to various motor and nonmotor areas in the cortex, particularly in the frontal lobes (Middleton and Strick, 1998). The internal circuitry of the cerebellum has been described as modular, with a local wiring diagram that is repeated again and again throughout the cerebellar cortex. This modularity raises the possibility that, although different regions of the cerebellar cortex receive different input, each region might perform a similar set of operations on that information before passing the results back out to the rest of the nervous system (Boyden *et al.*, 2004).

The cerebellum has long been associated with aspects of motor learning. For example, the cerebellum supports specific sensory-to-motor adaptations and adjustments of reflexes, such as changing the force that one exerts to compensate for a new load or acquiring conditioned reflexes that involve associating novel motor responses to a new stimulus. More recently, the cerebellum also has been associated with nonmotor learning and other examples of cognition and behavior. Based on the idea that the modular circuitry of the cerebellum offers a generalized capacity for processing of specific inputs, the present section focuses on one example of cerebellar-dependent learning as a framework for highlighting the role of the cerebellum in memory.

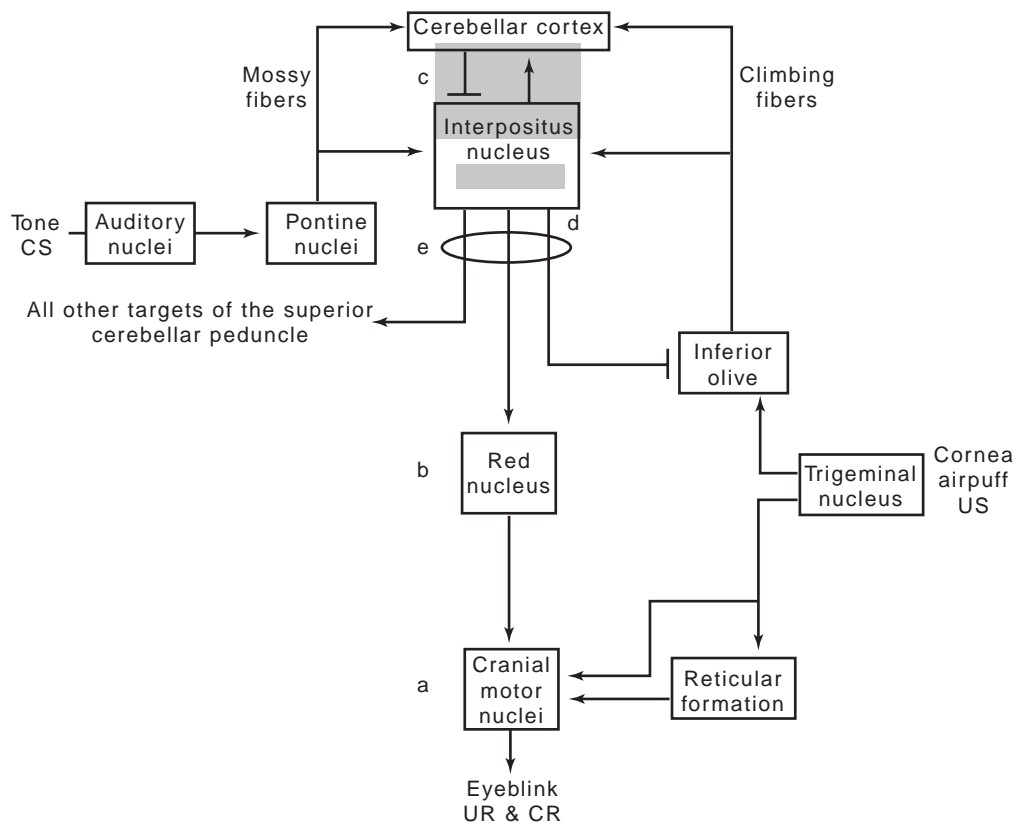

### *Eyeblink Classical Conditioning as a Prototype of Cerebellum-Dependent Memory*

Eyeblink classical conditioning has been used frequently as a model of cerebellum-dependent learning, and is perhaps the best understood form of associative memory in vertebrates. In this paradigm, experimental animals (typically rabbits due to their tolerance for physical restraint) are placed in restraining chambers

where a well-controlled tone or light is presented as the conditioning stimulus (the CS). In classic “delay” conditioning protocol, the CS lasts 250–1000ms and coterminates with an air puff or mild electrical shock to the eye (the unconditioned stimulus or US) that produces a reflexive, unconditioned eyeblink (the UR). After many pairings of CS and US, the animal begins to produce the eyeblink after onset of the CS and prior to presentation of the US. With further training, the conditioned response (CR) occurs earlier, and its timing becomes optimized so as to be maximal at the US onset. Amazingly enough, rabbits with no cerebral cortex, basal ganglia, limbic system, thalamus, or hypothalamus showed normal retention of the conditioned eyeblink response (Mauk and Thompson, 1987). Further, in humans, conditioning can proceed without knowledge of the relationships between the conditioning stimuli (Clark *et al.*, 2002).

The essential cerebellar and brain stem circuitry that supports eyeblink conditioning has been carefully delineated by Thompson and colleagues (Fig. 50.13;

Thompson, 2005). In their studies, permanent lesions or reversible inactivation of one particular cerebellar nucleus, the interpositus nucleus, resulted in impaired acquisition and retention of classically conditioned eyeblink reflexes without affecting reflexive eyeblinks (URs). Additional compelling data indicating an important role for the interpositus nucleus in this kind of motor memory come from studies using reversible inactivations of particular brain regions during training. These studies showed that drug inactivation of motor nuclei that are essential for production of the CR and UR prevented the elicitation of behavior during training. However, in trials immediately following removal of the inactivation, CRs appeared in full form, showing that the neural circuit that supports UR production is not critical for learning *per se*. A similar pattern of results was obtained with inactivation of the axons leaving the interpositus nucleus or their target in the red nucleus, showing that the final pathway for CR production is also not required to establish the memory trace. These results, in combination with

**FIGURE 50.13** A schematic diagram of principal pathways involved in classical conditioning of the eyeblink reflex. The role of structures at points a–e has been studied using reversible inactivation with a local anesthetic. Inactivation at point “c” (shaded areas) prevents learning, whereas inactivation at “a,” “b,” “d,” or “e” prevents the behavioral response during inactivation, but does not block learning. From Thompson and Kim (1996).

results from other studies that addressed candidate regions upstream from the interpositus nucleus, point to areas in the interpositus nucleus as an essential locus of plasticity in this form of motor learning. Additional studies have indicated that the cerebellar cortex is important for modulating the learning, such as by influencing the timing of the conditioned response to ensure that it is adaptive. As in animals, damage to the cerebellum in humans also retards the classically conditioned eyeblink reflex.

### Summary of Cerebellum

Eyeblink classical conditioning is one example of learning that depends on the cerebellum. Other frequently studied examples include adaptations of the vestibulo-ocular reflex and coordinated motor skill learning. The circuitry essential for eyeblink conditioning has been identified and provides an experimentally tractable opportunity to investigate what may be generalized learning processes supported by the cerebellum. These processes may contribute generally to motor reflex learning or even more generally to mental processing involved in precise timing.

## Amygdala

### Anatomy

The amygdala is a collection of anatomically and functionally heterogeneous nuclei (Swanson and Petrovich, 1998). The two major areas of the amygdala involved in emotional memory are the basolateral amygdala complex (BLA; includes the lateral, basolateral, and basomedial nuclei) and the central nucleus of the amygdala (CEA; Fig. 50.14B). The BLA receives input from widespread cortical areas as well as from sensory nuclei of the thalamus and thus has access to higher-level information from association areas as well as lower-level sensory information. In addition, the BLA has reciprocal connections with other brain systems, including the hippocampal and striatal memory systems. Areas within the BLA project to the central nucleus, which is the source of outputs to subcortical areas controlling a broad range of fear-related behaviors, including autonomic and motor responses (e.g., changes in heart rate, blood pressure, sweating, hormone release and alterations in startle response).

The amygdala contributes to emotion in several ways, including mediating emotional influences on attention and perception and regulating emotional responses (Phelps and LeDoux, 2005). The topic of the present section is the two ways in which the amygdala contributes to emotional memory. First, the amygdala supports the acquisition of emotional dispositions

toward stimuli. This kind of memory includes preferences and aversions that can be learned unconsciously and independent of declarative memory for the events in which the disposition was acquired. Second, the amygdala mediates the influence of emotion on the consolidation of memory in other memory systems.

### Role of the Amygdala in Acquiring Emotional Dispositions to Stimuli

Much of the research directed toward understanding the role of the amygdala in acquiring emotional dispositions to stimuli has focused on the circuitry that supports acquisition of fearful responses to simple auditory or visual stimuli (Davis, 1992; LeDoux, 2000; Fanselow and Gale, 2003). For example, in one frequently used task, rats are initially habituated to a chamber and then are presented with multiple pairings of a tone that terminates with a brief electric shock delivered through the floor of the cage (Fig. 50.14A). Subsequently, conditioned fear elicited by the tone is assessed by measuring autonomic responses, such as changes in arterial pressure, and motor responses, such as stereotypic crouching or freezing behavior. Rats with lesions in the BLA show dramatically reduced conditioned fear responses to the tone in measures of both autonomic and motor responses but still show normal unconditioned fear responses to the shock itself. Rats with lesions to the central nucleus show reduced fear responses to both conditioned and unconditioned stimuli. Thus, the BLA appears to be important for acquiring an aversion to the tone, whereas the central nucleus appears to be important for producing fearful responses in general.

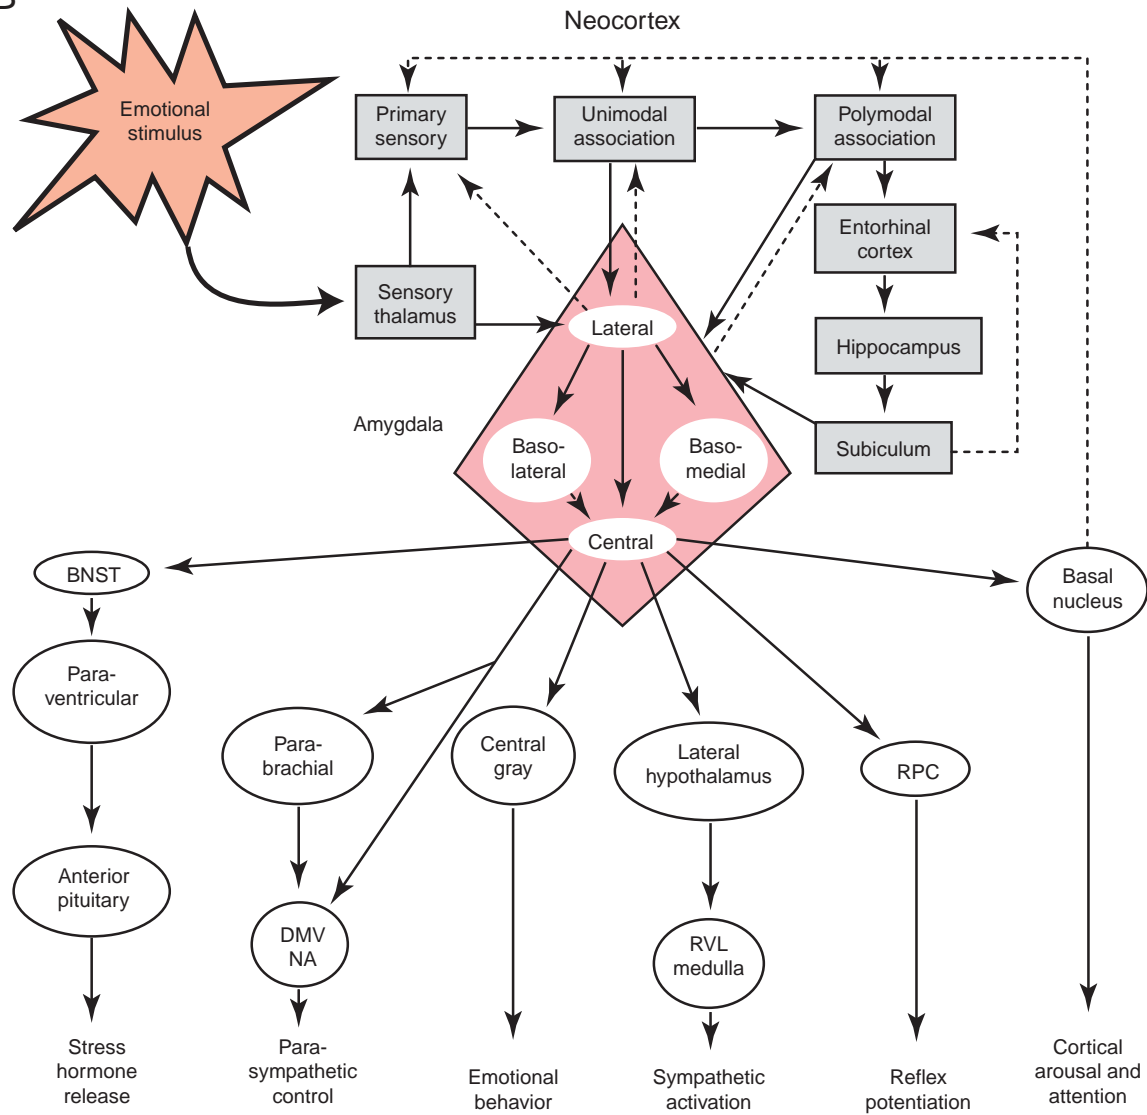

This basic procedure has been adapted for use with human participants, and one study that included patients with damage to the amygdala or hippocampus helped to distinguish the type of memory supported by these two structures (Bechara *et al.*, 1995). In this study, participants were trained in a discriminative fear-conditioning protocol in which, on some trials, a monochrome color stimulus (reinforced

**FIGURE 50.14** Fear conditioning. (A) Prior to training, the tone produces a transient orienting response. During training the tone is followed by a brief foot shock. Following training, the rat is reintroduced into the chamber and freezes when the tone is presented. (B) Anatomical pathways that mediate fear conditioning. A hierarchy of sensory inputs converges on the lateral amygdala nucleus, which projects to other amygdala nuclei and then to the central nucleus, which send outputs to several effector systems for emotional responses. conditioned stimulus, CS+) was presented for 2s and then was terminated just as an unconditioned stimulus was sounded briefly (US; a loud boat horn). Autonomic responses to these stimuli were measured as skin conductance changes through electrodermal recordings, a measure used often as an indicator of fear or anxiety. On other trials, different colors (unreinforced conditioned stimulus, CS-) were presented without the boat horn. Healthy individuals typically showed strong electrodermal responses to the US and with training came to show conditioned responses to the CS+ but smaller or no responses to CS- stimuli. Thus, the subjects acquired a specific fearful response to the CS+. One patient with selective damage to the amygdala showed normal unconditioned responses to the US but failed to develop conditioned responses to CS+ stimuli. In contrast, a patient with selective hippocampal damage showed robust skin conductance changes to the US and normal conditioning to CS+ stimuli and appropriately smaller responses to CS- stimuli. Control subjects and the patient with selective amygdala damage answered most of these questions correctly, but the patient with hippocampal damage was severely impaired in recollecting the training events. These findings indicated that emotional conditioning was disrupted by amygdala damage and that declarative memory for the learning situation was impaired by hippocampal damage.

### Role of the Amygdala in the Modulation of Memory

Memories of emotionally arousing events are often more vivid, more accurate, and longer lasting than memories of more neutral events. Indeed, it is adaptive for organisms to remember important events better than trivial events. Thus, it also makes sense that the brain should have evolved mechanisms for storing information in accordance with how much the information is worth remembering. Evidence from a large number of studies in experimental animals has indicated that the amygdala, in particular the BLA, mediates this memory enhancing effect (McGaugh, 2004).

Emotionally arousing events result in the release of epinephrine and glucocorticoids by the adrenal glands, which in turn result in the release of norepinephrine in the amygdala (Fig. 50.15). The release of norepinephrine leads to an increase in activity in the amygdala, which is thought to influence consolidation of memory in the other parts of the brain, either directly, though connections of the amygdala with the striatum, hippocampus, and cortex, or indirectly, through connections with nucleus basalis (which innervates much of the cortex). Data in support of this model include the findings that damage to the BLA or infusions of drugs in the BLA that interfere with norepinephrine

**FIGURE 50.15** A schematic representation of how hormonal systems and the amygdala complex can modulate the storage of memory for emotionally arousing events through influences on other brain systems. See text for details. From McGaugh *et al.* (1992).

block the memory enhancing effect of emotional arousal. In addition, damage to pathways out of the amygdala, in particular the stria terminalis, also have a similar effect. Furthermore, the modulatory influence of the BLA seems to be limited to the time of the learning event as well as a short period of time after. Inactivation of the amygdala during subsequent testing of retention does not influence memory performance. Thus, the amygdala is important in modulating storage in emotionally stressful situations, but not in the maintenance or retrieval of the memory that has been modulated.

The amygdala has been strongly implicated in the enhancement of memory for emotional material in humans as well as in experimental animals. In one study, a patient with damage to the amygdala was tested for memory of an emotional story along with a group of healthy individuals (Adolphs *et al.*, 1997). The participants watched a series of slides and listened to an accompanying narrative that told a story about a mother and son. One portion of the story involved a traumatic accident, and all participants rated this

portion as being strongly emotional. Compared to the healthy individuals, the patient with damage to the amygdala failed to show enhancement of memory for the emotional part of the story. However, the patient performed as well as others on neutral story material. In brain imaging studies with healthy individuals, the amygdala was activated during the viewing of emotional material that elicited either positive or negative emotional reactions, and this activation was related to the likelihood that participants subsequently were able to remember the emotional material. In these studies, there was no correlation between activation of the amygdala and subsequent memory performance for neutral material.

### *Summary of Amygdala*

The amygdala is well situated anatomically to attach emotional (positive and negative) dispositions to a broad range of stimuli and to mediate the acquisition of such dispositions in the absence of conscious recollection of the circumstances of the emotional experience. In addition, components of the amygdala also mediate the modulation of memory storage during and after emotional events. Memory-modulation mechanisms are an efficient, evolutionarily adaptive method of ensuring that the strength of a memory tends to be proportional to its importance.

## Cerebral Cortex

### *Anatomy*

As discussed in Chapter 2, the posterior half of the cerebral cortex contains many functionally distinct areas that are organized into hierarchies of serial and parallel processing for each sensory modality. Additionally, there are cortical areas where information from different modalities converges (so-called “association” areas) in the parietal and temporal lobes. The anterior cerebral cortex contains a similar hierarchy of motor areas, as well as association areas in the prefrontal cortex involved with motor planning, higher order cognition, and working memory (Fuster, 2001; Chapter 52).

Some of the examples provided so far, such as standard eyeblink classical conditioning, illustrate that some simple forms of learning can circumvent the cerebral cortex. Although simplified learning paradigms are indispensable as precise instruments to dissect local circuitry, these examples should not overshadow the fact that the global circuitry of each memory system discussed so far includes the cerebral cortex. The cerebral cortex provides access to incoming information as well as output routes to influence

behavior, access that is important for even the cerebellum. Yet plasticity in the cerebral cortex also directly supports types of memory that do not require components of the other memory systems. For each area of the cortex, the modification of its information processing circuitry through alterations in synaptic connectivity and membrane excitability underlies its direct participation in memory. These alterations can be dramatic, such as in examples of experience-dependent reorganization that occurs in perceptual learning, but can also be more subtle, such as in the phenomenon of repetition priming.

### *Perceptual Learning*

Specific training experiences can result in the modification of specific parts of the cortex. For example, in one study, monkeys were trained over a period of several weeks to discriminate small frequency differences in tone stimuli. In subsequent recordings, increases were observed in the size of the auditory cortex representation of the task-relevant frequencies and the sharpness of tuning to these frequencies (Recanzone *et al.*, 1993). Furthermore, changes in area of the cortical representation were correlated with the improvement in task performance. In other studies using classical conditioning in anesthetized guinea pigs, the tuning curves of single neurons in the auditory cortex were first characterized (Weinberger, 2007). Individual neurons typically showed preferences for a specific tone frequency. Subsequently, the animal was presented with repeated pairings of a nonpreferred tone and foot shocks. This training resulted in long-lasting shifts in the tuning curves of auditory neurons toward the frequency of the training stimulus. A similar expansion of perceptual representations for training stimuli has been observed in the somatosensory cortex of monkeys following acquisition of a tactile discrimination. The alterations of the sensory cortex following experience is thought to contribute to adaptations and tuning of perceptual representation systems and, in coordination with reorganization of cortical motor representations, may also contribute to procedural memories. In both cases, this contribution is derived specifically from alterations in the perceptual and motor processing for the relevant learning tasks.

Functional imaging studies in humans have revealed that perceptual learning can occur for stimuli that are more complex than simple tones, yet similar to the studies in guinea pigs with tones, these studies have also suggested that the cortical area important for perceiving the stimuli is also an important area of plasticity. For example, in one study participants were scanned while viewing pictures of nonsense objects

both before and after performing a perceptual discrimination task that included half of the objects (Op de Beeck, 2006). Following the perceptual discrimination task, the pattern of brain activity in object-responsive areas in visual cortex had changed for the objects included in the discrimination task but did not differ for the objects not included in the discrimination task. Thus, it appears that many of the areas in the cerebral cortex that are specialized for specific perceptual or information processing functions—from areas involved in perceiving simple tones to areas involved in perceiving complex objects—are capable of supporting perceptual learning for those stimuli.

### *Repetition Priming*

Another example of memory thought to be supported directly by the cerebral cortex is the phenomenon known as repetition priming (or priming). Priming involves initial presentation of a list of words, pictures of objects, or nonverbal materials and then subsequent reexposure to fragments or very brief presentation of whole items. For example, in one version of priming, words are flashed on a screen so briefly that many of the words are unreadable. The measure of priming is the increased likelihood of identifying previously viewed words as compared to words not encountered recently, and the benefit of repetition has been found to be independent of the ability to recognize which words had been read initially. Studies with brain-damaged patients suggest that priming depends on cortical areas involved in initially processing the stimuli. In one study, the amnesic patient H.M. and a patient with a large lesion in the right visual cortex attempted to read new and repeated words flashed on a computer screen (Keane *et al.*, 1995). Healthy individuals and H.M. showed evidence of priming for the repeated words, but the patient with visual cortex damage did not, suggesting that the priming effect depended on perceptual areas in the visual cortex. In contrast, the patient with visual cortex damage performed normally on conventional memory tests. In functional brain imaging studies with healthy individuals, the visual cortex showed decreased activation to recently presented materials, suggesting that less neural activity is required to identify words recently processed. These findings suggest that the neuronal basis of priming is an increase in the efficiency and bias in the direction of cortical sensory processing associated with perceptual identification.

### *Summary of Cerebral Cortex*

Studies in both animals and humans show that the cerebral cortex is highly plastic in that its representations can be altered after experience. Distinct cortical

areas are reorganized by specific training experiences to meet demands for specific types of perceptual representation and memory. Also, modality-relevant cortical circuits are able to support the priming of perceptual representations.

## BEHAVIOR SUPPORTED BY MULTIPLE MEMORY SYSTEMS

The discussion of memory systems so far has focused on dissociations between systems in illustrating the unique contributions of the central structure in each system. However, behavior is a product of the entire nervous system and typically is guided by contributions of more than one form of memory. For example, training in a sport normally results in declarative memory of instructions from one's coach but also leads to motor skill learning from repetitive practice. The following section considers emerging data regarding how the memory systems discussed so far might collaborate, compete, or operate in parallel and illustrates some progress in understanding how the distribution of memory throughout the brain ordinarily contributes to our day-to-day activities.

One example of a direct collaboration between two memory systems is the influence of the amygdala on hippocampus-dependent memory for emotion-inducing material. The section earlier in the chapter on the amygdala discussed how emotional arousal leads to the amygdala engaging in modulation of declarative memory, such that stimuli that elicit either positive or negative emotional responses tend to be remembered better than neutral stimuli. This process is thought to result from amygdalar projections modulating synaptic plasticity either in the hippocampus and parahippocampal region or in cortical areas fundamental to the hippocampal memory system. It has been suggested that the amygdala also modulates other memory systems, such as the striatal memory system, and that the amygdala may play a generalized role in memory modulation for emotion inducing stimuli in addition to its role in attaching positive or negative dispositions to stimuli (McGaugh, 2005).

Another example comes from an indirect collaboration between two very dissimilar memory systems, the hippocampal memory system and the cerebellar memory system. The section earlier in the chapter on the cerebellum detailed that the essential circuitry for standard eyeblink classical conditioning involved no forebrain structures and instead centered on deep cerebellar nuclei. Yet the situation changes if the parameters for standard eyeblink classical conditioning,

referred to as delay eyeblink conditioning, are altered slightly such that the tone that normally overlaps with the airpuff is moved earlier in time such that it terminates as little as a half second prior to the onset of the airpuff, a version called trace conditioning (Christian and Thompson, 2003). Trace eyeblink conditioning depends on the same cerebellar and hindbrain circuitry as delay eyeblink conditioning, but trace conditioning depends additionally on forebrain structures including the hippocampus and prefrontal cortex. In studies with healthy human participants, trace (but not delay) eyeblink conditioning was found to relate closely to participants' knowledge about the relationship between the tone and the airpuff (Clark *et al.*, 2001). A possible explanation of these findings is that the silent interval that separates the tone and airpuff may outstrip the learning abilities of the cerebellum and may cause it to require inputs from additional forebrain structures, such as the hippocampal system, to bridge that brief interval. The growing understanding of the relationship between hippocampus and cerebellum illustrates the tendency to collaborate between even the most dissimilar memory systems, and exemplifies the progress being made toward understanding how memory systems interact in general.

In other examples, memory systems may operate in parallel or may even compete for control of behavior. For example, the previously discussed studies contrasting the role of the striatum and hippocampus in supporting "response" learning and "place" learning, respectively, illustrate how the memory supported by different brain systems can be at odds with each other. Yet in the example of practicing a sport, the hippocampus-dependent memory for a coach's instructions and the striatal "response" learning would likely support a common behavior. In these instances, it is thought that the striatum and hippocampus contribute to behavior in parallel rather than directly interacting. One can start to get a sense of the often collaborative spirit of brain when one further considers that the emotional arousal that often accompanies athletic competition would likely engage amygdalar modulation of both the hippocampal memory system and the striatal memory systems.

## CONCLUSION

Several brain systems support distinct forms of memory characterized by unique operating features and ways in which memory is expressed. The hippocampus supports rapidly acquired memory that is experienced as conscious recollection and that can be

expressed flexibly. The striatum supports gradual acquisition of habits. The cerebellum supports learning related to timing and motor reflexes. The amygdala supports acquisition of emotional dispositions toward stimuli and also mediates the role of emotion arousal in modulating other forms of memory. The cerebral cortex participates in each of these types of memory, and mediates perceptual learning and the phenomenon of priming. These systems also often operate in concert to support the various ways that behavior and mental life can be modified by experience.

# Language and Communication

This chapter discusses the nature of language and the relationship of language to the brain. It begins with a discussion of animal communication, from which human language evolved and which provides a guide to the basic neural elements and processes that underlie our own system of communication. The next section of the chapter provides a brief summary of what human language is and how it is processed. The third section looks at how human language is related to the brain, relying on studies of patients with various types of neurological diseases and on brain imaging in normal subjects.

## ANIMAL COMMUNICATION

### Communication Is Important for Individual Survival

The ultimate goal of most animal communication, like that of behavior in general, is reproduction. Thus, signals that indicate the sender's species, gender, and degree of reproductive readiness account for the vast majority of natural communication. These are the messages being broadcast by chirping crickets, flashing fireflies, pheromone-releasing moths, and singing birds. Frequently, the mate-attraction call also is used to warn off potential rivals; for example, bird and cricket songs also are used to identify the boundaries of territories or personal space. Differences in signal quality are the usual basis of mate choice in species for which some degree of discrimination is evident. This competition for the attention of members of the opposite sex has led to the development of more conspicuous signals and, in many cases, to the evolution

of displays, signaling morphology (i.e., sounds vs. shapes vs. color vs. movement vs. odors), and messages that go far beyond the basic needs of species and sexual identification (Gould and Gould, 1996). Some researchers argue that sexual competition was an important selective factor in the evolution of human speech.

Most animals are solitary except when mating; they abandon their eggs or larvae before the offspring are born. However, a number of species engage in some degree of parental care. For them, signals between parent and offspring are often very important. Most birds, for instance, have about two dozen innate calls that communicate mundane messages such as the need to eat, defecate, take cover, and so on. In cases in which both parents tend the young—the usual circumstance in birds, for instance—additional signals are required to agree on a nest site, synchronize brooding shifts, and guard the nestlings. Most primates also come equipped with two to three dozen innate signals.

The minority of species that are highly social have the most elaborate communication systems of all. They need messages for a variety of elements of social coordination, including, in many cases, group hunting or foraging, defense, and working out of a social hierarchy.

### Animal Communication Strategies and Mechanisms

Attracting a mate is vital to the survival of an individual's genes. To ensure species specificity in mating, most organisms rely on more than one cue to identify a sexual partner. (Exceptions include some of the species that rely on pheromones.) Thus, multiple signals are sent, and a choice must be made between

sending simultaneous messages and sending sequential messages (or a combination of the two). The sequential strategy has the advantage that the individual signals must be correct *and* the order must be appropriate. A female stickleback, for instance, requires the male to have a red ventral stripe, perform a zig-zag dance, poke his nose in a nest, and then vibrate her abdomen; the odds of this concatenation of signals occurring together in this order by chance are remote. A human sentence in a word-order language like English operates roughly in this way. However, sequential signaling is time-consuming. A faster strategy is to provide all the cues in parallel, an approach that accepts the larger chance that these cues can occur together by chance. For example, when a parent herring gull waves its bill in front of chicks to see if they need to be fed, the young simultaneously see a vertical beak, a red spot, and a horizontal motion, each of which is a discrete cue that combine in the mind of the chick to elicit pecking.

Nearly all animal communication is innate: the sender produces the appropriate signal in the correct context even without any opportunity for learning, and it can be recognized for what it is by equally naive conspecifics. The basis of innate recognition appears to lie with feature detectors in the nervous systems—the inborn circuits that automatically isolate iconic visual or acoustic elements (Gould, 1982). The availability of many visual, auditory, tactile, and olfactory feature detectors, which can, in theory, be used in any specific combination or order, accounts for most of the diversity of animal communication, and reliance on these individual feature detectors, rather than pattern detection, accounts for its limitations.

### Innate Communication Systems Coupled with Learning

A common misapprehension is that complex behaviors must be learned. In fact, complex behavior in relatively short-lived species is usually innate, reflecting the reality that intricate activities are very difficult to learn and may require more time and risk of errors than an animal can afford (Gould and Gould, 1999). Thus, so far as is known, all bird nests are built on the basis of innate instructions, although some improvement with experience is also evident (Gould and Gould 2007). Therefore, looking at just how complex innate communication can be is a useful calibration for the often-made assumption that something as intricate as human language must be largely learned.

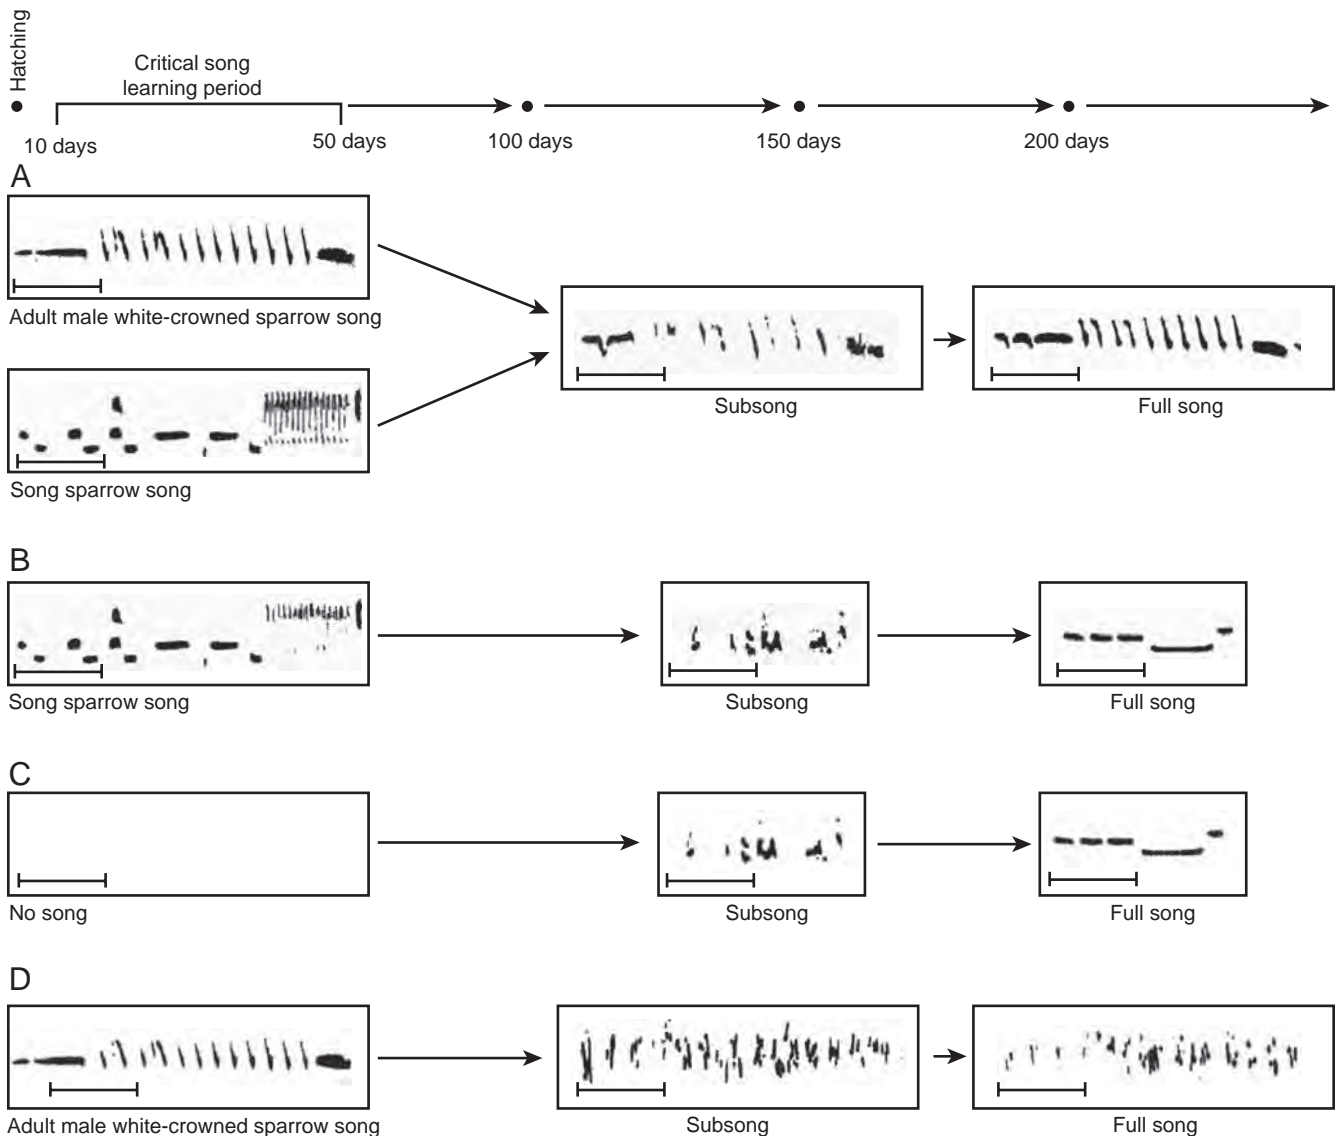

In terms of its ability to communicate information, the most complex system of nonhuman communication known at present is the dance of honey bees

(Gould and Gould, 1995). The system has some properties that are reminiscent of human language: it uses arbitrary conventions to describe objects distant in both space and time; that is, it does not reflect a real-time emotive readout, as might be the case when a primate gives an alarm call or grunts at a banana.

In terms of information content, a honey bee dance is second (albeit a very distant second) only to human speech, and so far as is known is far richer than the language of any primate. However the dance language suffers from at least two limitations: It is a closed system—there seems to be no way to introduce new conventions to deal with novel needs. It is also graded; instead of discrete signals for different directions or distances, single components are varied over a range of values (angles and durations). The less complex but more flexible systems of birds and primates are more likely to illustrate the evolutionary precursors of speech.

Some birds have innate songs. In these species, individuals raised in isolation produce songs that are indistinguishable from their socially reared peers and respond to calls appropriately without prior experience. Chickens, doves, gulls, and ducks are familiar examples. Most songbirds, however, illustrate a different pattern—one that shows how potent a combination instinct and innately directed learning can be. Isolated chicks sing a schematic form of the species song, but the richness of a normal song is absent. Adult conspecifics can recognize innate songs as coming from members of their species, but in general these impoverished vocalizations produce lower levels of response. Typically, there is a sensitive period during which exposure to song must occur if it is going to have any impact (Fig. 51.1). In most species, there is a gap between this sensitive period and the process of overt song development—that is, practice and perfection of the adult song are based on the bird's memory of what it heard during its sensitive period (Gould and Marler, 1987).

Giving a range of possible song models during isolated rearing, a chick selects an example from its own species and memorizes it. If it hears only songs of other species, the mature song is the unmodified innate song (Fig. 51.1). Thus there is an innate bias in the initial learning. Where this bias has been studied, it appears to depend on acoustic sign stimuli (i.e., species-specific “syllables”). Indeed, chicks are able to extract syllables of their species embedded in foreign songs, or scored in a way never found in their species (e.g., a syllable that is repeated at an accelerating rate presented to a species that sings syllables at a constant rate, or vice versa will be extracted and used in the species-typical manner).

**FIGURE 51.1** Birdsong development in most species is characterized by a sensitive period during which a song of the species must be heard. Later, during subsong, the bird practices making notes and assembles them into the correct order and pattern (A). Birds not allowed to hear their species' song sing a schematic version of the song (B and C); birds deafened before subsong cannot sing (D).

Practice is essential in the normal development of birdsong, and part of this practice occurs in a babbling phase known as subsong, which begins at a species-typical age. A bird deafened after its sensitive period, but before it begins producing notes in preparation for singing (subsong), is unable to produce even an innate song (Fig. 51.1). During the earliest parts of subsong, birds try out a number of notes. These notes are typical of the species, but most are absent from the song they eventually sing. The learning process may involve producing each member of an innate repertoire of notes, listening to them, checking to see if they match any element in the memorized

song, discarding the unnecessary ones, and rearranging, scoring, and modifying the others to produce a reasonable copy of the original song heard during the sensitive period.

There is some flexibility in song development. For example, when the chick has heard two very different specimens of its own species' song, it will often incorporate elements from each. Similarly, when the chick has been exposed to the sight of a singing conspecific and simultaneously the sound of a heterospecific song, it may pick out elements of the abnormal song and adapt them as best it can into its own species-specific organization.

Birdsong, therefore, depends on two processes that involve an interaction between innate capacities and learning: imprinting the song in memory and then learning to perform it. This system is flexible, but only within clear limits.

### Communication Systems in Primates

Primates are the species with the closest evolutionary links to humans, and therefore the communication systems found in these animals are important to study for clues regarding the neural basis of human language.

Vervets, a species of monkey, provide a good case study. Vervets, like all social primates, have a large repertoire of innate calls used for social communication. Among these approximately three dozen signals are four alarm calls (Cheney and Seyfarth, 1990). In some parts of their range, one of the calls is specific for martial eagles; in another the same call is used for certain hawks. In either case, the call causes monkeys to look up; those at the tops of trees drop to the interior, whereas those on the ground move into bushes or under trees. A second call, specific to leopards in one region and to other solitary hunters elsewhere, sends the warned individuals up to the tree tops. A third, specific for snakes, induces the other members of the troop to stand up and look around in the grass. A fourth call is heard in the presence of humans or group-hunting predators.

The development of calling is revealing. Young vervets appear to understand the class of animals each call refers to, but not the particular species that are dangerous. Thus, infants will give the eagle call to harmless vultures, storks, and even falling leaves, but not to snakes or leopards. Consequently, adults generally respond to the alarm calls of infants with a casual look around, followed by their own alarm if there is a genuine danger. Juveniles make fewer mistakes, and adult errors are confined to calls produced when the potential threat is so far away that human observers require binoculars to identify the species. In short, young vervets seem to learn the details of how to apply an innate categorical vocabulary.

Nonhuman primates have virtually no voluntary control over respiration, the vocal tract, or vocalization, so this modality is not available for producing a large number of differentiated signals. Other modalities of communication, such as gesture, however, are also used for relatively restricted purposes, mostly related to items of immediate biological importance and social hierarchy. Recent detailed studies of gesture use in captive chimpanzees indicate that the meaning of particular gestures differ from one group to another.

Researchers have attempted to teach chimpanzees to use a variety of communicative systems that bypass their vocal limitations, such as sign language and manipulation of object tokens, in an effort to determine to what extent these naturally occurring communication systems can be augmented. If anything, this work emphasizes the ways in which nonhuman primates are not capable of full human language. There are dramatic differences between trained chimpanzees and humans in terms of vocabulary size (chimps never get beyond what a 2-year-old can do), conceptual capacities, complex grammar, and so on, despite the fact that chimps have remarkable skills at social cognition.

### Neural Structures for Animal Communication Systems

The neural mechanisms that underlie animal communication may give clues as to those that allow for human language. These systems of course differ in different phyla and species. This section briefly reviews aspects of the neural basis for birdsong and primate communication. It would be of great interest to report on the neural basis for the dance of the bees, but nothing is known about this subject.

#### *Birdsong*

Birdsong appears to be produced by a small number of nuclei (collections of nerve cells). In the canary, four important nuclei are involved: HVC, RA, DM, and nXIIIts. Lesions in any of these nuclei destroy or seriously impair song production. These nuclei also respond when song is presented, and some neurons in some nuclei in some species (e.g., neurons in nXIIIts in the zebra finch and the white-crowned sparrow) respond specifically to particular aspects of song. This indicates an overlap in the neural mechanisms involved in song perception and production, a feature that may carry over to humans as well.

Birdsong is produced by a structure between the trachea and the bronchi called the syrinx. There is one syrinx on each side of the trachea. In some species, song is entirely, or mainly, produced by one of these two structures; in other species, both syrinxes participate in song, with each producing different parts of the song. Each syrinx is controlled by structures in its corresponding side of the brain and, when one syrinx is responsible for song, these structures are larger on that side. The perceptual system is also duplicated on both sides of the brain, and, in some species, the two sides of the brain respond to different aspects of song.

In species in which only male birds sing (most species), song nuclei are much larger in males than in

females (“sexual dimorphism”). This is not true in those species in which males and females perform duets. In general, there is a correlation between song nucleus size and song complexity in individual birds. Furthermore, song nuclei grow by a factor of almost 100% during the spring mating season (when birds sing) compared to the fall and winter (when they do not).

Changes in the size of song nuclei are related to testosterone production (they can be induced in females by testosterone injection in some circumstances) and by other factors usually related to day-length—part of the birds’ innate calendar. They are due to many changes in nerve cells: increase in the number of dendrites, increase in cell size, and, most interestingly, increase in the number of cells. Studies using labeled thymidine, which is taken up by dividing DNA, have shown neurogenesis in neurons in the HVc nucleus in relationship to periods of increased song, indicating that new nerve cells are formed. These neurons project to the RA nucleus, strongly suggesting that they play a role in song.

### *Primates*

The neural basis for primate vocalizations is beginning to be charted. Unlike humans, vocalizations in primates do not appear to begin in a lateral cortical region but rather in the medial portion of the brain (the cingulate), a region involved in connecting basic instinctual to more advanced cognitive functions. Actual motor planning appears to involve mainly brain stem nuclei. On the perception side, there are neurons in the auditory cortex of some species of macaque monkeys that selectively respond to conspecific calls. These regions show some degree of functional asymmetry in some species, with responses from cells in the left hemisphere and not the right.

### **Possible Lessons from Nonhuman Species Regarding Language and Its Neural Basis**

It is dangerous to infer too much about human language, or about how the human brain may support language, from studies of species that are very distant, such as birds. However, these species provide evidence for the possibility of certain aspects of language and its neural basis that could have developed several times in evolution or that could date to a distant common ancestor.

At a behavioral level, human speech and language could have developed from the repertoire of two to three dozen innate calls that are typical of birds and primates. In that case, we would expect to find that

language contains elements that are innately recognized and that may be distinguished by the sorts of acoustic features that provide the basis for the innate discrimination of sign stimuli in other species. In fact, babies have an innate ability to discriminate a small number of sounds found in human languages, which function as acoustic sign stimuli. The evolution of human speech could also have retained the sorts of sensitive periods and innate learning biases so evident in song birds and vervet monkeys. In this case, we might expect to see a species-typical babbling phase, and perhaps a sensitive period for easy learning of new languages. If the evolution of speech and language preserves the use of preexisting (innate) forms, we might expect there to be innate aspects of human language, which would presumably be found in all languages and which might surface in situations where we see a “default grammar,” not unlike the unlearned and impoverished songs of birds reared in isolation. Creoles potentially exemplify such cases. Creoles are languages developed by the children of people speaking different languages who are drawn together and communicate with very simple pidgin. They have a number of features not present in the languages spoken by the parents of the children who spoke the pidgin, which have been taken to be related to innately specified features of language (Bickerton, 1990).

From the neurological perspective, several features of the neural organization for communication systems appear to be found in humans in a way that is relevant to language. These features are the fact that there are specialized neural nuclei for song production; that the neural basis for song production is often asymmetric, with one hemisphere producing most of song or the two hemispheres producing different aspects of song; that production and perception of song make use of same structures to some degree; and that there is a relationship of size to function. However, other important features of the neurobiology of birdsong, such as the neurogenesis that is important in the seasonal changes in song production, are not known to play a role in human speech and language. As for primates, the neural system responsible for call production is quite different from that in humans, being based in the cortex that is transitional from limbic to association regions (reflecting the limited semantic content and immediate biological relevance of most calls). Asymmetries in the neural basis for call perception, and the existence of neurons in the auditory association cortex that selectively respond to conspecific calls, may be quite direct evolutionary precursors of the human neural substrate for language.

## HUMAN LANGUAGE

Although animal communication systems can be quite sophisticated and some of them share attributes with human language, human language is far more complex than animal communication. There are many features of human language that distinguish it from animal communication systems.

One is what messages human language can convey. As we have seen, most animal communication systems serve the purposes of identifying members of a species. These systems do sometimes designate items of immediate biological significance, such as designation of predators by monkeys or food sources by bees. Human language differs from these systems with respect to the number of items that can be designated and the relationship of these items to present biological necessity. Human language allows us to designate an infinitely large number of items, actions, and properties of items and actions, and to do so with respect to items that are not immediately biologically compelling.

Human language also allows us to relate items, actions, and properties to one another. This propositional level of semantic content is beyond the scope of any known animal communication system. At a yet higher level, human language allows us to express relationships between events and states of affairs in the world, such as temporal order and causation. Again, this level of meaning is far beyond anything available to other species as far as we know. It reflects the human ability to conceive of an enormous number of concepts and to relate them to one another.

Language expresses these different semantic values with different types of representations: words, words made from other words, sentences, and discourse. Each of these “levels” of linguistic representation consists of specific forms that are related to specific aspects of meaning. The forms at each level are intricately structured, and there are an infinite number of different structures that can be built at each level of the system.

### Words

Simple words are defined and distinguished from each other primarily by their phonemes. A phoneme is a single distinct sound that contrasts with another (Fig. 51.2) and makes it possible to determine the existence of a word in a language. For instance, in English /p/ and /b/ are different phonemes because they determine the separate existence of the members of word pairs such as pat-bat, pale-bale, pull-bull, lap-lab. A major distinction between different types of

FIGURE 51.2 Schema of sound spectrographs of nine phonemes followed by a short “a” sound. The sound bands are called “formants.” The first (bottom) two formants are independent; the third is a harmonic of the second.

phonemes is the difference between vowels and consonants. Consonants involve some degree of constriction of the vocal tract; vowels are produced with a relatively open vocal tract. Each language “selects” its inventory of phonemes from a relatively small set of phonemes found across languages. American English phonemes have 25 consonants and 17 vowels.

At the semantic level, put in very simple terms, words designate concrete objects, abstract concepts, actions, properties, and logical connectives. Many philosophers and psychologists, and most neurologists who have considered the subject, have thought that the meaning of a word consists of a set of features of objects and actions that are associated with the word’s sound through one’s experience. However, the meaning of a word also includes unobserved properties of the item that the word designates, such as our knowledge that cats can swim even if we have never observed one swimming. This knowledge may be based on inductive generalizations, logical inferences, or innate concepts regarding the structure of items. Tulving (1972), who called the complex set of properties that make up word meaning “semantic memory,” emphasized that the hallmark of this type of knowledge is the relations that items have to one another.

### Words Formed from Other Words

The word-formation level of language allows words to be formed from other words. Language uses many devices to accomplish this—compounding, affixation,

agglutination, and others. English affixation provides a useful illustration. There are two main types of affixes in English: inflection and derivation. Inflection is related to the syntactic structure of a sentence, as in agreement between subjects and objects (I see; he sees). English is relatively poor in overt inflectional features; languages such as Dutch and German have more complete and complex agreement systems that affect adjective–noun agreement, verb inflections, and the case markers on nouns. Derivational processes are those that create new syntactic categories of words (e.g., destroy–destruction; happy–happiness). Derivation allows the meaning associated with a simple lexical item to be used as a different syntactic category without coining a large number of new lexical forms that would have to be learned.

## Sentences

The sentential level of language consists of syntactic structures (Chomsky, 1965, 1981, 1986) into which words are inserted. Individual words are marked for syntactic category (e.g., cat is a noun (N); read is a verb (V); of is a preposition (P)). These categories combine in a hierarchy to create nonlexical nodes (or phrasal categories), such as noun phrase (NP), verb phrase (VP), and sentence (S). The way words are inserted into these higher order phrasal categories determines a number of different aspects of sentence meaning. For instance, in the sentence “The dog that scratched the cat killed the mouse,” there is a sequence of words—*the cat killed the mouse*—that, in isolation, would mean that the cat killed the mouse. However, “The dog that scratched the cat killed the mouse” does not assert that the cat killed the mouse, but rather that the dog did. This is because *the cat* is not the subject of *killed* and does not play a thematic role around *killed*. The cat is the object of the verb *scratched* in the relative clause—*that scratched the cat*—and is the theme of *scratched*. *The dog* is the subject of the verb *killed* and is the agent of that verb. The syntactic structure of “The dog that scratched the cat killed the mouse” is shown in Fig. 51.3, which demonstrates these relationships.

At the sentence level the set of semantic values that language can express expands greatly (Pinker, 1994). Sentences convey aspects of the structure of events and states in the world. These semantic values collectively are known as the propositional content of a sentence. These values include thematic roles (information about who did what to whom), attribution of modification (information about which adjectives go with which nouns, such as the fact that in the sentence “The big boy chased the little girl,” the boy is big and girl is little), scope of quantification (information about what

The dog that scratched the cat killed the mouse

FIGURE 51.3 Syntactic structure of the sentence “The dog that scratched the cat killed the mouse” indicating the hierarchical structure responsible for its meaning.

items are included in the scope of quantifiers, such as the fact that in the sentence, “None of the boys wearing hats was cold,” the quantifier “none” applies to the boys wearing hats, not just to the boys), the reference of pronouns and other anaphoric elements (information about which words in a set of sentences refer to the same items or actions, such as the fact that in the sentence “The brother of the visitor shaved himself,” “himself” refers to “brother” and not to “visitor”), and so on.

Sentences are a crucial level of the language code because the propositions they express make assertions about the world. These assertions can be added to an individual’s knowledge of the world (i.e., they can add to semantic memory). Because they can be true or false (something that is not possible with words), they can be entered into logical systems. They are likely critical in certain aspects of thinking, such as decision making and planning actions.

## Discourse

The propositional meanings conveyed by sentences are entered into higher order structures that constitute the discourse level of linguistic structure. Discourse includes information about the general topic under discussion, the focus of a speaker’s attention, the novelty of the information in a given sentence, the temporal order of events, causation, and so on. Discourse also conveys information about the intentions of a speaker and a listener and the current attentional foci.

The structure of discourse involves establishing relationships between items and propositions. Some part of this structure is derived from the form in which propositions are expressed. In a sequence of sentences such as

*John and Henry went to Bill's last night. They were really glad they did. They raved about the dessert the whole next day.*

The reader will take “they” as referring to John and Henry, partly because “John and Henry” and “they” are the subjects of successive sentences. However, part of the information conveyed at the discourse level depends upon associations and inferences that listeners make. For instance, in the same passage, the reader will likely infer that John and Henry ate dinner at Bill's—something not stated in the passage but that makes the sentences in the passage coherent.

## Language Processing

Current models of language processing subdivide functions such as reading, speaking, auditory comprehension, and writing into many different, semi-independent components, which are sometimes called “modules” or “processors.” These components can be further divided into variable numbers of highly specialized operations, such as those involved in mapping features of the acoustic signal onto phonemes or in constructing syntactic structures from words. Each operation accepts only particular types of representations as input and produces only specific types of representations as output.

Models of language processing often are expressed as flow diagrams (or “functional architectures”) that indicate the sequence of operations of the different components that perform a language-related task. Figure 51.4 presents a model indicating the sequence of activation of components of the lexical processing system. Figure 51.4 simplifies information flow in four ways. First, it does not specify the nature of the operations in each of the major components of the system. Second, it does not fully convey the extent to which the components of the system operate in parallel. Third, it does not convey the extent of feedback among the components of the system. Lastly, not all components are represented. Despite these simplifications, the model captures enough aspects of information processing in the language system to give an idea of what functional architectures of language processing look like.

Beyond specifying the flow of information through the language processing system, researchers have begun to understand the operating characteristics of its components. Several important features of language

processing operations have been demonstrated in experimental laboratories or in studies of patients.

1. They are specialized for language. For instance, recognition of phonemes is probably accomplished by mechanisms that separate very early in the processing stream from those that recognize other auditory stimuli.
2. They are obligatorily activated when their inputs are presented to them. For instance, if we attend to a sound that happens to be the word “elephant,” we must hear and understand that word; we cannot hear this sound as just a noise.
3. They generally operate unconsciously. We usually have the subjective impression that we are extracting another person's meaning and producing linguistic forms without being aware of the details of the sounds of words, sentence structure, and so on.
4. They operate quickly and accurately. For instance, it has been estimated on the basis of many different psycholinguistic experimental techniques that spoken words usually are recognized less than 125 ms after their onset—that is, while they are still being uttered. The speed of the language processing system as a whole occurs because of the speed of each of its components, but also is achieved because of the massively parallel functional architecture of the system, which leads to many components of the system being simultaneously active.
5. They require processing resources. Although we do not appreciate it consciously, language processing demands some effort. It is unclear whether there are separate pools of processing resources for each language processing component or for language processing as a whole or whether language processing can “borrow” resources from other systems if it needs to.

We have discussed language processing in the auditory-oral modality. However, humans who are deaf can develop language in the visual and gestural modalities, and the structures of these language are essentially the same as those of spoken language, once allowances are made for the fact that they are signed instead of spoken. Languages can also be represented orthographically. Orthographies range from alphabetical scripts such as English, to syllabic, consonantal, and ideographic orthographies. Orthography is not acquired in the way spoken and signed language is; reading and writing require instruction to master. Many of the features of spoken language processing we have reviewed apply to the processing of spoken, written, and signed language as well. We cannot review

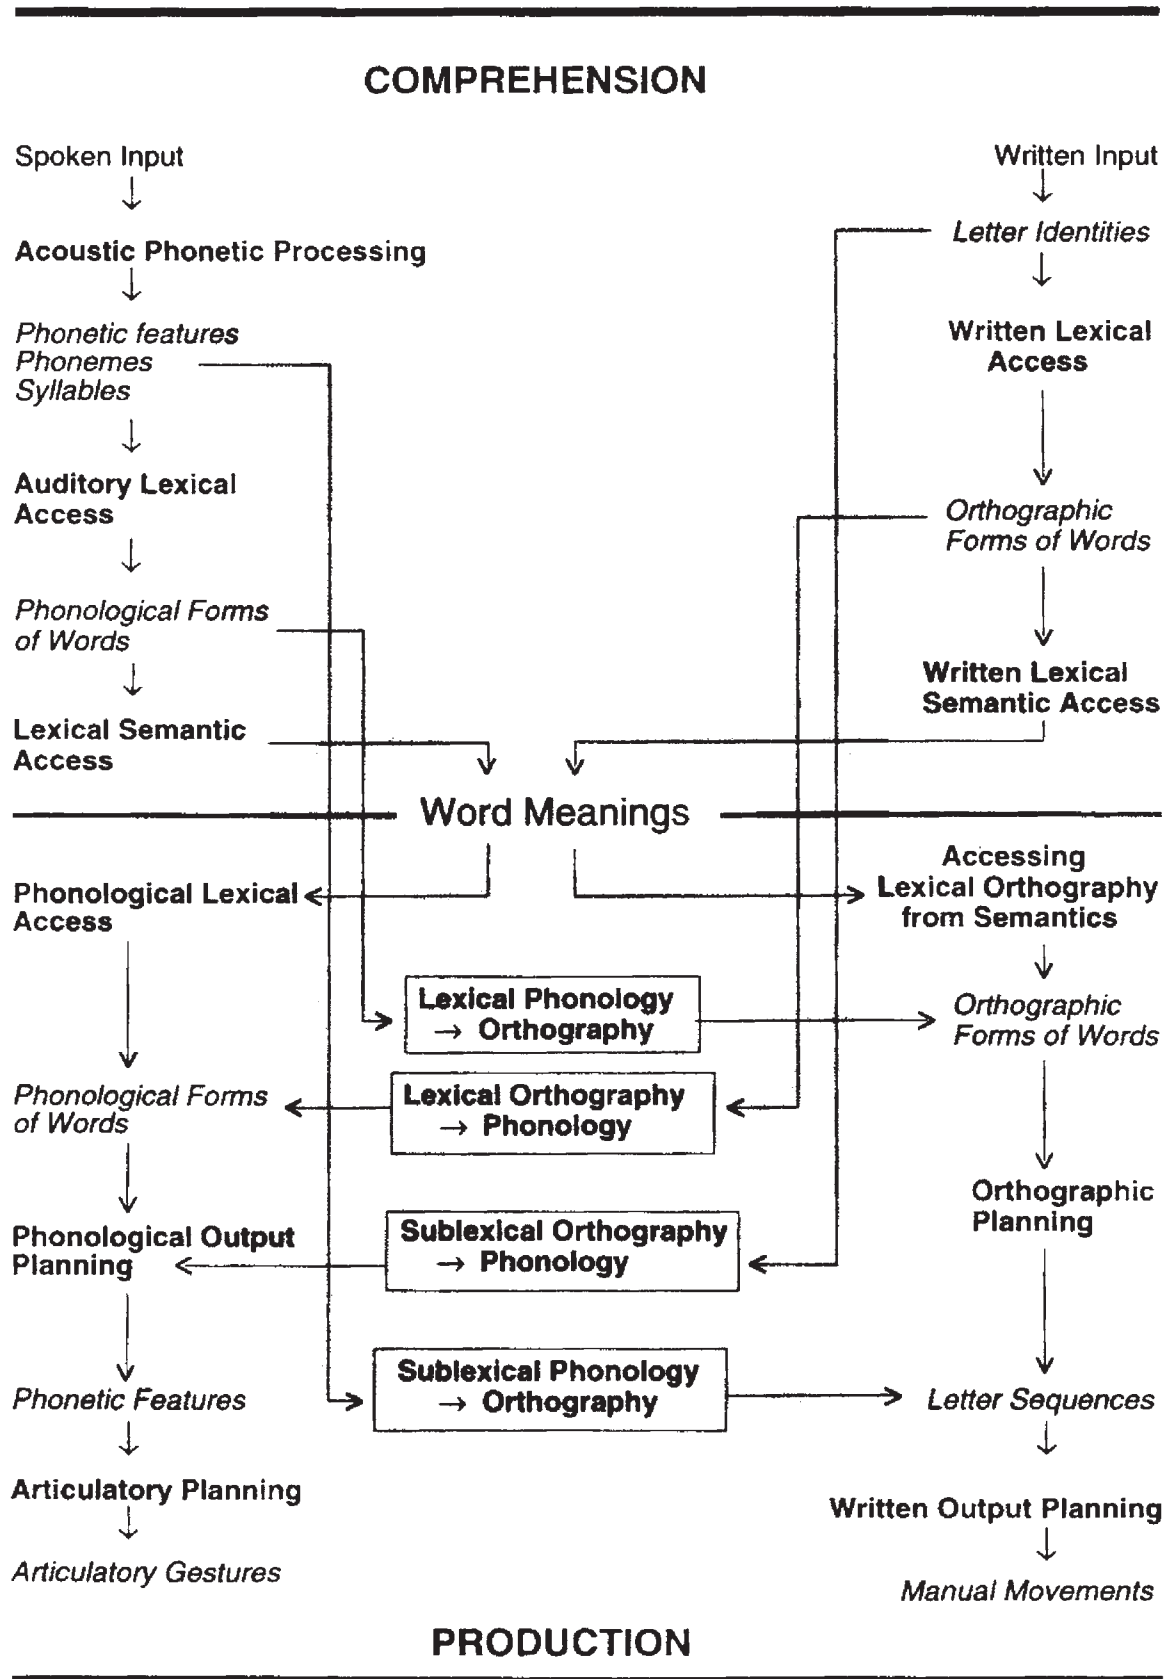

FIGURE 51.4 A model of the major psycholinguistic operations involved in processing simple words.

these modalities of language use here; for an introduction to signed language and its neurology, see Bellugi *et al.* (1990); for a discussion of orthographic representational systems, see Henderson (1982); for models of written language processing, see Plaut *et al.* (1996).

The operations of the language processing system are regulated by a variety of control mechanisms. These control mechanisms include both ones internal to the language processor itself and those that are involved in other aspects of cognition. The first category—language-internal control mechanisms—consists of a large number of operations that schedule psycholinguistic operations on the basis of the ongoing nature of a given psycholinguistic task. The second category of control mechanisms—those that are related to cognitive processing outside the language system—determine what combinations of processors become active in order to accomplish different tasks such as reading, repeating what one has heard, and taking notes on a lecture.

Functional communication involving the language code occurs when people use these processors to inform others, to ask for information, to get things done, and so on. The use of language is thus one type of intentional action. There are conventions (or rules) that regulate the use of language for these purposes. However, it is a mistake to think that language is only used, or even mainly used, for functional communication and that language is, at its core, a communication system. The heart of human language is a system of representations relating forms to meaning. In fact, as Chomsky has pointed out, far and away the most common use of language is not interpersonal communication at all, but talking to oneself.

### Language Universals, Language Acquisition and Language Evolution

By some counts, there are over 6500 languages in the world. These languages differ in many ways from one another: they have different vocabularies, use different sounds, and have different ways of forming words and different syntactic rules. However, beyond these surface level differences, there are features that are common to all human language. For instance, the sound systems of all human languages consist of alternations of consonants and vowels; no language forms different words by varying features of sound such as its loudness or whether a word is whispered. These “linguistic universals” form a framework within which the features of individual languages occur.

Linguistic universals can arise because of universal features of motor or sensory systems or, possibly, because of constraints on cognitive computational capacities. They may also arise because language itself

is constrained to have certain features. Chomsky’s work in the area of syntax is the best known and most controversial example of analyses along these lines. Chomsky and his colleagues and students have argued that very abstract features of syntax are common to all languages. There have been numerous suggestions as to what these features are; one recent proposal is that they include the ability to generate an infinite number of expressions from a finite set of elements (Hauser *et al.*, 2002). Many linguists believe that the structure of language is much less abstract than Chomsky and his colleagues have suggested and, accordingly, that universal “laws” of linguistic structure are also less abstract, mostly taking the form of statements that the presence of one type of element in a language implies that a second type will also be present.

The issues of how abstract linguistic representations are and what universal properties of language exist are bound up with two major issues—how language is acquired and how language evolved—that are in turn relevant to the neural basis for language. Chomsky’s view is that language acquisition consists of fixing the parameters in an innate language template that correspond to the constraints on possible forms of human language that are present in the language a child is exposed to. Models of language that see language structures as much less abstract make very different claims about the nature of innate features of language and the balance between innate knowledge and learning in the development of language abilities (e.g., Tomasello, 2003). In the past few years, some theorists have argued that the bulk of language acquisition is the result of a massive pattern-association process, supported by mechanisms that can be simulated in “connectionist” (or “neural net”) models (Seidenberg, 1997). Although such models have had important successes in simulating many aspects of language processing at the single word level, they have not been able to account for the most complex combinatorial features of syntax. However, these models tend to be more realistic from a neurological point of view, whereas the neural mechanisms that underlie the representation of the abstract categorical features of language proposed by Chomsky and many linguists remain quite mysterious.

The same disagreements affect ideas about how language evolved. In Chomsky’s model, a critical neural development is the emergence of structures and processes in the brain that support recursive properties of language in the human brain. The recent finding that starlings can discriminate recursive from nonrecursive sequences of notes (Gentner *et al.*, 2006) implies that these neural structures are not unique to humans, but if recent studies showing that some species of monkeys do not recognize recursive structures are true of all

higher primates, the evolutionary path for these features must have taken a number of divergent paths and reemerged in humans. The major alternative to the view that language evolution consisted of the emergence of neural structures capable of supporting abstract organizational features that are found in all human languages is that language rests upon an evolutionary change that supports much less complex and abstract representations and the complexity of human language is a cultural development, like architectural complexity.

One well-known model of this sort that has a neural basis has been developed by Rizzolatti and Arbib (1998), who have argued that the neural structures that are critical for language are modifications of the mirror neurons found in monkeys that fire both when the monkey grasps particular objects and when the animal sees a person grasping those objects. In Arbib and Rizzolatti's view, these neurons encode the relation of a number of actors to an action and an object, and thus lay the basis for neural mechanisms that allow an arbitrary number of substitutions of actors and objects in relation to the action described by a verb. In their view, the complexity of human language is a cultural development, like architecture, not due to massive change in neural capacity due to a sudden evolutionary change. Support for this position comes from findings that suggest that culture influences the forms in a language. A much cited recent study (Everett, 2005), for instance, argues that one language spoken by an isolated group of Amazon natives lacks recursive structures because people do not need them to convey messages in that culture. If correct, such analyses would be critical evidence in favor of a minimal evolutionary change and cultural development being the basis for human languages, but the data are very sparse and hard to verify, and the question remains open.

There are very limited empirical data regarding the genetic basis for human language development. Lieberman (2006) argues that the critical evolutionary change that made for human language was not specifically neural, but consisted of the descent of the root of the tongue into the oropharynx, which allows humans to produce the inventory of speech sounds of a language. In his view, two genetic effects—increases in the size of the hominid brain related to the ASPM gene and, more importantly, changes in the ability to exploit the increased channel capacity in humans by changes in the FOXP2 gene—underlie the use of the resulting increase in the vocal repertoire for communicative purposes. Deficits in the FOXP2 gene in a single family have been associated with a variety of language and articulation problems and the FOXP2 gene has been referred to as a (or “the”) “language gene” by some researchers.

However, the deficits in affected family members are not specific to syntax or word formation, and, as Lieberman argues, it is more likely that this gene codes for neuronal features of subcortical gray nuclei, in particular the basal ganglia and, to a lesser extent, the cerebellum that make for more elaborate and efficient control of sequencing abilities than for cortical structures that represent and process language *per se*.

### Neural Organization for Language: An Inventory of Brain Structures Related to Language

Human language depends on the integrity of the unimodal and multimodal association cortex in the lateral portion of both cerebral hemispheres. This cortex surrounds the sylvian fissure and runs from the pars triangularis and opercularis of the inferior frontal gyrus (Brodmann's areas (BA) 45, 44: Broca's area) through the angular and supramarginal gyri (BA 39 and 40) into the superior temporal gyrus (BA22: Wernicke's area) (Fig. 51.5). For the most part, the connections of these cortical areas are to one another and to the dorsolateral prefrontal cortex and lateral inferior temporal cortex. These regions have only indirect connections to limbic structures. These areas consist of many different types of association cortex, devoted not to sensation or motor function but to a more abstract type of analysis. The nature of this cortex and its patterns of connectivity are thought to combine to give

**FIGURE 51.5** A depiction of the left hemisphere of the brain showing the main language areas. The area in the inferior frontal lobe is known as Broca's area, and the area in the superior temporal lobe is known as Wernicke's area, named after the nineteenth century physicians who first described their roles in language. Broca's area is adjacent to the motor cortex and is involved in planning speech gestures. It also serves other language functions, such as assigning syntactic structure. Wernicke's area is adjacent to the primary auditory cortex and is involved in representing and recognizing the sound patterns of words.

language its enormous representational power and to allow its use to transcend biological immediacy.

The evidence that language involves these cortical regions originally was derived from deficit-lesion correlations. Patients with lesions in parts of this cortex have been described who have had long-lasting impairments of language (“aphasia”). Disorders affecting language processing after perisylvian lesions have been described in many different types of disease, in all languages that have been studied, in patients of all ages and both sexes, and in both first and subsequent tongues, indicating that this cortical region is involved in language processing independent of these factors. Functional neuroimaging studies have documented increases in regional cerebral blood flow (rCBF) using PET or blood oxygenation level-dependent (BOLD) signal using fMRI in tasks associated with language processing in this region. Event-related potentials whose sources are likely to be in this region have been described in relationship to a variety of language processing operations. Stimulation of this cortex by direct application of electrical current during neurosurgical procedures interrupts language processing. These data all converge on the conclusion that language processing is carried out in the perisylvian cortex.

Regions outside the perisylvian association cortex also appear to support language processing. Working outward from the perisylvian region, evidence shows that the modality of language use affects the location of the neural tissue that supports language, with written language involving the cortex closer to the visual areas of the brain and sign language involving brain regions closer to those involved in movements of the hands than movements of the oral cavity. Some ERP components related to processing improbable or ill-formed language are maximal over high parietal and central scalp electrodes, suggesting that these regions may be involved in language processing. Both lesion studies in stroke patients and functional neuroimaging studies suggest that the inferior and anterior temporal lobe is involved in representing the meanings of nouns. Activation studies also implicate the precentral gyrus and premotor cortex in word meaning. Injury to the supplementary motor cortex along the medial surface of the frontal lobe can lead to speech initiation disturbances; this region may be important in activating the language processing system, at least in production tasks. Activation studies have shown increased rCBF and BOLD signal in the cingulate gyrus in association with many language tasks. This activation, however, appears to be nonspecific, as it occurs in many other, nonlinguistic, tasks as well. It has been suggested that it is due to increased arousal and deployment of attention associated with more complex tasks.

Subcortical structures may also be involved in language processing. Several studies report aphasic disturbances following strokes in deep gray matter nuclei (the caudate, putamen, and parts of the thalamus). It has been suggested that subcortical structures involved in laying down procedural memories for motor functions—in particular, the basal ganglia—are involved in “rule-based” processing in language, such as regular aspects of word formation, as opposed to the long-term maintenance of information in memory, as occurs with simple words and irregularly formed words. The thalamus may play a role in processing the meanings of words. In general, subcortical lesions cause language impairments when the overlying cortex is abnormal (often the abnormality can be seen only with metabolic scanning techniques), and the degree of language impairment is better correlated with measures of cortical than subcortical hypometabolism. It may be that subcortical structures serve to activate a cortically based language processing system but do not themselves process language.

The cerebellum also has increased its rCBF in some activation studies involving both language and other cognitive functions. This may be a result of the role of this part of the brain in processes involved in timing and temporal ordering of events, or in its being directly involved in language and other cognitive functions.

In summary, a large number of brain regions are involved in representing and processing language. Ultimately, they all interact with one another as well as with other brain areas involved in using the products of language processing to accomplish tasks. In this sense, all these regions are part of a “neural system,” but this does not imply that every part of this entire system is responsible for computing specific linguistic representations. The most important part of the neural system involved in language is the dominant (usually left-sided) perisylvian cortex.

## Lateralization

Most language processing goes on in one hemisphere, called the “dominant” hemisphere. Which hemisphere is dominant shows considerable individual differences and bears a systematic relationship to handedness. In about 98% of right-handed individuals, the left hemisphere is dominant. The extent to which left hemisphere lesions cause language disorders is influenced by the degree to which an individual is right-handed and by the number of nonright-handers in his or her family. About 60 to 65% of nonright-handed individuals are left-hemisphere dominant; about 15 to 20% are right-hemisphere dominant; and the remainder appear to use both hemispheres for lan-

**FIGURE 51.6** Depiction of a horizontal slice through the brain showing asymmetry in the size of the planum temporale related to lateralization of language.

guage processing. The relationship of dominance for language to handedness suggests a common determination of both, probably in large part genetic.

The neural basis for lateralization was first suggested by Geschwind and Levitsky (1968), who discovered that part of the language zone (the planum temporale—a portion of the superior temporal lobe; Fig. 51.6) was larger in the left than in the right hemisphere. Subsequent studies have confirmed this finding and identified specific cytoarchitectonically defined regions in this posterior language area that show this asymmetry. Several other asymmetries that may be related to lateralization also have been identified. The exact relationship between size and function is not known, as there are instances of individuals whose dominant hemisphere is not the one with the larger planum temporale. In general, however, relative size is a good predictor of lateralization. This is another example of the “bigger is better” principle that we saw applied to song nuclei in birds.

Although language was the first function known to be lateralized, and is still the best example of a lateralized function, it is not completely lateralized. Although not as important in language functioning as the dominant hemisphere, the nondominant hemisphere is involved in many language operations. Evidence from the effects of lesions and split brain studies, experiments using presentation of stimuli to one or the other hemisphere in normal subjects, and activation studies all indicates that the nondominant hemisphere understands many words, especially concrete nouns,

and suggests that it is involved in other aspects of language processing as well. Some language operations may be carried out primarily in the right hemisphere. The best candidates for these operations are ones that pertain to processing the discourse level of language, interpreting nonliteral language such as metaphors, and appreciating the tone of a discourse; for example, the fact that it is humorous. Some scientists have developed models of the sorts of processing that the right hemisphere carries out. For instance, it has been suggested that the right hemisphere codes information in a more general way compared to the left, representing the overall structure of a stimulus as opposed to its details. This may be true for language as well as for other functions, such as visual perception. This and other suggestions provide the bases for ongoing research programs into the nature of language processing in the right hemisphere.

### Organization of the Perisylvian Cortex for Language Processing

The way the perisylvian cortex is organized to support these functions has been the subject of much investigation. Two general classes of theories of the relationship of parts of the perisylvian association cortex to components of the language processing system have been developed. One is based on “holist” or distributed views of neural function and one on localizationist principles. The basic tenet of holist/distributed theories is that linguistic representations are

distributed widely and that language processing components rely on broad areas of the association cortex. Localizationist theories maintain that language processing components are localized in specific parts of the cortex. The first author of this chapter has argued that some language operations are localized, but that their localization varies across the population.

## Holist Theories

Lashley (1950) identified two functional features of holist/distributed models that determine the effects of lesions upon performance: equipotentiality (every portion of a particular brain region carries out a particular function in every individual) and mass action (the larger the neuronal pool that carries out a function, the more efficiently that function is accomplished). The features of equipotentiality and mass action jointly entail that (1) lesions of similar sizes anywhere in a specified brain region have equivalent effects on function and (2) the magnitude of any functional deficit is directly proportional to the size of a lesion in this specified area. Modern work with parallel distributed processing models provides formal models of holist concepts.

There is some evidence for holist theories. Lesions throughout the language area have been found in some studies to have similar effects on language functions, consistent with the principle of equipotentiality. There is an effect of lesion size on the overall severity of functional impairments in several language spheres, consistent with the principle of mass action. These results are consistent with a distributed, or holistic, neural basis for linguistic representations and processes. However, they do not necessarily show that these models are correct because they also could result from variability in the localization of language processing components across the population.

The functional neuroimaging literature does not support holist models; every study of a language function has yielded neurovascular responses in one area or a small number of areas. However, this may be a result of the way functional neuroimaging data are analyzed: standard analyses are designed to identify small areas in which there are large changes in BOLD signal (relative to the variability of BOLD signal in the entire brain), not large areas in which there are small changes. Thus, if language operations were widely distributed and resulted in small increases in neurophysiological activity throughout the perisylvian cortex, it is not clear that these changes would be detected by present day functional neuroimaging.

Holist models appear to apply to individual areas of the brain. Modern “neural net” (connectionist) com-

puter simulations provide a formal basis for holist models of language processing. As noted earlier, these models have been extremely successful in modeling certain aspects of normal language processing and language deficits. A very reasonable view is that different neural areas support different language functions and that each of these areas works as a whole, as holist models claim. Holism thus may not be wrong; it just needs to be applied on the right scale. As has been said, the brain may be “globally local and locally global.”

## Localizationist Theories

Evidence against any holist model is the finding that multiple individual language deficits arise in patients with small perisylvian lesions, often in complementary functional spheres. For instance, some patients have trouble producing the small grammatical function words of language (such as *the, what, is, he*), whereas others have trouble producing common nouns. The existence of these two disorders indicates that the tissue involved in producing function words is not involved in producing common nouns in the first set of patients, and vice versa in the second set. Strong evidence against holist models also comes from activation studies that demonstrate vascular responses to particular types of language stimuli in restricted cortical areas. How language is organized at this finer-grained level in the perisylvian association cortex is an ongoing topic of research.

### *Classical Clinical Localizationist Models*

The first localizationist theories emerged from clinical observations in the mid- and late nineteenth century. The pioneers of aphasiology—Paul Broca, Karl Wernicke, John Hughlings Jackson, and other neurologists—described patients with lesions in the left inferior frontal lobe whose speech was hesitant and poorly articulated and other patients with lesions more posteriorly, in the superior temporal lobe, who had disturbances of comprehension and fluent speech with sound and word substitutions. These correlations led to the theory that language comprehension went on in the unimodal auditory association cortex (Wernicke’s area, Brodmann area 22) adjacent to the primary auditory cortex (Heschl’s gyrus, Brodmann area 41) and that motor speech planning went on in the unimodal motor association cortex in Broca’s area (Brodmann areas 44 and 45) adjacent to the primary motor cortex (Brodmann area 4). These theories incorporated the idea that localization of a language operation depends on the way it is related to sensory and motor processes. According to this view, speech planning goes on in Broca’s area because Broca’s is imme-

diately adjacent to the motor area responsible for movement of the articulators and Wernicke's area is involved in comprehension because it is immediately adjacent to primary auditory cortex.

These ideas and models were extended by Norman Geschwind and colleagues in the 1960s and 1970s. Geschwind (1965) added the hypothesis that word meaning was localized in the inferior parietal lobe (Brodmann areas 39 and 40) because word meanings consist of associations between sounds and properties of objects, and the inferior parietal lobe is an area of multimodal association cortex to which fibers from the unimodal association cortex related to audition, vision, and somesthesia project. Geschwind's model remains the best-known localizationist model of the functional neuroanatomy of language and is widely cited in clinical practice. The model is said to receive support from the existence of about 10 aphasic syndromes that serve the clinical purpose of helping to localize lesions.

However, despite its widespread use, this model has distinct limitations. Although some of the classic aphasic syndromes describe deficits at the level of word formation and sentence production, the model itself deals only with words, not with other levels of the language code. From a linguistic and psycholinguistic point of view, the syndromes all are composed of many processing deficits, which are different in different patients with the same syndrome. The correlations between syndromes and lesions are far from perfect. They are found primarily in the chronic stage of recovery from stroke, not in acute or subacute phases of stroke and not in other diseases, and even in chronic strokes a very large number of patients do not fall into the standard categories or their lesions do not occur where the model predicts they will. Indeed, the correlations between syndromes and lesions may reflect the fact that speech fluency is a critical dimension along which patients are classified, and nonfluent aphasias tend to be due to anterior lesions that affect motor structures whereas fluent aphasias tend to be due to posterior lesions that do not.

In the past 20 years or so, a number of researchers have sought to reinterpret the classic syndromes in terms of more specific components of the language processing system. For instance, the classic syndrome of conduction aphasia, in which patients have difficulty producing the correct sequences of sounds for words despite being able to produce individual sounds clearly and knowing what the words mean, has been divided into two separate deficits—one affecting short-term verbal memory and one affecting speech planning (Shallice and Warrington, 1972). Both of these more fine-grained disorders have been studied in considerable detail, with the consequence that we now

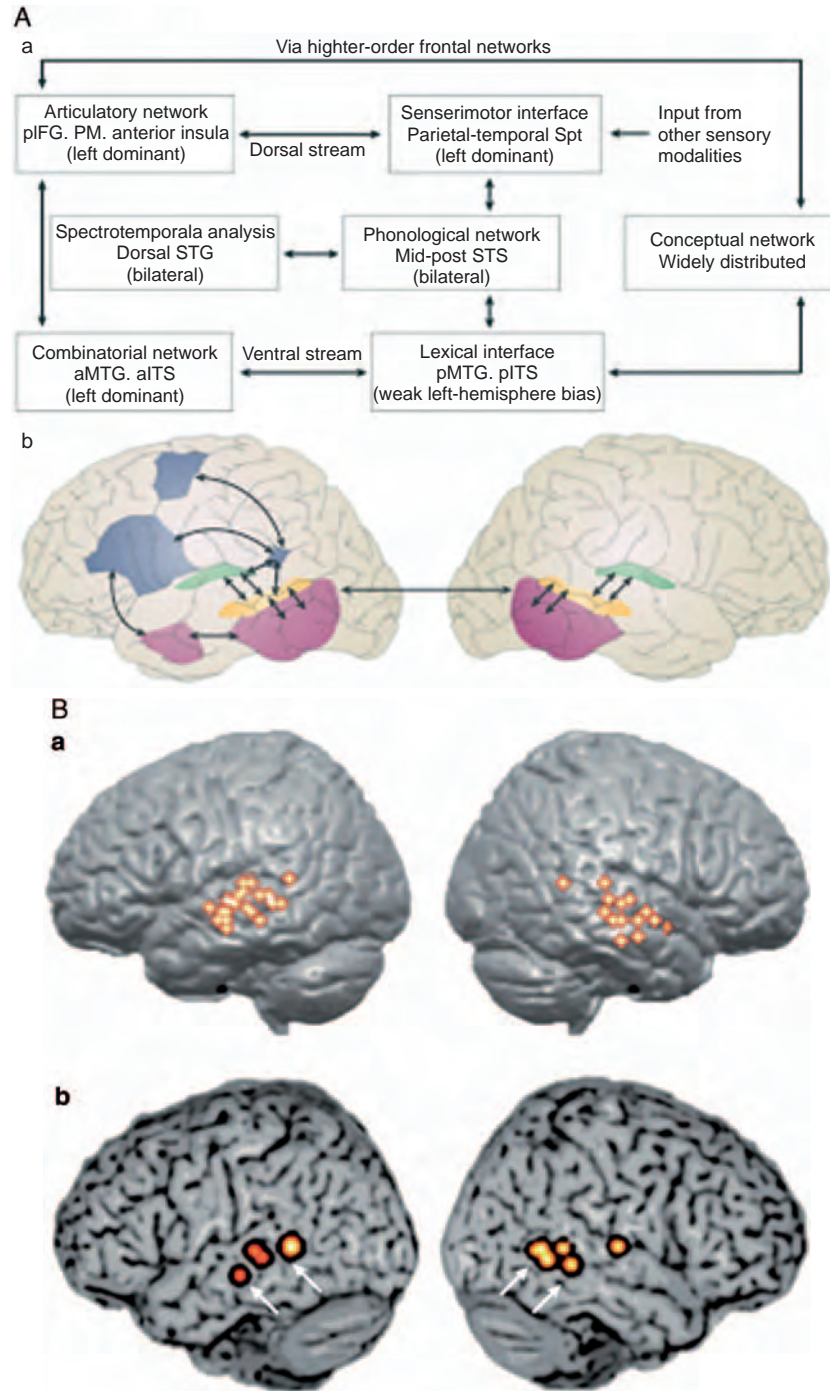

have a much better understanding of what aspects of short-term memory and speech planning are affected in these patients. In fact, these studies have led to important new ideas about the nature of both short-term memory and word production. Prior to these studies, it was thought that short-term memory was a gateway to long-term memory, but patients with the short-term memory type of conduction aphasia have excellent long-term memory, making this sequential model untenable; in another vein, additional study of patients with short-term memory disturbances has led to the identification of a short-term semantic memory system, not previously considered to exist on the basis of work with normals (Martin and He, 2004). In the area of word sound planning, study of patients with the second type of conduction aphasia (reproduction conduction aphasia) has led to computer-implemented models of word planning (Dell *et al.*, 1996) that differ in some interesting and important ways from models that emerge from studies of normals (Levelt *et al.*, 1999).

These modern studies of the classic aphasic syndromes have been part of a more radical transition to describing deficits in aphasic patients in terms of specific linguistic representations and psycholinguistic processes. The next sections review studies of location of two language processes—word recognition and comprehension, and syntactic operations—that cover the spectrum of abstractness of linguistic representations.

## Lexical Access and Word Meaning

Evidence from normal and impaired human subjects suggests that temporo-spectral acoustic cues to feature identity appear to be integrated in unimodal auditory association cortex lying along the superior temporal sulcus immediately adjacent to the primary auditory koniocortex (Binder *et al.*, 2000). Some researchers have suggested that the unconscious, automatic activation of features and phonemes as a stage in word recognition under normal conditions occurs bilaterally, and that the dominant hemisphere is the sole site only of phonemic processing that is associated with controlled processes such as subvocal rehearsal and conscious processes such as explicit phoneme discrimination and identification, making judgments about rhyme, and other similar functions.

Based on functional neuroimaging results, activation of the long-term representations of the sound patterns of words is thought to occur in the left superior temporal gyrus. Scott and her colleagues have argued that there is a pathway along this gyrus and the corresponding left superior temporal sulcus such that

**FIGURE 51.7** (A) Depiction of the lateral surface of the brain showing areas involved in the functional neuroanatomy of phonemic processing. H is Heschl’s gyrus, the primary auditory cortex. STP is the superior temporal plane, divided into posterior and anterior areas. STG is the superior temporal gyrus. Traditional theories maintain that pSTP and STG are the loci of phonemic processing. Hickok and Poeppel (2000) argue that these areas in both hemispheres are involved in automatic phonemic processing in the process of word recognition. Other research suggests that more anterior structures, aSTP and the area around the superior temporal sulcus (STS), are involved in these processes. The inferior parietal lobe (AG, angular gyrus; SMG, supramarginal gyrus) and Broca’s area (areas 44 and 45) are involved in conscious controlled phonological processes such as rehearsal and storage in short-term memory (from Hickok and Poeppel, 2007). (B) Activation of left superior temporal sulcus by the contrast of discrimination of phonemes and discrimination of matched nonlinguistic sounds (from Hickok and Poeppel, 2007).

word recognition occurs in a region anterior and inferior to primary auditory cortex, and that word meanings are activated further along this pathway in anterior inferior temporal lobe bilaterally (Scott and Johnsrude, 2003; Scott and Wise, 2004). This pathway constitutes the auditory counterpart to the visual “what” pathway in the inferior occipital-temporal lobe (Fig. 51.7).

Speech perception is connected to speech production, especially during language acquisition when imitation is crucial for the development of the child’s sound inventory and lexicon. On the basis of lesions in patients with reproduction conduction aphasia, the neural substrate for this connection has been thought to consist of the arcuate fibers of the inferior longitudinal fasciculus, which connect auditory association cortex (Wernicke’s area in the posterior part of the superior temporal gyrus) to motor association cortex (Broca’s area in the posterior part of the inferior frontal gyrus). Recent functional neuroimaging studies and neural models have partially confirmed these ideas, providing evidence that integrated perceptual-motor processing of speech sounds and words makes use of a “dorsal” pathway separate from that involved in word recognition (Hickok and Poeppel, 2007).

As described earlier, traditional neurological models maintained that the meanings of words consist of sets of neural correlates of the physical properties that are associated with a heard word, all converging in the inferior parietal lobe. It is now known that most lesions in the inferior parietal lobe do not affect word meaning and functional neuroimaging studies designed to require word meaning do not tend to activate this region. Evidence is accruing that the associations of words include “retroactivation” of neural patterns

back to unimodal motor and sensory association cortex (Damasio, 1989), and that different types of words activate different cortical regions. Verbs are more likely to activate frontal cortex, and nouns temporal cortex, possibly because verbs refer to actions and nouns refer to static items. More fine-grained relations between words and activation of sensory-motor brain areas have been described. Hauk *et al.* (2004) has found activation in primary motor and premotor cortex at the homuncular level of the leg when subjects recognize the written word “kick,” the mouth when they recognize “lick,” and the hand when they recognize “pick” (Fig. 51.8).

Both deficits and functional activation studies have suggested that there are unique neural loci for the representation of object categories such as tools (frontal association cortex and middle temporal lobe), animals and foods (inferior temporal lobe and superior temporal sulcus), and faces (fusiform gyrus) (see Caramazza and Mahon, 2006, for review), and some of these localizations are adjacent to areas of the brain that support perception of features that are related to these categories (animals activate an area of lateral temporal adjacent to the area sensitive to biological motion). Debate continues about how these category effects arise, and whether these activations should be taken as reflecting the meanings of these words. At the same time as these specializations receive support, evidence from patients with semantic dementia and from functional neuroimaging indicates that another critical part of the semantic network that represents word meanings and concepts is located in the anterior inferior temporal lobes.

### Syntactic Operations

We shall review the use of syntactic structure to determine sentence meaning in the comprehension process. Deficits of this ability typically are established by showing that patients can understand sentences with simple syntactic structures (e.g., *The boy chased the girl.*) and sentences with complex syntactic structures in which the relationships between nouns and verbs can be inferred from a knowledge of real-world events (e.g., *The apple the boy ate was red.*), but not sentences with complex structures in which the relationships between nouns and verbs depend on a syntactic structure that needs to be constructed (e.g., *The boy the girl pushed was tall.*). A variety of models have been proposed regarding the neural basis for sentence comprehension, ranging from localization, though distribution to variable localization.

A very well-known theory—the trace deletion model (Grodzinsky, 2000)—has centered on the finding that Broca’s aphasics who produce “agrammatic”

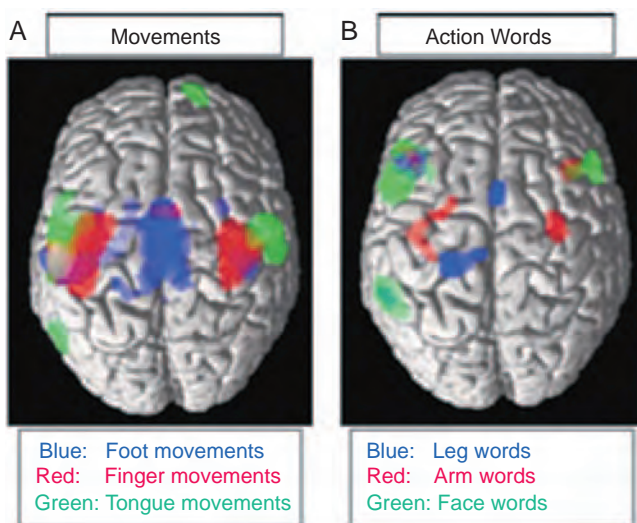

FIGURE 51.8 (A,B) Activation of areas of the motor strip and premotor area by actions and action words (from Hauk *et al.*, 2004).

speech (speech that lacks function words and morphological markers) often have difficulty understanding sentences whose meanings depend the use of these elements to construct syntactic structures. The similarity of comprehension deficits and expressive language problems of these patients—both involving problems with function words, morphology, and syntax—has suggested that these deficits are connected, and that they are linked to lesions in the area of the brain that are associated with expressive agrammatism.

However, the data that are available indicate that deficits in syntactic processing in sentence comprehension occur in all aphasic syndromes and after lesions throughout the perisylvian cortex (Caplan *et al.*, 1985, 1996; Caramazza *et al.*, 2001). Conversely, patients of all types and with all lesion locations have been described with normal syntactic comprehension (Caplan *et al.*, 1985). We have just reported the most detailed study of patients with lesions whose syntactic comprehension has been assessed (Caplan *et al.*, 2007). We studied 42 patients with aphasia secondary to left hemisphere strokes and 25 control subjects for the ability to assign and interpret three syntactic structures in enactment, sentence-picture matching and grammaticality judgment tasks. In regression analyses, lesion measures in both perisylvian and nonperisylvian regions of interest predicted performance after factors such as age, time since stroke, and total lesion volume had been entered into the equations. Patients who performed at similar levels behaviorally had lesions of very different sizes, and patients with equivalent lesion sizes varied greatly in their level of performance. The data are consistent with a model in which the neural tissue that is responsible for the operations underlying sentence comprehension and syntactic processing is localized in different neural regions, possibly varying in different individuals.

Functional neuroimaging studies have led many researchers to articulate models in which one or another aspect of parsing or interpretation is localized in Broca's area, or in portions of this region (Grodzinsky and Freiderici, 2006). However, most neuroimaging studies actually show that multiple cortical areas are activated in tasks that involve syntactic processing (Fig. 51.9). Overall, the data are inconsistent with invariant localization, and suggest multifocal or variable localization of the areas that are sufficient to support syntactic processing within the language area across the adult population. It may be that language operations more closely tied to early perceptual and late motor planning processes are invariantly localized whereas those that compute more abstract aspects of the language code can be supported by a larger number of regions of association cortex.

**FIGURE 51.9** Activation of Broca's area and superior temporal sulcus when subjects processed sentences with particular syntactic features (questioned noun phrases) compared to matched sentences without those features (from Ben Shachar *et al.*, 2004).

## CONCLUSIONS

Human language is a unique representational system that relates aspects of meaning to many types of forms (e.g., phonemes, lexical items, syntax), each with its own complex structure. Animal communication systems are neither as complex nor as powerful as human language. Nonetheless, they have some similarities to language and provide clues as to the neural basis of human language. Some language traits are part of a shared evolutionary ancestry with other species, others represent convergent, independent evolution of analogous processes, and yet others must be unique to our species. Perhaps the most important lessons learned from animal studies are that complex communication systems can be innate, that learning can shape an innately specified range of behavioral possibilities, and that communication systems can rely

on specific nuclei within the brain and be lateralized. Other features of the neural basis for animal communication systems, such as seasonal variation in the size of birdsong nuclei and the mechanisms that underlie this phenomenon, are not obviously relevant to human language.

Deficit-lesion correlations and neuroimaging studies are beginning to provide data about the neural structures involved in human language. It appears that one area of the brain—the left perisylvian association cortex—is especially important in representing and processing language (although other regions are involved as well), and that, within this area, particular language operations are localized in specific regions. The exact details of these localizations are just beginning to be understood, as the modern tools of cognitive neuroscience are applied to this problem.

# The Prefrontal Cortex and Executive Brain Functions

## INTRODUCTION

What controls your thoughts? How do you decide what to pay attention to? How do you act appropriately while dining in a restaurant or listening to a lecture? How do you plan and execute errands? How do you manage to pursue long-term goals, like obtaining a college degree, in the face of the many distractions that can knock you “off task”? In short, how does the brain manage to orchestrate the activity of millions of neurons to produce behavior that is willful, coordinated, and extends over time? This is called cognitive control, the ability of our thoughts and actions to rise above mere reactions to the immediate environment and be proactive: to anticipate possible futures and coordinate and direct thought and action to them. It is a hallmark of intelligent behavior.

Because cognitive control necessarily involves the coordination of many different brain processes, it no doubt depends on circuits that extend over much of the cerebral cortex. However, one cortical region, the prefrontal cortex (PFC), seems to play a central role. It is the cortical area that reaches the greatest relative size in the human brain and is thus thought to be the neural instantiation of the mental qualities that we think of as “intelligent.” Accordingly, the PFC receives converging information from many brain systems processing external and internal information and it is interconnected with motor system structures needed for volitional action.

Here, we discuss anatomical, neuropsychological, and neurophysiological evidence for, and theories of, the role of the PFC in cognitive control. We will begin with a discussion of the characteristics of volitional, or

controlled, processes as they can provide predictions about the neural mechanisms likely to underlie them.

## CONTROLLED PROCESSING

Behavior varies along a continuum from mindless, automatic behaviors to willful and purposeful (i.e., controlled) behaviors (see Barsalou, 1992). Automatic processes are reflexive. If a car or a predator is bearing down on us, we leap out of the way before we even have had a chance to form the intention to do so; our mind seems to “catch up” afterward. Automatic processes thus seem to depend on relatively straightforward, hardwired relationships between the brain’s input and output systems. In neural terms, it seems that they depend on well-established, neural pathways just waiting to be triggered by the right sensory cue. That is, automatic processes are driven in a “bottom-up” fashion: they are determined largely by the nature of the sensory stimuli and whatever reaction they are most strongly wired to.

These relatively simple, hardwired, cue-response mappings are useful in many situations. Because they can simply be fired off by the environment, they are quick and can be executed without taxing the limited capacity of our conscious thoughts. But a creature that is only at the mercy of its immediate environment is not well equipped to deal with the ambiguity, and exploit the opportunity, of a complex and dynamic world. Sometimes, the course of action is not obvious because cues are ambiguous (i.e., they activate more than one possible internal representation), or multiple

behaviors might be triggered and the one that is optimal for a given situation is at a disadvantage relative to better established (more automatic) alternatives. In these situations, ambiguity needs to be resolved by our internal states and intentions, by knowledge of possible and desired future outcomes (goals) and what means have been successful at achieving them in the past as well as their relative costs and benefits. This information is used to activate the same basic sensory, memory, and motor processes that are engaged during automatic behaviors. Only now, they are not triggered by cues from the environment. They are orchestrated in a top-down fashion by our expectations about goals and the means to achieve them. So, this mode of behavior is controlled in the sense that we (our knowledge and intentions) are in charge, not the environment. A tenet of modern studies of behavior is that this knowledge is obtained by learning mechanisms that detect and store associations between cues, internal states, and actions that predict goal attainment (reward) (see Dickinson, 1980). Insofar as primates are capable of navigating situations that involve diverse, arbitrary, relationships across a wide range of informational domains, it follows that a neural system for cognitive control must have access to information from many brain systems and the ability to encode the goal-relevant relationships between them.

The cognitive control system must also have the ability to select which sensory, memory, and motor processes are activated at a given moment. Selection is central because of our very limited capacity to engage in controlled behaviors. This is evident to anyone who has tried to talk on the phone and answer an e-mail at the same time; we can think about only a limited number of things at a time. This is in contrast to our high capacity for automatic processes. Because they can be triggered by the environment, any number of them can be fired off at once, as long as they do not come into direct conflict with one another. It makes sense that brain mechanisms for cognitive control would evolve with this capacity limitation. There is the tradeoff between amount of information and depth of analysis; focusing processing on a narrow band of information relevant to a current goal allows a much more elaborate analysis of a situation and available options. This single-mindedness also allows us to stay on track; processing information not relevant to a current goal increases the chance for distraction. In fact, in many views of cognition, control and attention are virtual synonyms. It follows that a neural system for cognitive control must have the infrastructure and mechanisms for selecting goal-relevant, and suppressing goal-irrelevant, processes throughout the cerebral cortex.

The cognitive control system must also have a way to deal with the gaps in time that are inevitable with goal-directed behaviors. Information about predicted goals and means must be brought online before the behaviors are executed and maintained until the current task is completed. Also, because goal-directed behaviors typically are extended over time, we often must wait for additional information or for a more opportune time to execute an action. The ability to keep goal-relevant information online and available for processing is called working memory (Baddeley, 1986). It is less critical for automatic processes because they are immediate: a stimulus triggers an already established circuit.

Finally, and perhaps most importantly, the cognitive control system must be highly plastic and flexible. Virtually all voluntary, goal-directed behaviors are acquired by experience, and given that humans and other primates are capable of rapid learning of new volitional behaviors, the cognitive control system must have an equal capacity for rapid learning. Primates are also remarkably flexible with their controlled behaviors. One may learn how to navigate a specific circumstance, but one can quickly generalize this to new situations, conjoin them with others, and rearrange them to produce novel behaviors. Goal-directed behaviors can also be temporarily interrupted and resumed at ease. One might temporarily divert oneself from wine shopping, for example, to pick up some cheese. By contrast, automatic behaviors are characterized by their rigidity. They are initiated by specific trigger events and are "ballistic"; once activated they tend to run off in pretty much the same way every time. It stands to reason that the cognitive control system must represent goal-relevant information in a format that is compatible with such flexibility.

## Summary

There are two general modes of information processing that underlie thoughts and behaviors, automatic and controlled. Automatic processes are relatively simple, straightforward, reflexive reactions to whatever information happens to be flowing into the senses at a given moment. By contrast, controlled processes are engaged when a task has additional constraints and requires knowledge about goals and means.

From this brief review of some of the main characteristics of controlled processing, it is possible to make some predictions about the nature of any brain system involved in goal-directed (executive) control of cognitive functions:

1. It must have extensive and diverse connections to other regions of the brain in order to have access

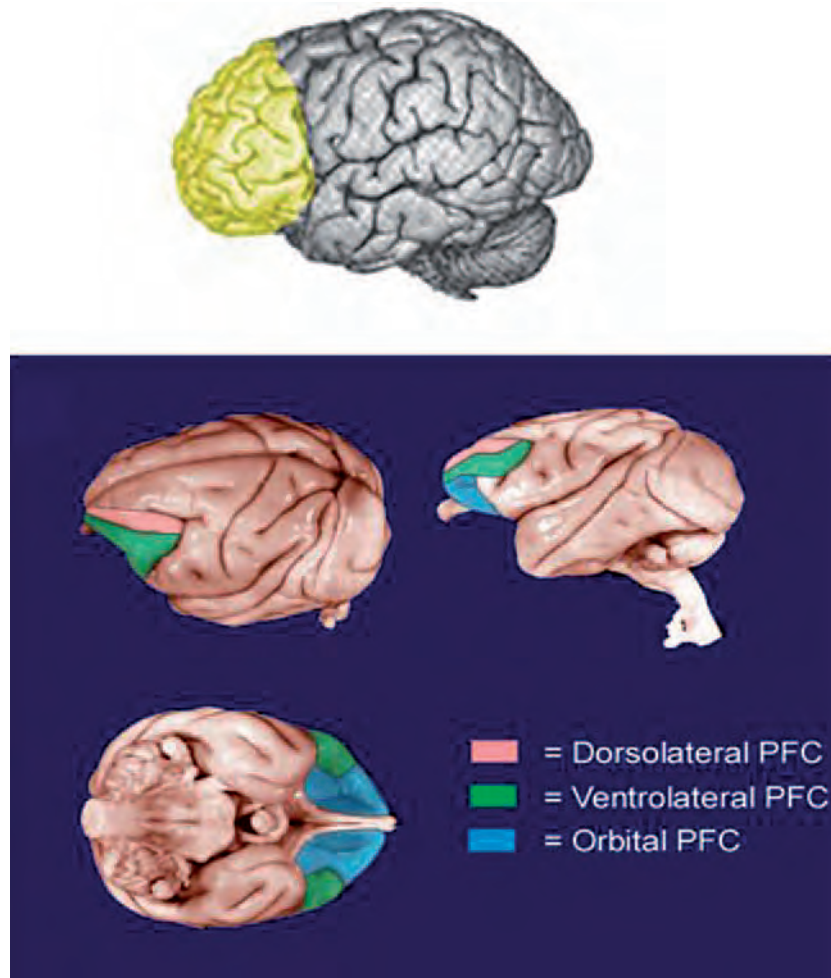

to information from, as well as influence, widespread brain systems.

2. It needs to have information about goals and the means to achieve them, and this necessarily involves representing diverse multivariate relationships between a wide variety of sensory information, stored knowledge, actions, and consequences. It needs to be plastic and modifiable by experience in order to acquire this information.
3. There must be short-term storage mechanisms to keep goal-related information online and available until the goal is achieved.
4. It must represent goal-related information in a form that is flexible and easy to modify.

For many reasons, many investigators have argued that the neural instantiation of executive functions are, to a large degree, in the PFC. The remainder of this chapter discusses why.

## ANATOMY AND ORGANIZATION OF THE PREFRONTAL CORTEX

The PFC consists of a collection of cortical areas that differ from one another on the basis of size, density, and distribution of their neurons. Its location in the human brain and major divisions in the monkey brain are shown in Figure 52.1, but these can be further subdivided into at least 18 distinct areas. The PFC is well positioned for a central role in cognitive control. Collectively, these areas have interconnections with brain areas processing external information (with all sensory systems and with cortical and subcortical motor system structures) as well as internal information (limbic and midbrain structures involved in affect, memory, and reward). The subdivisions have partly unique, but overlapping, patterns of connections with the rest of the brain, which suggests some regional

**FIGURE 52.1** Location of the prefrontal cortex in the human brain (top) and its major subdivisions in the macaque monkey brain (bottom).

differences in function (Fig. 52.2). As in much of the neocortex, however, there are local connections between different PFC areas that can result in an intermixing and synthesis of disparate information needed for cognitive control. Indeed, the PFC has long been suggested to be the great integrator, a brain region that synthesizes information about the external and internal world for the purpose of producing goal-directed behavior.

### The PFC Is Connected with Sensory Systems

The dorsolateral and ventrolateral portions of the PFC receive visual, auditory, and somatosensory information from the occipital, temporal, and parietal cortices, whereas orbitofrontal cortex receives chemo-

sensory and visceral information (Fig. 52.2). Many PFC areas receive converging inputs from at least two sensory modalities. For example, the dorsolateral (areas 8, 9, and 46), and ventrolateral (12 and 45) areas both receive projections from visual, auditory, and somatosensory cortex. Further, the PFC is interconnected with other cortical regions that are themselves sites of multimodal convergence. Many PFC areas (9, 12, 46, and 45) receive inputs from the rostral superior temporal sulcus, which has neurons with bimodal or trimodal (visual, auditory, and somatosensory) responses to external stimulation. The arcuate sulcus region (areas 8 and 45) and area 12 seem to be particularly multimodal. They contain zones that receive overlapping inputs from all three sensory modalities. In all these cases, the PFC is not connected directly

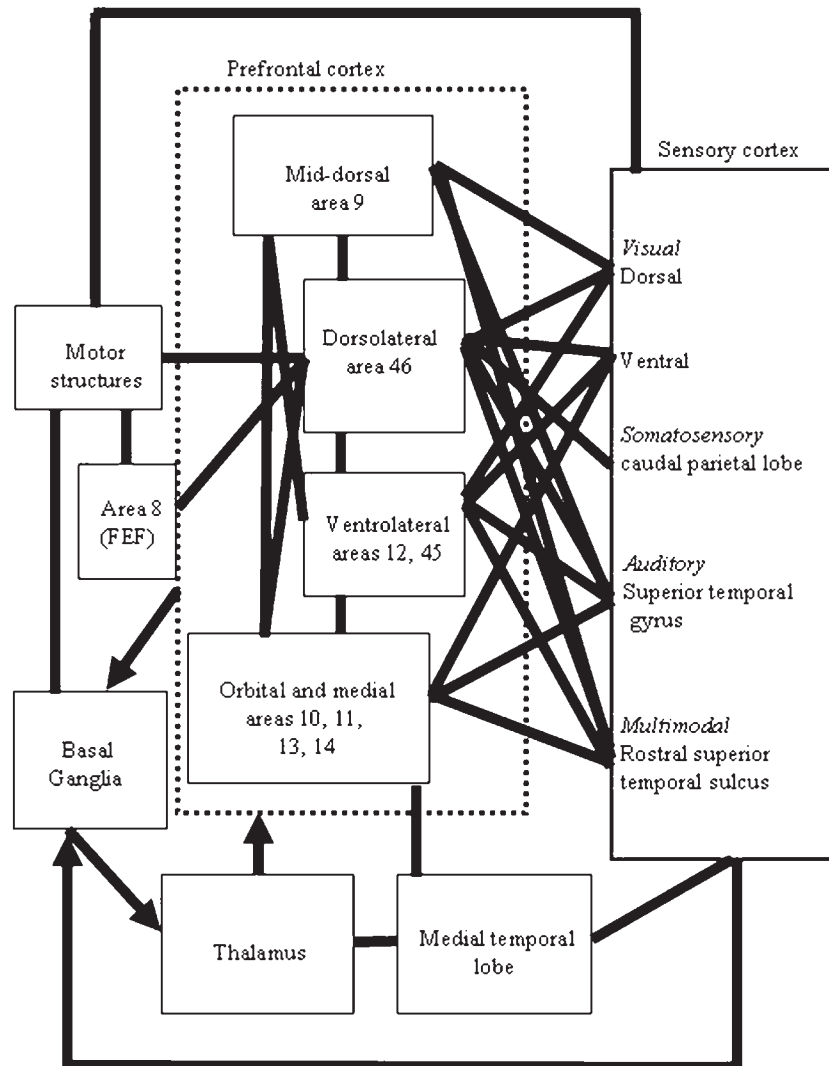

FIGURE 52.2 Schematic diagram of some of the extrinsic and intrinsic connections of the PFC. Most connections are reciprocal; the exceptions are noted by arrows. From Miller and Cohen (2001).

with primary sensory areas, but instead interconnected with secondary or “association” sensory cortex.

### The PFC Is Connected with Motor System Structures

The dorsal PFC, particularly dorsolateral area 46, has preferential connections with many motor system structures, and may be the primary region by which the PFC exerts control over behavior. Dorsolateral area 46 is interconnected with motor areas in the medial frontal lobe such as the supplementary motor area (SMA), pre-SMA, and the rostral cingulate, with the premotor cortex on the lateral frontal lobe, and with cerebellum and superior colliculus. Dorsolateral area 46 also sends projections to area 8, which contains the frontal eye fields, a region important for voluntary shifts of gaze. As with sensory cortex, there are no direct connections between the PFC and primary motor cortex; the PFC is instead connected with premotor areas that, in turn, send projections to primary motor cortex and the spinal cord. Also important are the dense interconnections between the PFC and basal ganglia (see later).

### The PFC Is Connected with the Basal Ganglia

The basal ganglia (BG) are a set of subcortical structures that are closely associated with both the motor system and the PFC. The anatomy of the BG are similar to that of the PFC in that they receive converging inputs from virtually every cortical system and many subcortical structures. The region of the BG that receives inputs, the striatum (which includes the caudate and putamen) receives a heavy projection from the PFC. Information then travels through loops of subcortical nuclei, which project back to the frontal cortex via the thalamus. Whereas the PFC projects back to the same wide range of cortical areas that give input to the basal ganglia, the basal ganglia project largely to the frontal lobe motor system structures and the PFC. Thus, the BG are well-positioned to influence a wide range of brain functions, albeit with an emphasis on motor output. The anatomical “loops” between the PFC and BG have inspired theories of their close interdependency. This will be discussed later. Basal ganglia anatomy and functions are discussed in greater detail in Chapter 31.

### The PFC Is Connected with the Limbic System

The orbitofrontal PFC is more closely associated with medial temporal limbic structures critical for

long-term memory and “internal” information, such as affect and motivation, than other PFC regions. It has direct and indirect (via the thalamus) connections with the hippocampus and associated neocortex, the amygdala and hypothalamus. It has strong connections with olfactory and gustatory cortices, but weaker connections than the lateral PFC to parietal and temporal cortices.

### Intrinsic PFC Connections May Provide a Substrate for Diverse Information to Interact

Like most of the neocortex, many PF connections are local. There are not only interconnections between the major subdivisions, but also interconnections between their constituent areas. The lateral PFC is particularly well connected. Ventrolateral areas 12 and 45 are interconnected with dorsolateral areas 46 and 8, with dorsal area 9 as well as with orbitofrontal areas 11 and 13. Intrinsic PFC connections presumably allow information from a given PFC afferent or from a given process within a PFC subregion to be distributed to other parts of the PFC.

### Summary

The PFC is anatomically well situated to play a role in cognitive control. It receives information from and sends projections to forebrain systems that process information about the external world, motor system structures that produce voluntary movement, systems that consolidate long-term memories, and systems that process information about affect and motivational state. This anatomy long has suggested that the PFC may be important for synthesizing external and internal information needed to produce complex behavior.

## EFFECTS OF DAMAGE TO THE PREFRONTAL CORTEX IN HUMANS

### PFC Damage in Humans Results in a Dysexecutive Syndrome

The PFC occupies a far greater proportion of the human cerebral cortex than in other animals, suggesting that it might contribute to those elusive cognitive capacities that separate humans from animals. However, unlike electrical stimulation of more posterior regions that produce hallucinations or motoric responses, stimulation of the PFC produces no obvious effect. This led it to be termed *silent cortex*. Similarly,

at first glance, PFC damage has remarkably little overt effect; patients can perceive and move, there is little impairment in their memory, and they can appear remarkably normal in casual conversation. The most infamous case is that of Phineas Gage, a railway construction foreman. In 1848 he suffered an accident in which an iron bar exploded and was projected up through his chin and out of the top of his head, destroying much of his medial PFC in the process (Damasio *et al.*, 1994) (Fig. 52.3). He survived but it soon became clear that Gage had changed. He once had been an efficient foreman, but now he was irreverent and profane, rude to his coworkers, and unable to organize and plan the work that needed carrying out.

Despite the superficial appearance of normality, PFC damage seems to devastate a person's life. Take the case of Elliot, a successful, happily married accountant, and by all accounts a responsible person. In his late thirties, he was diagnosed as having a prefrontal meningioma, and during the removal of the tumor his PFC was damaged. Within a few of years of the operation, Elliot had divorced his wife, got married and divorced again, lost touch with his family and friends, acquired a disreputable business partner, and lost his business. All of Elliot's basic mental functions seemed to be intact, his language and memory abilities seemed normal, and on tests of intelligence he consistently performed in the superior range. What Elliot seemed to lack was the ability to coordinate his mental func-

FIGURE 52.3 Reconstruction of damage to Phineas Gage's brain. From Damasio *et al.* (1994).

tions in a manner that took long-term concerns (unseen goals) into account. He became impulsive, lurching from one catastrophe to another based on his momentary whims.

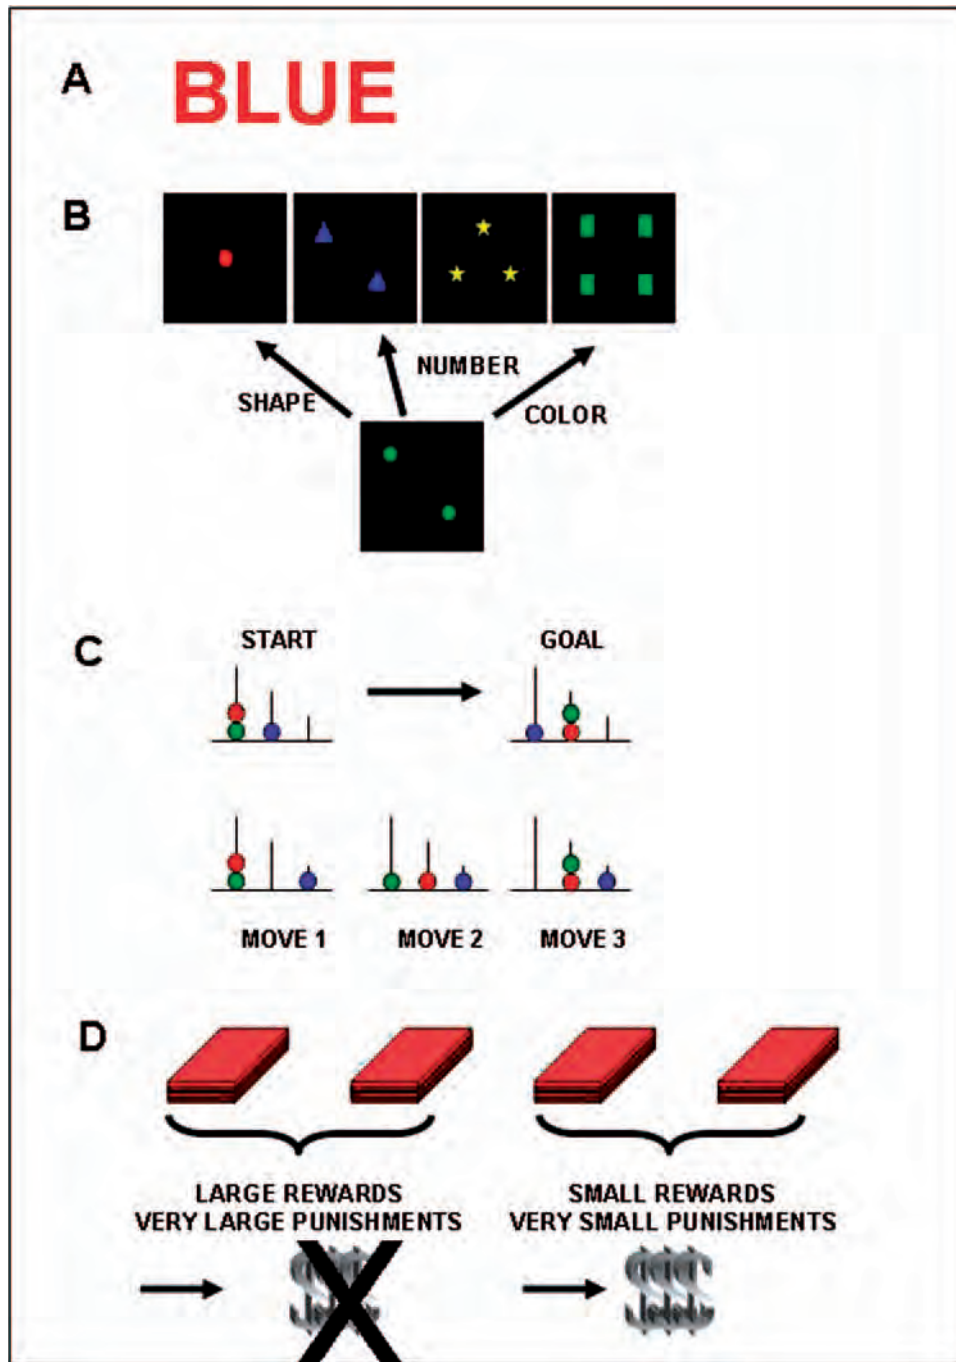

Note that this scenario is exactly what would be expected from the loss of a cognitive control system. Damage to the higher-order, executive functions leaves the components of complex behavior intact and able to be elicited by the appropriate external trigger. But the individual would not be able to coordinate these behaviors with respect to goals and task-specific constraints. For example, there was a PFC patient who, when preparing coffee, first stirred and then added cream. Because of this apparent dysfunction in the top-down control over behavior, the pattern of deficits following frontal lobe damage has been thought to reflect a lack of goal-directedness, and the result is called the *dysexecutive syndrome* (see Box 52.2).

### Humans with Frontal Damage Are Disinhibited

One of the most striking features of prefrontal patients is their disinhibition and lack of behavioral control. The patients are often impulsive, quick to anger, and prone to making rude and childish remarks. For example, one patient complained of being "much more outspoken" since her injury, and another stated, "I've become impulsive since the accident. If I have something to say I can't wait and have to say it straight away."

An example of disinhibition is utilization behavior. During a medical examination, a patient with PFC damage will pick up and use items that have been left on the doctor's desk. For example, the doctor might leave a comb on the desk, and the patient will pick the comb up and start combing his or her hair. In one extreme case a patient used a urinal that the doctor had left on the desk! More formal tests of disinhibition include the Stroop test (Fig. 52.4A). It requires the patient to name the color of the ink in which a word is written. The catch is that the word is the name of another color. Patients have difficulty inhibiting the saying of the word itself because the word elicits a strong, prepotent tendency to read it.

Such tests require patients to inhibit previously established specific responses, but PFC patients are also impaired at inhibiting more abstract behavioral demands like rules. Consider the Wisconsin Card Sorting Test (WCST) (Fig. 52.4B). The patient is required to sort a deck of cards, on which are printed a number of symbols. The cards differ from one another in the color and shape of the symbols, and the number of symbols per card. The patient's task is to sort the cards

**FIGURE 52.4** Tasks used to assess PFC dysfunction in humans. (A) Stroop task. (B) Wisconsin Card Sort. (C) Tower of London task. (D) Gambling task. See text for explanation of tasks.

according to a given criterion; for example, sort by shape. At this point the patients perform the task as well as control subjects. However, when the criterion is changed, for example to sort by number, the patients are impaired; they are unable to inhibit sorting by the previous rule. This behavior, that is continuing to perform a previously reinforced behavior even though

it is no longer rewarded, is called perseveration and is characteristic of a prefrontal patient's performance on a wide variety of tasks.

This inability to ignore irrelevant stimuli and the actions they trigger has led PFC patients to be described as stimulus-bound, and the disruption of the patient's ability to think and plan has been termed goal neglect

(Duncan *et al.*, 1996). Without the influence of the goal-related signals from the executive functions, the systems always respond reflexively to an input with whatever output is strongly connected to it.

### Humans with Frontal Lobe Damage Have Emotional Impairments

PFC damage produces a marked alteration of a patient's moods and emotions. In the case of Phineas Gage, these changes were so profound that his friends commented, "Gage is no longer Gage." Patients typically display an emotional shallowness, being indifferent and apathetic both to their own situation and to the needs of others. For example, one patient stated, "If I saw someone cry I'd just laugh—people look silly getting upset." Formal tests show that patients are less able to recognize the emotional expressions of others, though their ability to identify faces remains intact. Patients also become more irritable, aggressive, and prone to angry outbursts. Their humor, termed *Witzelsucht*, becomes compulsive, puerile, and facetious. The patients are aware of these changes even if they are indifferent to them. For example, one patient commented, "Emotion, tears, that's all gone out of the window," and another stated, "I'm much more aggressive, and I feel much less fear. I go fighting for no reason: I don't get anxious."

### Humans with Frontal Damage Have Difficulty in Planning

Prefrontal patients have a great deal of difficulty planning and organizing their lives. Wilder Penfield, a neurosurgeon during the mid-twentieth century, described the case of his sister, on whom he operated to remove a large frontal tumor. Prior to the surgery she had been an excellent cook, and though her basic culinary skills remained subsequent to the operation, she seemed unable to organize her behavior so that all the elements of the meal were ready simultaneously. Instead she would move haphazardly from preparing one part of the meal to another, so that some parts of the meal would be burnt while others had hardly been started.

Formal tests have been developed to measure the ability of patients to organize their behavior. For example, the Tower of London Test requires the patient to think several moves in advance (Fig. 52.4C). There are three vertical posts that have three colored rings that can be placed on the posts. The three posts are of different lengths such that the first post can accommodate all three rings, the second post can accommodate two, and the third post just one. From an initial

starting position the patient is asked to move the rings one at a time, from one post to another, to attain a specified goal position. This task requires the patient to plan a number of subgoal positions in order to reach the final goal. Patients with prefrontal damage are greatly impaired at this task, making many more moves than necessary to reach the final goal position. The Multiple Errands Test taxes more everyday planning abilities. The test takes place in a shopping center, and the patient is required to perform various errands, such as obtaining a copy of the previous day's newspaper. The patients take much longer than control subjects. They go into inappropriate (irrelevant) shops as they pass them and repeatedly become distracted from their principal goal.

Impairments in planning might be related partly to difficulties evaluating the consequences of actions. Faced with a number of different, competing actions, patients might not choose wisely because they are less sure of the consequences of those actions. Evidence for this arises from a "gambling" task (Fig. 52.4D). The patient has to choose cards from four different decks in an effort to win play money from the experimenter. Each card wins the patient some money, but some cards also lose money and the patient has to pay the experimenter. Unbeknownst to the patient, cards from the first two decks will win large amounts of money, but are also occasionally associated with very large losses, and repeatedly choosing from these two decks will result in a net loss. By contrast, cards in the other two decks win smaller amounts of money, but the losses are also a lot smaller, and overall, choosing from these two decks will result in a net profit. Control subjects initially choose from the two decks associated with the larger rewards, but after a few very large losses, they switch to choosing from the other decks and earn a profit. Patients with PFC damage also initially choose from the decks associated with larger rewards, but then fail to alter their behavior until they lose all their money. This task is appealing because it is closely related to the types of problems that prefrontal patients experience in real life.

### Humans with Frontal Lobe Damage Have Impaired Working Memory

Patients also might have difficulties planning due to a problem with holding information in mind for a short while. This is the kind of short-term memory that one relies on when reading a phone number and then dialing that number. This function is called working memory because the information is forgotten as soon as it is no longer relevant. The concept of working memory is influenced by the observation that monkeys

with lesions of the PFC have deficits on a spatial delayed-response task that requires them to remember the location of a stimulus or behavioral response over a brief delay of several seconds. Early studies failed to find this deficit in humans with prefrontal damage, possibly because the patients verbalized the location of the stimulus (e.g., “it’s on the left”), which presumably makes the task much easier. Later studies, however, in which the prefrontal damage was more extensive and bilateral, did show a spatial delayed response deficit. Other studies used abstract patterns that could not be easily verbally encoded, and found that the patient’s nonspatial working memory was also impaired.

## Summary

We have seen that the PFC poses a complex problem. Damage to a relatively circumscribed region of cortex in humans produces a bewildering array of symptoms. But one caution in interpreting clinical studies concerns the size of the damage that typifies the prefrontal patient. Not only does the damage often encompass many different PFC regions, each of which may have different functions, but it also often encroaches onto neighboring regions, such as the premotor cortex, the cingulate cortex, and the insular cortex. Plus, it should be remembered that the PFC comprises many different anatomically defined areas, each possessing unique patterns of connections with the rest of the brain; it might be that each component of the dysexecutive syndrome arises from damage to different areas of the PFC. These matters are difficult to explore in humans with PFC damage, because the damage is typically so extensive that it encompasses many brain regions both within and external to the PFC. There are two solutions to this problem. The first is to use neuroimaging techniques, such as functional magnetic resonance imaging (fMRI), in healthy humans. This technique can detect areas of increased neuronal activity in specific brain regions with a resolution of 2–4 mm<sup>3</sup>. A second method is to study the effects of experimentally produced focal lesions in monkeys. We will discuss each of these approaches in turn.

## NEUROIMAGING STUDIES AND PFC

Neuroimaging studies have shown that many of the tasks with which patients with PFC damage struggle also activate PFC in healthy subjects. However, an advantage of the technique is that specific regions within PFC can be identified that are activated prefer-

entially by specific cognitive processes. For example, fMRI studies show that performing the WCST activates ventrolateral PFC. In general, a number of trends have emerged from this field regarding the functional organization of PFC.

The clearest functional distinction is between orbitofrontal cortex and lateral PFC. Orbitofrontal cortex consistently is activated by tasks requiring the processing of rewarding or emotional information. For example, it shows more activation to pleasant images (e.g., a baby’s face) or unpleasant images (e.g., mutilated bodies) as opposed neutral images. Similar results are seen in other modalities such as pleasant or unpleasant smells, tastes, sounds, and touches. Orbitofrontal cortex even responds to abstract rewards such as winning or losing money. Orbitofrontal cortex is not simply responding to the presence of these rewards, but seems to use this information to guide our decisions and choices. For example, orbitofrontal cortex is activated when subjects are choosing a meal from a menu, but not if they are simply reading the menu with no intention of ordering.

In contrast, lateral PFC is activated by a wide assortment of cognitive tasks. These include tests of inhibitory control (such as the Stroop task), rule switching tasks (such as the WCST), and working memory tasks. A distinction that has emerged from these studies concerns the respective roles of dorsolateral and ventrolateral PFC regions. Ventrolateral PFC is activated predominately by tasks that require holding information in working memory whereas dorsolateral PFC is activated when that information must be manipulated in some way. We return to this idea later in the chapter when we discuss the “multiple processing levels” theory of prefrontal function. Recently investigators have begun to focus on the most anterior portions of PFC, referred to as the *frontal pole*, which corresponds to area 10. There is some evidence that this region might be responsible for controlling the transfer of information between dorsolateral and ventrolateral PFC.

In sum, neuroimaging studies have helped to show that we cannot consider the PFC as a single unitary area, but that distinct subregions of PFC are responsible for carrying out specific processes. The clearest distinction is between the emotional and reward-based processing occurring in orbitofrontal cortex, and the more cognitive processes occurring in lateral PFC. A problem with fMRI, however, is that although it can identify which regions are more active during a given task, it does not tell us whether those regions are *necessary* for the performance of the task. To determine whether a given PFC subregion is necessary for a specific cognitive process, findings from monkey

neuropsychology are useful. We discuss these findings in the next section.

## **EFFECTS OF DAMAGE TO THE PREFRONTAL CORTEX IN MONKEYS**

Studying the effects of experimentally induced lesions in monkeys has two advantages. First, because the lesions are experimentally induced they can be small and focused on specific subregions of PFC. Second, they are a strong test of whether a specific subregion is necessary for the performance of a given cognitive task. However, we must also bear in mind a number of points when evaluating primate neuropsychological findings.

First, in order to conclude that two different prefrontal areas are performing, or at least emphasize two different functions, it is necessary to demonstrate a double dissociation. A monkey with lesion X must be impaired at process A, but not process B, and a monkey with lesion Y must be impaired at process B, but not process A. A single dissociation, for example showing that lesion X impairs process A, but not process B, is insufficient evidence because this pattern of results could be achieved simply because the test used to assess A is more sensitive than the test used to assess process B. In many studies, monkeys were tested on just one task and any evidence for a double dissociation can only be inferred across different studies and (often) different laboratories. This complicates the interpretation because any differences in training and testing procedures and in the extent of the lesions are potential confounding factors.

Second, early studies produced large lesions. These lesions often produced damage to the underlying white matter, potentially disconnecting regions of cortex outside of the site of the lesion and often damaging underlying structures such as the basal ganglia. In recent years, excitotoxins have been developed. These drugs can be injected into an area and overexcite the cells located there. The cells subsequently die, but the underlying white matter is left intact.

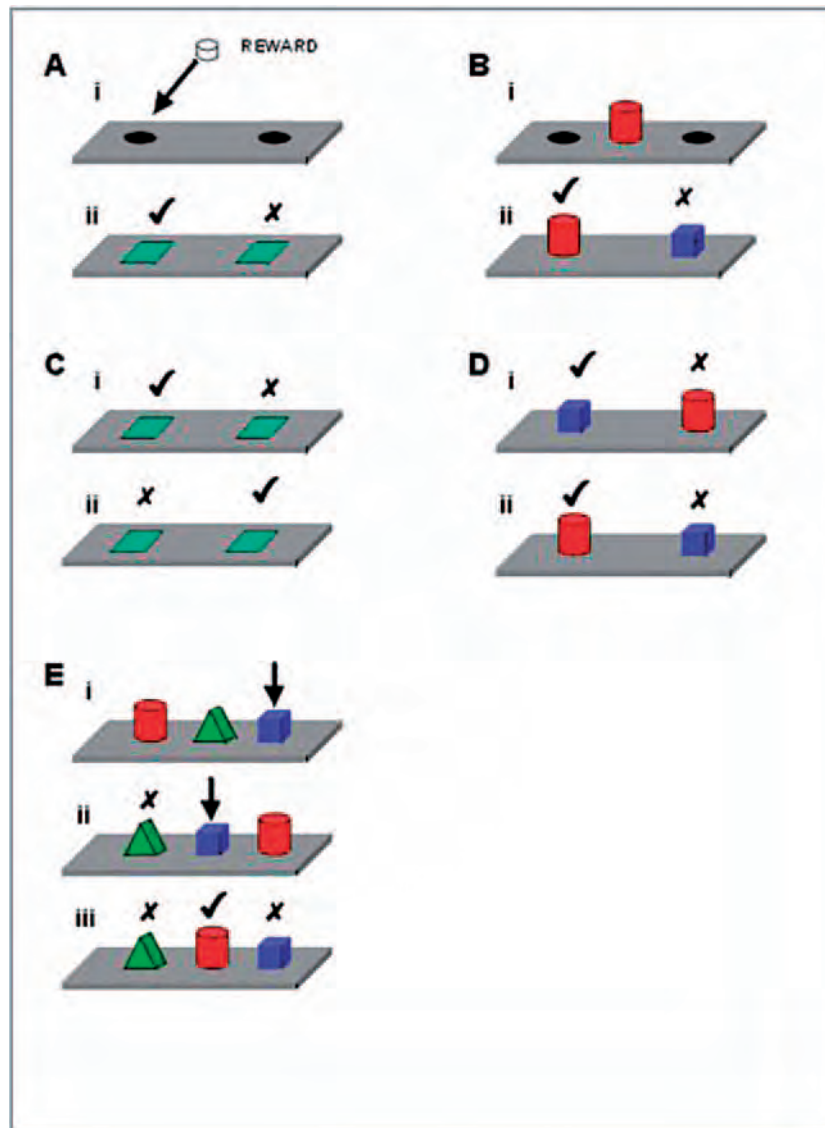

Third, studies in monkeys are useful only if we can show that the results are applicable to understanding the organization of human PFC. The close anatomical correspondence between monkey and human PFC suggested that there might also be close functional correspondence. However, there was a lack of direct evidence that this was indeed the case. Recently, a number of studies have used identical behavioral paradigms in monkeys and humans, and found that the paradigms tax similar PFC regions. For example, a

recent fMRI study showed that both monkeys and humans activate ventrolateral PFC when they are performing the WCST. Such findings help validate the monkey as a model for understanding the organization of human PFC.

### **Monkeys with PFC Damage Are Impaired on Delayed Response Tasks**

In 1935, Jacobsen published a seminal paper showing that lesions of the frontal lobe in monkeys produced deficits on a spatial delayed response task. In this task, the monkey sees a reward hidden at one of two locations, and then after a brief delay is allowed to retrieve it (Fig. 52.5A). Monkeys with large PFC lesions behave as if they forgot where the reward was hidden, even after delays of just a few seconds. Subsequent experiments showed that lesions restricted to the dorsolateral PFC alone could produce the same deficit. By contrast, damage to the ventrolateral PFC impaired object delayed response tasks. Monkeys with such damage have difficulty with delayed matching-to-sample (DMS) tasks in which they are shown an object (the sample) and then, after a brief delay of several seconds, must choose the same object (the match) from one or more nonmatching objects (Fig. 52.5B). The most severe deficits are observed when the same two objects are used repeatedly, requiring the monkey to remember which of the two objects it has seen most recently as the sample. Monkeys with orbital (ventral) PFC lesions tend to show the greatest deficit in tasks requiring reversal of previously successful actions. For example, they are impaired at spatial reversal tasks, in which the reward is alternated between two locations (Fig. 52.5C) and object reversal tasks, in which a reward is alternated between each of two objects (Fig. 52.5D). In both tasks the monkeys perseverate, continuing to choose the location or object under which the reward first had been hidden. Such observations led to the suggestion that the dorsal PFC might be responsible for processing spatial information, the ventral PFC for object-related information, and the orbital PFC for inhibitory control in accord with their preferential connections with the parietal, inferior temporal, and limbic system structures, respectively.

The picture, however, is not so simple and straightforward; a clear double dissociation between these impairments has not been demonstrated. Consider the hypothesized spatial versus object dissociation in the PFC. Dorsolateral PFC can impair performance on tasks that do not have a spatial component, such as object self-ordered search tasks. In this task the monkey is presented with three objects covering rewards. They must move each object in turn to get the reward, but

**FIGURE 52.5** Some of the tasks on which monkeys with PFC damage are impaired. Check indicates correct choice, **x** indicates incorrect choice. Arrow in E indicates monkey's choice in self-ordered task. (A) Spatial delayed response. (B) Delayed matching-to-sample. (C) Spatial reversal. (D) Object reversal. (E) Object self-ordered search task.

after each choice a screen is lowered and the object's positions are shuffled (Fig. 52.5E). Thus, the monkey must continually remember which of the three objects it has already checked for a reward. Also, as noted earlier, monkeys with ventral (orbital) PFC lesions are impaired on both object and spatial reversal tasks. Neurophysiological studies paint a similar picture. Although there may be some bias in the distribution of neurons that are sensitive to object identity or location in space (especially for the small population of highly specialized "face cells"), there is also a good deal of intermixing of neurons encoding these attributes, especially when the integration of these attributes is relevant to task performance.

Likewise, the notion that orbital PFC is responsible for inhibitory control is not so straightforward. It has subsequently been shown that inhibitory control is not unique to the orbital PFC. If the appropriate test is used, inhibitory control deficits can also be observed in monkeys with lesions of dorsolateral PFC. Marmosets were trained on a task similar to the WCST. They had to choose complex stimuli on the basis of a rule, such as "choose by shape." When they were required to switch between different rules, monkeys with lesions of the dorsolateral PFC perseverated by continuing to choose on the basis of the previous rule, whereas monkeys with lesions of the orbital PFC were unimpaired. In contrast, when the same stimuli were used

in an object reversal task, monkeys with lesions of the orbital PFC perseverated by continuing to choose the stimulus that initially had been rewarded, but the performance of monkeys with lesions of the dorsolateral PFC was normal. This suggests that both the dorsolateral and orbital PFC contribute to inhibitory control, but the dorsolateral PFC may be more engaged by inhibitory control over rules, whereas the orbital PFC may be more engaged by inhibitory control over choices based on objects and rewards. For more discussion of the issue of PFC functional topography, see Box 52.1.

### Monkeys with PFC Damage Are Impaired on Conditional Learning Tasks

Conditional learning tasks often are used to test the ability to gain volitional control over behavior. Conditional learning refers to a class of tasks in which associative relationships must be learned that are arbitrary

and extend beyond the simple one-to-one mappings that underlie reflexive reactions. Whether or not a given response is successful depends on additional, contextual, information. For example, reaching for popcorn can be rewarding, but only if one takes other information into account; if the popcorn belongs to another patron, the result could be disastrous. The need to take into account complex relationships in order to decide among alternative actions is presumably why cognitive control has evolved.

Monkeys with PFC damage are impaired at such tasks. For example, when monkeys are trained to learn associations between three visual cues and three directional movements of a joystick, simply moving the joystick is not enough to produce reward. Rather, the specific movement direction is dependent on the specific cue. One means “up,” the other “down,” and so on. Bilateral damage to the ventrolateral and orbital PFC severely impairs this learning. Depriving the PFC of its inputs from high-order sensory cortex also results

#### BOX 52.1

### FUNCTIONAL TOPOGRAPHY

Information about topography of neural properties in the PFC can provide important insights into its function. For example, knowing that primary visual cortex is organized into groups of neurons with similar tuning for orientation provides important clues to how it analyzes visual inputs. The anatomically complex nature of the PFC, coupled with the unique patterns of connections that each prefrontal area possesses, would certainly suggest a degree of functional fractionation. But one immediate problem that investigators face when trying to address this issue is that it is not clear how to subdivide cognitive processing. It is far easier to specify the sensory attributes of an apple, than it is to list the different processes involved in planning or reasoning.

One possibility is that PFC is organized by function, with different regions carrying out qualitatively different operations. One longstanding view is that the orbitofrontal area is associated with behavioral inhibition whereas ventrolateral and dorsolateral regions are associated with memory or attentional functions (Goldman-Rakic, 1987; Fuster, 1989). Other recent suggestions include the idea that ventrolateral regions support maintenance of information (memory) and dorsolateral regions are responsible for the manipulation of such information, as well as schemes based on stimulus dimensions such as segregation of information about object form and color (what

from information about its location (where). None of these schemes is mutually exclusive.

There is undoubtedly some spatial organization of processing within the PFC, but no clear global scheme has emerged. There is no overwhelming evidence for any one hypothesis and for some there are countervailing data. Perhaps this is not surprising. We do not yet understand the functional topography of the higher-order sensory and motor cortical areas that are interconnected with the PFC. We can, however, make some general predictions. First, PFC functional topography is likely to be based on broad categories or gradients of organization with overlap and intermixing of diverse information. Complex behavior requires that we recognize and respond to relationships across diverse dimensions, and representing these relationships is a prerequisite for cognitive control. Indeed, the majority of outputs of a given prefrontal area are to other prefrontal areas, so it is not surprising that many prefrontal neurons are multimodal. Second, because learning is central to cognitive control and modulates the properties of many PFC neurons (see *Neurophysiology of the Prefrontal Cortex*), it should have a large influence on PFC topography. Indeed, the flexible nature of controlled behaviors likely requires a dynamic anatomy, with neuronal properties changing to reflect the demands of the current task.

in conditional learning impairments. Humans with PFC damage are impaired on conditional learning tasks analogous to those conducted in monkeys. Conditional learning impairments seem to be dependent on which PFC region is damaged; some studies report no conditional learning deficit following dorsolateral PFC damage in monkeys.

### Monkeys with PFC Damage Show Emotional Impairments

Like humans, monkeys with large PFC lesions display marked changes in social and emotional behavior. Monkey society is dictated by a dominance hierarchy and each monkey knows its place; a monkey is submissive to monkeys higher in the hierarchy (for example, the monkey grooms them) and is aggressive and threatening to monkeys lower in the hierarchy. Monkeys with large PFC lesions, however, disregard this hierarchy, and also decrease their interactions with troop members. This typically results in their being ostracized from the troop.

### Monkeys with PFC Damage Are Impaired at Object Recognition

Monkeys with lesions of the ventromedial PFC show impairments in visual recognition. This ability is tested using a delayed nonmatching-to-sample task (DNMS). The monkey is presented with an object, and then after a brief delay of a few seconds, they are presented with that same object along with a novel object. New objects are used on each trial so the monkey can solve the task by recognizing which of the two objects it has previously seen in order to pick the novel object. However, patients with damage to the ventromedial PFC do not show these recognition deficits. One possibility for this discrepancy is that the deficit does not lie in recognition per se, but rather in the ability to learn the rules of the task. In particular, it has been suggested that the difficulty lies in making the association between the abstract quality of novelty and receiving a reward. This aspect of the task is not required in human patients, because the patients are explicitly told the rules of the task; monkeys have to learn them by trial and error.

### Summary

Humans with damage to the PFC present a wide variety of symptoms including a lack of inhibitory control, a shallowness of emotion, difficulty planning and organizing behavior, and impaired working memory. In general, they seem to have difficulty in

exerting volitional control and organizing their mental processes and actions in order to direct them toward unseen goals. As a result, their behaviors are simple, reactive, and emitted without concern for future consequences.

Just like humans, monkeys with extensive prefrontal damage can appear remarkably unimpaired to the casual observer. They have no motoric impairments, and their ability to discriminate a variety of sensory stimuli remains intact. They are also capable of simple learning, such as Pavlovian and instrumental conditioning. However, they are impaired when behavioral demands extend beyond this to include additional task-specific constraints and/or involve overcoming a previously established response. Localizing a specific deficit to any one PFC subregion has proven difficult; double dissociations between different PFC regions are rare.

The pattern of deficits observed after PFC damage in humans and monkeys makes sense in light of the cognitive architecture depicted in Figure 52.2. The deficits seem to reflect a selective loss of higher-level functions. Lower-level, well-established routines are intact, but without the information about future goals and means provided by the higher-level functions, processing would be at the mercy of the environment. Behavior would be ruled by whatever sensory inputs happen to flow into the system and by whatever thoughts, emotions, and actions are strongly associated with these inputs. Behavior would seem impulsive and disinhibited, and emotional reactions inappropriate, because they would be emitted reflexively without any consideration of the future. Further, without the influence of future goals to continually drive task-appropriate processes, individuals would be distractible and would easily go “off track” when there are temporal gaps between sensory inputs, or between those inputs and the individual’s responses.

## NEUROPHYSIOLOGY OF THE PREFRONTAL CORTEX

PFC anatomy suggests it has the means for executive functions, and the effects on behavior after damage to the PFC support this idea. So do neurophysiological studies; they have shown that PFC neurons have the properties one would expect from a region intimately involved in goal-directed behavior.

### The PFC Is Multimodal

PFC anatomy indicates that it is interconnected with many different brain systems, a prerequisite for

cognitive control. This high degree of connectivity is reflected in the neural activity observed in the PFC. Its neurons are activated by visual, auditory, tactile, and gustatory stimulation (and their memory) as well as voluntary limb and eye movements. Further, these neurons seem capable of synthesizing this information in accord with task demands. For example, after monkeys are trained to make arm movements to visual and auditory targets appearing in different locations, many lateral PFC neurons are activated by both kinds of targets. Interestingly, few bimodal neurons were found in studies in which monkeys passively experienced visual and auditory stimuli. This finding suggests that task demands can exert a strong modulatory influence on PFC activity, which is consistent with its putative role in cognitive control.

### PFC Neurons Can Sustain Their Activity

The first observations of PFC neural activity that were related to a cognitive process were made in the 1970s by Fuster, Niki, and their colleagues (Kubota and Niki, 1971; Fuster, 1973). Guided by lesion studies in monkeys, they recorded from the PFC while monkeys performed delayed response tasks. They found that, during the memory delay, many PFC neurons showed sustained activity that seemed to keep information about a spatial or object cue online (Fig. 52.6). In spatial delayed response tasks, cue-related “delay activity,” in principle, could reflect either sensory information related to the cue or movement information related to the behavioral response. Both are found in the PFC, each with different temporal characteristics. Sensory-related activity tends to be stronger nearer in time to the cue and then weakens as time passes, whereas movement-related neurons tend to increase their activity over time as the movement draws nearer. Goldman-Rakic and colleagues used a refined oculomotor version of the delayed response task to demonstrate that dorsolateral PFC neurons have precise tuning for memories of particular visual field locations (Funahashi *et al.*, 1989) (Fig.

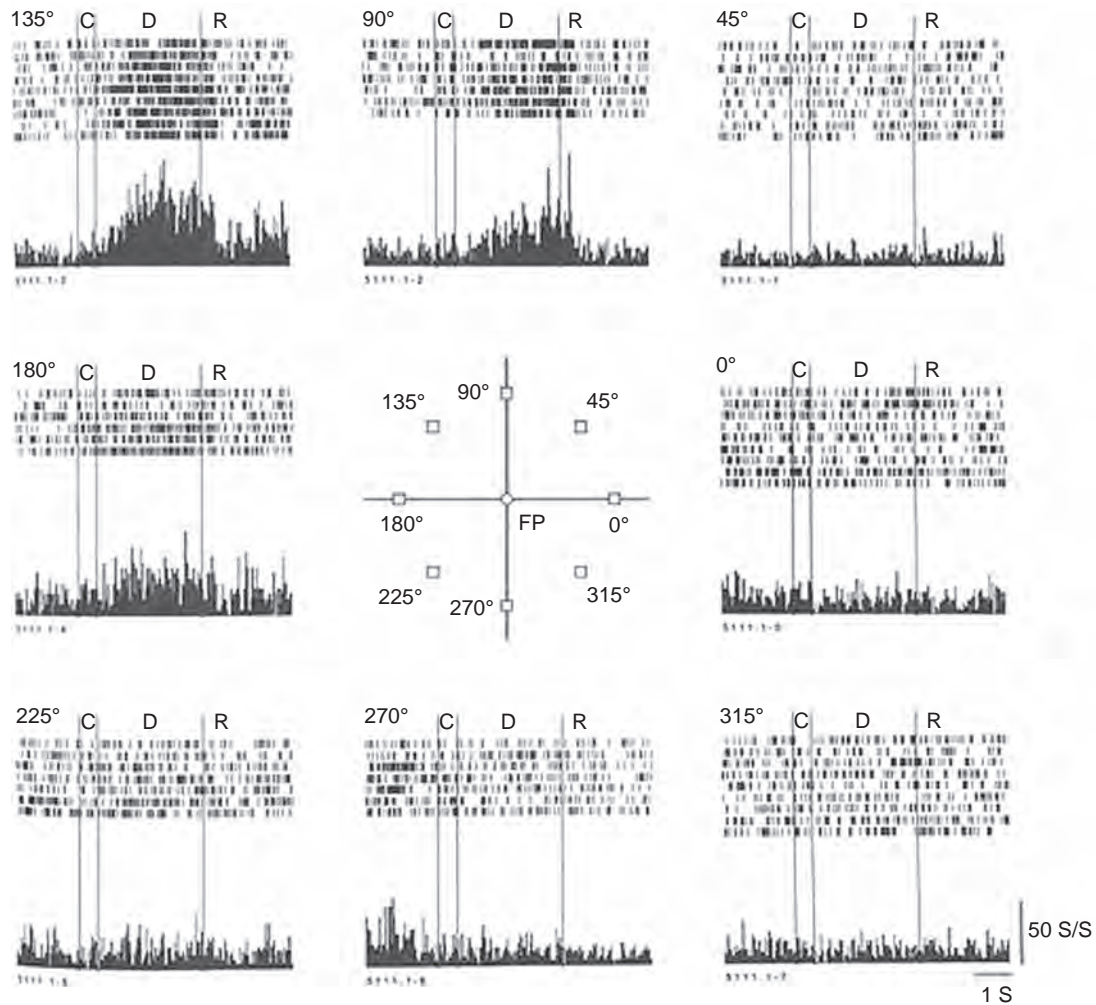

52.7). They also demonstrated that PFC delay activity depends on dopamine receptors, a neurotransmitter implicated in signaling reinforcements and thus central to acquiring and sustaining goal-directed behaviors.

PFC delay activity has been shown to convey a wide range of behaviorally relevant cues: objects, colors, sounds, the frequency of a vibration to the hand, and forthcoming eye and arm movements. Similar activity is also evident in the sensory cortical areas and motor areas primarily responsible for analyzing inputs and generating behaviors, especially the higher-order areas that are one or more steps removed from primary sensory and motor cortex. This is not surprising; sustained activity is apparent in many brain structures and must play a role in many neural processes. For example, it is likely to underlie iconic memory, the very brief lingering “after image” of recent sensory events. However, what separates more “cognitive” working memory processes from such lower-level processes as iconic memory, is their ability to robustly sustain memories over potential distractions. PFC neurons do have this ability. For example, when monkeys are required to sustain the memory of a sample object across a delay period filled with visual distractors that require attention and processing, sustained activity within the prefrontal cortex can still maintain a memory of the sample object. By contrast, sustained activity in visual cortical areas seems more labile; it is disrupted by the presence of distractors. Following a distracting stimulus, neural activity reflects the distractor rather than the stimulus the monkey is retaining in working memory. This particular ability is not unique to the PFC. Some neurons in the entorhinal cortex, a region critical for memory, can also maintain sample-specific delay activity across intervening stimuli.

How does the PFC “latch” onto goal-relevant information and maintain it without disruption? Several models have been suggested. These typically employ a form of gating signal that instructs the PFC network when to maintain a given activity state. This gating

**FIGURE 52.6** PFC delay activity. This figure shows the activity of a single PFC neuron during five trials of a spatial delayed response task. The arrow indicates the monkey’s behavioral response at the end of the memory delay. Each small vertical line indicates an action potential from the neuron. Note the increased activity in the delay relative to other epochs. From Fuster (1973).

**FIGURE 52.7** Activity of a single PFC neuron during performance of an oculomotor spatial delayed response task. Each trial starts with the monkey fixating the central fixation point (FP) indicated in the central diagram. After a delay (D), the monkey was allowed to respond by moving its eyes to the remembered location of the cue. Neural activity from cueing each location is shown by the corresponding histogram. The scale bars in the lower right indicate one second of time (1S) and 50 spikes per second of neural activity (50S/S). From Funahashi *et al.* (1989).

signal may come from dopaminergic (DA) neurons in the midbrain. These neurons respond when monkeys are rewarded or, importantly, when monkeys can first predict that a reward is forthcoming. In many behavioral tasks, presentation of the cue at the start of the trial is a good predictor that reward is soon coming. Such a well-timed DA burst could strengthen current PFC representations, protecting them against interference from disruption by irrelevant, distracting information until another DA influx reinforces another representation. Local injection of DA antagonists in the PFC does block delay activity in the PFC. The anatomical loops between the PFC and basal ganglia have been suggested to play a role here. Neural activity propagating around the loops may help sustain activ-

ity, and the basal ganglia have been suggested to provide a means by which DA signals can influence PFC activity.

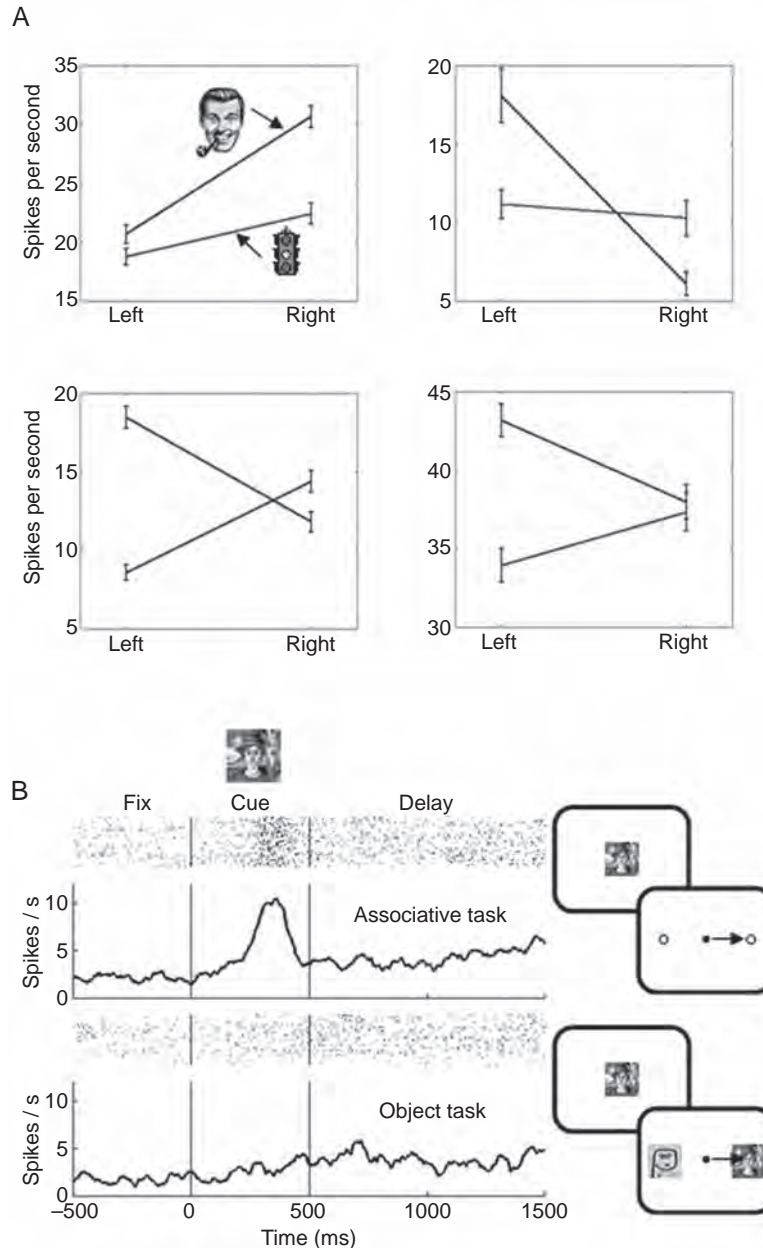

### PFC Neural Activity Reflects Task Rules

Playing the game requires knowing the rules. To explore how these rules might be represented in the PFC, experimenters manipulate task demands: monkeys are trained on tasks in which the physical cues are held constant while their behavioral meaning changes.

These studies suggest that PFC neurons represent task contingencies, the associative relationships that describe the logic needed to perform a task. Further

support comes from investigations that have shown that PFC activity reflects more complex task information such as rules. Monkeys can be taught to rapidly alternate between different rules. For example, following a given cue, they can learn to direct a response to

either the cue's location (spatial matching rule) or an alternate location associated with the cue (associative rule), depending on which rule is currently in effect. When tested in this fashion, many PFC neurons show rule-specific activity (Fig. 52.8B). For example, a PFC

**FIGURE 52.8** (A) The activity of four single PFC neurons when each of two objects, on different trials, instructed either a saccade to the right or a saccade to the left. The lines connect the average values obtained when a given object cued on the other saccade. The error bars show the standard error of the mean. Note that in each case, the neuron's activity depends on both the cue object and the saccade direction and that the tuning is nonlinear or conjunctive. That is, the level of activity to a given combination of object and saccade cannot be predicted from the neuron's response to the other combinations. (Adapted from Asaad *et al.*, 1998). (B) A PFC neuron whose neural response to a cue object was highly dependent on the rule the monkey is currently using. The bottom half shows an example of a single PFC neuron's response to the same cue object during an object task (delayed matching to sample) and during an associative task (conditional visual motor). Note that the neuron is responsive to the cue during one task but not during the other, even though sensory stimulation is identical across the tasks. (Adapted from Asaad *et al.*, 2000).

## BOX 52.2

## ATTENTION DEFICIT HYPERACTIVITY DISORDER

Do you pay attention to captivating yet irrelevant stimuli? Do you have trouble acting appropriately, fidgeting while listening to a lecture? Do you have difficulty planning and pursuing long-term goals? Do distractions knock you “off task”? When these not uncommon difficulties occur to a severe degree, they are symptoms of Attention Deficit Hyperactivity Disorder (ADHD), a disorder seen in children and adults. It is estimated that 3 to 5% of children have this disorder, with about half retaining problems into adulthood. The symptoms of ADHD involve dysfunction of the prefrontal cortex (PFC) and its cortical and subcortical connections.

The criteria for diagnosis of ADHD include symptoms of “inattention” and “hyperactivity/impulsivity.” Patients can have either the combined type, or predominantly inattentive or predominantly hyperactive/impulsive types. Many of the symptoms for inattention used to diagnose ADHD relate to attentional abilities of the PFC: for example, difficulty sustaining attention or organizing, easily distracted and forgetful. Similarly, many of the symptoms of hyperactivity/impulsivity describe PFC deficits: for example, difficulty awaiting turn. The PFC controls attention via its projections to the parietal and temporal cortices (see Chapter 48), while it controls motor responses via its projections to the motor cortices and striatum. These circuits appear to be impaired in patients with ADHD. ADHD symptoms are especially evident in “boring” settings that require endogenous rather than exogenous regulation of behavior. For example, ADHD children can sit still and play video games for hours, but have trouble attending in school. ADHD patients have difficulty sustaining a behavior or thought over a delay. As described in this chapter, PFC cells exhibit sustained firing over a delay that regulates thought and behavioral output.

Structural and functional imaging studies show consistent alterations in PFC-striatal-cerebellar circuits in ADHD patients. Volumetric measures have detected smaller right-sided PFC regions (the right side is most associated with attention, and the right inferior prefrontal cortex with behavioral inhibition; see Chapter 48). Changes in the size of the striatum also have been reported, and functional imaging studies have shown abnormal activity of both the PFC and striatum in ADHD patients performing tasks that require PFC inhibitory or attentional functions. Structural imaging studies also have shown consistent decreases in the size of the cerebellar vermis, a region that may exert regulatory influences on the noradrenergic

(NE) cells of the locus coeruleus (LC) and the dopaminergic (DA) cells of the ventral tegmental area. These NE and DA cells in turn have profound influences on PFC-striatal circuitry (see later). Thus, a smaller vermis in ADHD patients may lead to impaired catecholamine inputs to PFC and striatum. Some evidence supports this idea: a neuroreceptor imaging study suggests there are reduced numbers of catecholamine terminals in the PFC of adults with ADHD.

NE and DA have a critical influence on PFC-striatal circuits, and thus changes in these inputs can have tremendous import on PFC cognitive functions. The current chapter describes how DA has an important effect on PFC function, and the same is true for NE. NE cells fire when a stimulus is of interest to the animal, releasing NE in the PFC. NE stimulates post-synaptic  $\alpha_{2A}$ -adrenoceptors, enhancing delay-related firing and strengthening regulation of behavior and attention. This is accomplished by  $\alpha_{2A}$ -adrenoceptor inhibition of cAMP production, resulting in the closure of HCN channels (Hyperpolarization-activated Cyclic Nucleotide-gated cation channels). HCN channels are colocalized with  $\alpha_{2A}$ -adrenoceptors on the dendritic spines of PFC neurons in the superficial layers of PFC, especially on spine necks. Thus,  $\alpha_{2A}$ -adrenoceptors are ideally localized to control the neurochemical microenvironment around these channels. When cAMP builds up, HCN channels open, and synaptic inputs onto the spines are effectively shunted, thus functionally disconnecting PFC neuronal networks. In contrast, when  $\alpha_{2A}$ -adrenoceptor stimulation inhibits the production of cAMP, HCN channels are closed and the networks are able to connect to control attention and behavior. In contrast, very high levels of NE and DA, such as released during stressful conditions, can impair PFC function via excessive cAMP production (e.g., from very high levels of  $\beta_1$  and DA D1 receptor stimulation), and from activation of high levels of protein kinase C signaling initiated by NE  $\alpha_1$ -adrenoceptor stimulation. Thus, the PFC has to have just the right neurochemical conditions to function optimally.

What causes ADHD? ADHD is highly heritable, and has been linked with genetic alterations that interfere with NE or DA signaling. These linkages include the DA transporter; the D1, D5, and D4 receptors (the D4 receptor also has very high affinity for NE); the synthetic enzyme for NE (dopamine beta hydroxylase); and the  $\alpha_{2A}$ -adrenoceptor. Environmental factors may also lead to disruption of PFC-striatal circuits. For example, some kinds of infection

(continues)

### BOX 52.2 (cont'd)

may lead to autoantibodies that attack PFC-striatal circuits, and perinatal injury may impact these circuits.

Medications for ADHD likely reduce symptoms of inattention and impulsivity by optimizing the neurochemical environment in the PFC and in the striatum. All effective treatments for ADHD interact with catecholamines: Stimulants such as Ritalin (methylphenidate) and Adderall (a mixture of amphetamines) increase NE and DA release and/or block catecholamine reuptake. Recent research in rats suggests that low, therapeutic doses of these compounds preferentially increase release in PFC, and have a greater effect on the release of NE than DA. Consistent with these data, NE reuptake blockers are also used to treat ADHD (e.g., desipramine), including highly selective NE agents (atomoxetine, also known as Strattera). Drugs that mimic NE at  $\alpha_{2A}$ -adrenoceptors (e.g., guanfacine) are effective, especially in decreasing impulsivity and distractibility. Wellbutrin (also known as Zyban or bupropion) is a DA reuptake blocker that is used to treat ADHD.

How do these medications actually work to ameliorate ADHD symptoms? There have been several ideas proposed: 1) the etiology of ADHD involves insufficient catecholamine innervation of PFC-striatal circuits, and drugs that increase catecholamine receptor stimulation correct

this; 2) ADHD involves excessive catecholamine release and low doses of these medications correct this by promoting negative feedback, decreasing phasic catecholamine release; or 3) catecholamines are normal in ADHD patients (e.g., it is simply that their cortex is immature or inflamed), and amplification of catecholamine mechanisms enhances PFC function and reduces symptoms. Support for this latter idea arises from the fact that normal individuals are improved by small doses of these medications as well, as when college students sometimes take low doses of stimulants to focus on writing a paper.

All of us experience PFC dysfunction as part of daily life, especially when we are tired or stressed. These effects are likely due to neurochemical changes—for example, in NE and DA—that have great impact on the functional integrity of the PFC. But for people with ADHD, dysfunction of the PFC is much more constant and often beyond their control. Perhaps it is this prevalence of PFC dysfunction in otherwise healthy individuals, and its association with stress, that lead to the dismissal of ADHD by some as not a real disorder. It is hoped that as we come to better understand the neurobiological bases of ADHD, we will gain a fuller perspective of ADHD and its symptoms.

Amy Arnsten

neuron might respond to a given visual cue when the monkey is using an associative rule but exhibit weak or no activity under identical sensory and attentional conditions that differed only in that the monkey was using a spatial rule instead. Such effects have been found in PFC for associative versus spatial rules, for object matching versus spatial matching versus associative rules, and for shape matching versus object matching rules (Asaad *et al.*, 2000).

Primate behavior is not limited to following literal associations and specific rules. Primates can also abstract general rules or principles, not tied to any particular stimulus or response. This ability allows behavior to extend beyond specific circumstances that have been experienced directly. For example, humans learn the “rules” for restaurant dining from specific experiences and can then generalize and apply them to new restaurants. Wallis and colleagues (Wallis *et al.*, 2001) investigated this process in monkeys by recording from single neurons in the PFC. Monkeys were trained to use two abstract rules; they indicated

whether two successively presented pictures were either the same (match) or different (nonmatch). The monkeys could perform this task with novel pictures, thus demonstrating that they had learned two general principles that could be applied to stimuli that they had not experienced directly. The most prevalent neuronal activity observed in the dorsolateral, ventrolateral, and orbital PFC reflected the coding of the abstract match and nonmatch rules. This finding suggests that rule representation may be a cardinal PFC function. Recent findings using fMRI showed that humans also activate PFC when performing the exact same task.

### PFC Neurons Are Flexible

Another hallmark of primates is the ability to quickly learn new behaviors. PFC neurons are capable of a correspondingly rapid modification of their properties to meet task demands. Monkeys can learn new conditional visuomotor associations in just a few trials and

as they do, PFC neural activity rapidly modifies to reflect the new contingencies. Striking examples of rapid experience-dependent neural plasticity come from studies of the frontal eye fields, part of Brodmann's area 8 that is important for voluntary shifts of gaze (Bichot and Schall, 1999). Normally, neurons in this area are selectively activated by saccade targets that appear in certain visual field locations. Monkeys also were trained to search for a target defined by a particular visual attribute (e.g., red). In this case, the neurons in the frontal eye fields acquired sensitivity to that attribute. They also trained monkeys to search for a different target every day and found that neurons discriminated not only the current target but also distracting stimuli that had been a target on the previous day relative to stimuli that had been targets even earlier. Monkeys were also more likely to make errors in choosing that distracting stimulus. It was as if the previous day's experience left an impression in the brain that influenced neural activity and task performance.

### PFC Neurons Encode Rewards

Feedback about the consequences of actions is key to acquiring new goal-directed behaviors. Consequently, a large proportion of PFC neurons encode information about rewards. For example, some neurons are activated by the delivery of a reward, whereas others respond when an expected reward is not delivered. PFC neurons also encode the type of reward that the monkey expects to receive, for example a piece of cabbage versus a raisin, as well as the quantity of reward the monkey expects. Further, the neurons appear to encode the monkey's relative preference for the rewards that are available, rather than some absolute measure of reward. Thus, a neuron might prefer reward A when the monkey's choice of reward is between A and B, but reward B when the choice is between B and C. The orbital PFC is the area of the PFC that receives gustatory and olfactory information, and indeed neurons responsive to rewards are found there. But many neurons responsive to reward are also found in the dorsolateral PFC.

### Summary

As might be expected from a brain region suspected to orchestrate complex behavior, neural activity in the PFC conveys information about a wide range of external and internal information. But its activity is not limited to simple responses to sensory events or actions. Rather, the behavioral context has a pervasive influence on PFC activity. After training, many (up to

half) of dorsolateral, ventrolateral, and orbital PFC neurons encode information about the formal demands of behavior: contingencies between a wide range of stimuli, actions, and reward consequences, and behavior-guiding rules. By robustly sustaining their activity, PFC neurons can keep this and other behaviorally relevant information online to guide behaviors that extend over time. Also consistent with its role in guiding goal-directed behavior, PFC neurons process information about the expected results of achieving goals: rewards.

## THEORIES OF PREFRONTAL CORTEX FUNCTION

### Working Memory

One proposal is that the cardinal function of the PFC is to hold recent sensory inputs and movement-related information in active short-term memory, or working memory (Goldman-Rakic, 1987). In this view, the PFC acts as a temporary scratch pad that sustains the inputs it receives from other cortical areas. This hypothesis has its roots in observations of deficits in performance of delayed response tasks following PFC damage and of PFC neurons that show sustained activity over a memory delay. Other deficits following PFC damage are thought to be sequelae of the working memory deficit. For example, patients might be impaired at planning because they are unable to keep in mind all the different variables that need to be considered. This in turn might make them appear disinhibited as their behavior becomes directed toward more immediate goals, rather than toward longer-term, more delayed goals.

Working memory maintenance functions are central to cognition; complex, goal-directed behaviors typically are drawn out and thus are impossible without mechanisms that extend information over time. There is ample evidence that these mechanisms are abundant in the PFC. Working memory is unlikely to be the whole story, however. Many of the tasks on which prefrontal patients and monkeys show impairment do not have an obvious working memory component, such as the WCST and reversal tasks.

Recent studies have explicitly investigated this issue, by examining the performance of monkeys with lesions of the ventrolateral PFC on a simultaneous color-matching task. In this task the monkey is presented with a sample color and two test colors simultaneously. The monkey must choose the test color that matches the sample color. PFC lesioned monkeys were impaired at this task, despite the fact the task involved

contains no delays and therefore no working memory requirements. The task does, however, require conditional rules (e.g., if the sample color is red, then choose the red test stimulus), and the role of the PFC in the representation of such rules (see later) might explain this impairment.

### Somatic Marker Hypothesis

It has been suggested that the orbitofrontal PFC is responsible for labeling people, objects or situations with an “affective significance” (Damasio, 1994). This is achieved by associating memories of past, affectively-laden events with a representation of the somatic state which that event evoked. Thus, the memory of the past event is labeled with a “somatic marker” that helps individuals make decisions. Rather than having to evaluate all the pros and cons of prior circumstances to decide on the present, one can simply recall the associated somatic marker, providing the individual with the appropriate affective state and, in effect, a “gut-feeling” of which alternative is correct. Patients with damage to this system might be unable to reach a decision, simply because they become incapacitated by contemplating irrelevant information. None of the outcomes of their actions will be obviously more emotionally preferable than alternative outcomes, and patients might make decisions randomly or impulsively, and as such appear to be disinhibited.

A deficient somatic marker system would explain the impairments that patients with damage to the orbitofrontal PFC exhibit on the gambling task (Fig. 52.4D). The reward contingencies associated with each deck of cards are designed to be too complex to be ascertained purely by logical reasoning. Control subjects succeed at the task because they associate a somatic marker with each deck of cards, warning the subject as to whether the choice he or she is about to make is risky. Further support comes from measures of skin conductance responses (SCRs) that reflect autonomic nervous system processing. Control subjects show SCRs prior to the selection of a card, and choices from risky decks are preceded by a larger SCR than choices from less risky decks. Patients with damage to the ventromedial PFC showed no anticipatory SCRs, although their SCRs when actually receiving the reward or punishment are intact.

This hypothesis is similar to one advanced by William James in the nineteenth century. He proposed that emotional feelings depend upon feedback from the autonomic nervous system. For instance, running from a bear because we are afraid evokes a particular autonomic state (such as increased heart rate and blood

pressure) that makes us feel afraid. Thus, as James stated, we do not run because we are afraid, but we are afraid because we run. A problem with simply using autonomic nervous system signals, however, is that autonomic states produced by different emotions can be identical. Later studies showed that manipulations of the autonomic nervous system, for example, by administering adrenaline, could alter the magnitude but not necessarily the type of emotion experienced in human subjects. These problems are avoided if the orbitofrontal cortex does not need to access the autonomic nervous system directly, but rather can use a conditioned association between the autonomic state and various cortical representations. For example, associations with the somatosensory cortex may be involved in emotional interpretations; patients with damage to the somatosensory cortex have difficulty recognizing facial emotions as do patients with orbital frontal damage.

### Multiple Processing Levels

It has been proposed that the PFC is organized by level of processing, much as there are primary and higher-order sensory cortices (Petrides, 1996). The ventrolateral PFC is primary. It receives inputs from sensory cortex and is responsible for their simple maintenance in working memory and for retrieval of information from long-term memory. The dorsolateral PFC then takes this information and performs more executive processes, such as monitoring multiple behaviors and manipulating information. For example, simply rehearsing a phone number is a ventrolateral PFC function while saying that same number backwards is a dorsolateral PFC function. It should be noted that such an arrangement would preclude the possibility of demonstrating a functional double dissociation between these two areas, since the dorsolateral PFC is able to perform executive processes only on information after it had been received by the ventrolateral PFC. Thus, removing the dorsolateral PFC would impair the higher-level processes, whereas removing the ventrolateral PFC would impair both.

This hypothesis has been supported by evidence from neuroimaging in humans. Subjects were required to perform five spatial working memory tasks while they were scanned using positron emission tomography. This technique enables the visualization of areas of the brain with the increased blood flow that is related to neural activity. Two of the tasks had simple maintenance requirements; they activated the ventrolateral PFC. The three other tasks also had manipulation requirements and they activated the dorsolateral PFC.

## Rule Representation

Several investigators have pointed out that because knowledge about goals, means, and consequences is vital to planning and implementing complex goal-directed behavior, the PFC is likely to play a central role in its acquisition and representation. The neural instantiation of task demands in the PFC was first proposed by Joaquin Fuster (Fuster, 1989). Based on behavioral and neurophysiological experiments in monkeys, he hypothesized that sustained activity in the PFC was not used merely to retain recent sensory events but also to link together behavioral relevant, but temporally separate, events and actions into a representation of task contingencies.

Other investigators have reached similar conclusions. Grafman (1994) suggested that the PFC contains managerial knowledge units (MKUs), sets of task contingencies linked under common themes that can be flexibly combined into extended routines. A MKU may describe the expected events and appropriate responses for dining in a restaurant, for example. Passingham (1993) suggested that many of the deficits following PFC damage can be explained by a loss of the ability to acquire conditional if-then rules. Wise *et al.* (1996) proposed complementary roles in rule learning for the PFC and the basal ganglia. The PFC is thought to act when new rules are learned whereas the basal ganglia is thought to potentiate (select) the previously learned rules that are appropriate for the current situation.

Cognitive control also has been studied by developing simulated neural network models that can perform tasks that depend on controlled processing, such as the Stroop Test. These models invariably include units dedicated to representing task rules and contingencies. Analogies often are drawn between these units and the PFC.

How might the PFC acquire rule information and use it for cognitive control? Miller and Cohen (2001) proposed that reward signals from midbrain dopamine systems act on the multimodal circuitry in the PFC to strengthen connections between neurons that process the information that led to the reward. This action results in a model of the task contingencies, which in neural terms amounts to a representation of the pattern of connections between the sensory, motor, and mnemonic representations needed to solve that task. Maintenance mechanisms in the PFC sustain this representation during task performance. This produces feedback signals to posterior cortex that bias the flow of activity along lines that match the PFC representation, that is, along task-relevant neural pathways. In short, the PFC plots a “map” of which neural pathways in the forebrain are successful at solving a task

and then holds it online in the PFC so that the rest of the neocortex can follow it.

Evidence for this proposal comes from the finding that PFC neurons show neural activity that reflects behaviorally relevant associations between disparate and arbitrary events and actions, behavioral context and rules. Behavioral and neurophysiological studies of focal attention also point to the operation of top-down signals on the visual cortex (presumed to come from the PFC) that enhance representations of behaviorally relevant stimuli and visual field locations at the expense of irrelevant ones. Evidence that such signals come from the PFC was supported by a recent observation that disconnecting the PFC from the temporal cortex prevented the activation of stored memories in the latter and caused monkeys to fail at a recall test (Tomita *et al.*, 1999).

## The Flexibility and Limited Capacity of Controlled Processing

Sustained activation is central in many views of PFC functions. This is not surprising considering the importance of working memory for cognitive control and that sustained activity is common in the PFC. But as O'Reilly and Munakata (2000) have pointed out, representing information through sustained activity offers more than just the ability to bridge gaps; it has other advantages for cognitive control.

It is universally assumed that long-term storage in the brain depends on changing synaptic weights, by strengthening some neural connections and weakening others. Encoding information in structural changes has obvious advantages for long-term storage, but the resulting memories are relatively inflexible. Also, changing synaptic weights has local effects; only the two neurons sharing the synapse are affected. The information contained in a set of synaptic weights is thus expressed only when the circuit is fired. By contrast, the information needed to guide goal-directed behavior must be expressed in a format that allows it to affect the ongoing processing in other brain systems. Sustained activity is such a format. It is extended over time and information contained in a pattern of activity can be propagated across the brain. Thus, the ability of sustained activity to tonically influence other brain systems is likely important for coordinating diverse processing around a specific goal. It also affords flexibility; if cognitive control stems from a pattern of information maintained in the PFC, changing behavior is as easy as changing the pattern (O'Reilly and Munakata, 2000; Miller and Cohen, 2001).

Finally, the neuronal mechanisms by which information needed for cognitive control is expressed might

explain the severely limited capacity of controlled processes. A vast amount of information can be stored by changing synaptic weights of a network that contains many neurons, each with many potential connections. At any given time, however, most of this information is latent; it is expressed only when the relevant circuit is activated. By contrast, if the information for cognitive control is expressed in a unique pattern of ongoing activity distributed across many simultaneously active neurons—a population code—then there will be a natural capacity limitation. Trying to represent more than just a few items at the same time would degrade information because the unique patterns impinging on a given set of neurons would overwrite and interfere with one another.

### The PFC versus the Basal Ganglia: Model-Building versus “Snapshots”

The prefrontal cortex (and other frontal cortical areas) forms anatomical loops with the basal ganglia (BG), a set of subcortical structures that have motor and learning functions (see Chapters 31 and 51). Different regions of the frontal lobe (e.g., the lateral PFC, orbital PFC, premotor cortex) have anatomically segregated loops with the BG that are “closed,” meaning that the same region of the frontal cortex that gives rise to the loop is also the target of that loop via BG’s connections with the thalamus. Closed loops are noteworthy because they may allow recursive processing in which the results of processing are fed back into the loop for further elaboration. It is possible, if not likely, that some form of recursive processing is responsible for the open-ended nature of advanced thought.

Daw *et al.* (2005) suggested functional specializations for the PFC and BG (specifically the striatum, the BG structure that receives input from the cerebral cortex). They suggested that the PFC builds models of an entire behavior—it retains information about the overall structure of the task, following the whole course of action from initial state to ultimate outcome. They liken this to a “tree” structure for a typical operant task: Behaviors begin in an initial state with two or more possible response alternatives. Choosing one response leads to another state with new response alternatives, with this process continuing throughout the task, ultimately leading to a reward. The PFC is able to capture this entire tree structure, essentially providing the animal with an internal model of the task. By contrast, the striatum is thought to learn the task piecemeal, with each state’s response alternatives individually captured as separate “frames.” This “caching reinforcement learning” system retains infor-

mation about which alternative is “better” in each state but nothing about the overall structure of the task (i.e., the whole tree). In short, the BG learns each fork in the road whereas the PFC puts together the whole route.

This is thought to explain observations of tasks that use reinforcer devaluation. In such tasks, you change the value of the reward by saturating the animal on a given reward (for example, overfeeding on chocolate if chocolate is a reward on that task). This has revealed two classes of behavior. Behaviors that are affected by reinforcer devaluation are considered to be goal-directed because changing the goal changes the behavior. As discussed earlier, goal-directed behaviors depend on the PFC. By contrast, overlearned behaviors whose outcomes remain relatively constant can become habits, impervious to reinforcer devaluation. Because these behaviors are not affected by changing the goal, they seem to reflect control by a frame-based caching system in which the propensity for a given alternative in each situation is stored independently of information about past or future states. Indeed, such a piecemeal caching system could acquire only complex tasks as habits because it can learn them only if they always conducted in the same fashion. Habits have long been thought to be a specialization of the BG.

Support for this model comes from recent observations that during conditional visuomotor rule learning, the dorsal striatum of the BG (the portion that receives direct projections from the lateral PFC and whose output ultimately loops back to the lateral PFC) showed very fast, almost bistable changes in neural activity (Pasupathy and Miller, 2005). By contrast, the lateral PFC showed slower gradual changes in neural activity. This may reflect the much heavier input from midbrain dopaminergic reward-related neurons in the striatum than the PFC. The fast plasticity in the striatum could be ideal for learning the reinforcement-related snapshots that capture the immediate circumstances and which alternative is preferable for a particular state. The slow plasticity in the PFC is better suited for the linking in of additional information about past states that is needed to learn and retain an entire model of the task and thus predict future states.

### Summary

The ability to take charge of one’s actions and direct them toward future aims is called cognitive control. Virtually all theories of cognition posit that cognition depends on functions specialized for the acquisition of information about goals and means. These functions

exert a top-down influence on the lower-level automatic processes that mediate sensory analysis, memory storage, and motor outputs, orchestrating and directing them toward a given goal.

The PFC, a brain structure that reaches its greatest complexity in the primate brain, seems to play a central role in cognitive control. It has the requisite anatomical infrastructure. It has access to, and the means to influence processing in, all major forebrain systems and can provide a means to synthesize the diverse information related to a given goal. Indeed, its damage in humans and monkeys results in a dys-executive syndrome; individuals are stimulus-bound and seem capable only of reacting to the immediate environment. Information about unseen goals and potential consequences of actions has little influence on behavior. PFC neurons also have properties consistent with their participation in cognitive control: they are multimodal, reflect task demands, and can sustain their activity to keep task-relevant information online during task performance.

Theories of PFC function suggest that it makes several contributions important for cognitive control: maintenance and manipulation of information in working memory, the assignment and recall of the affective tags related to different choices, and the acquisition and representation of behavior-guiding rules that help orchestrate goal-directed behaviors. None of these theories is mutually exclusive, and indeed, different theories may be focusing on different aspects of a complex system that is involved in a wide range of brain processes.

# Consciousness

Consciousness is one of the most enigmatic features of the universe. People not only act but feel: they see, hear, smell, recall, plan for the future. These activities are associated with subjective, ineffable, immaterial feelings that are tied in some manner to the material brain. The exact nature of this relationship—the classical mind-body problem—remains elusive and the subject of heated debate. These first-hand, subjective experiences pose a daunting challenge to the scientific method that, in many other areas, has proven so immensely fruitful. Science can describe events microseconds following the Big Bang, offer an increasingly detailed account of matter and how to manipulate it, and uncover the biophysical and neurophysiological nuts and bolts of the brain and its pathologies. However, this same method has as yet failed to provide a satisfactory account of how first-hand, subjective experience fits into the objective, physical universe. The brute fact of consciousness comes as a total surprise; it does not appear to follow from any phenomena in traditional physics or biology. Indeed, some modern philosophers even argue that consciousness is not logically supervenient to physics (Chalmers, 1996). Supervenience is used to describe the relationship between higher-level and lower-level properties such that the property X supervenes on property Y if Y determines X. This implies, for example, that changing Y will, of necessity, change X. In that sense, biology is supervenient to physics. Put differently, two systems that are physically alike will also be biologically alike. Yet it is not at all clear whether two physically identical brains will have the same conscious state.

Note that it is not yet generally accepted that consciousness is an appropriate subject of scientific

inquiry. A number of neuroscience textbooks provide extended details about brains over hundreds of pages yet leave out what it feels like to be the owner of such an awake brain, a remarkable omission.

People willingly concede that when it comes to nuclear physics or molecular biology, specialist knowledge is essential; but many assume that there are few relevant facts about consciousness and therefore everybody is entitled to their own theory. Nothing could be further from the truth. There is an immense amount of relevant psychological, clinical, and neuroscientific data and observations that needs to be accounted for. Furthermore, the modern focus on the neuronal basis of consciousness in the brain—rather than on interminable philosophical debates—has given brain scientists tools to greatly increase our knowledge of the conscious mind.

Consciousness is a state-dependent property of certain types of complex, biological, adaptive, and highly interconnected systems. The best example of consciousness is found in a healthy and attentive human brain, for example, the reader of this chapter. In deep sleep, consciousness ceases. Small lesions in the midbrain and thalamus can lead to a complete loss of consciousness, and destruction of circumscribed parts of the cerebral cortex can eliminate very specific aspects of consciousness, such as the ability to be aware of motion or to recognize faces, without a concomitant loss of vision in general.

Brain scientists are exploiting a number of empirical approaches that shed light on the neural basis of consciousness. This chapter reviews these approaches and summarizes what has been learned.

## What Phenomena Does Consciousness Encompass?

There are many definitions of consciousness (Koch and Tononi, 2007). A common philosophical one is “*Consciousness is what it is like to be something*,” such as the experience of what it feels like to smell a rose or to be in love. This what-it-feels-like-from-within definition expresses the principal irreducible characteristic of the phenomenal aspect of consciousness: *to experience something*. “What it feels like to be me, to see red, or to be angry” also emphasizes the subjective or *first-person perspective* of consciousness: it is a subject who is having the experience and the experience is inevitably private.

What it feels like to have a particular experience is called the *qualia* of that experience: the qualia of red is what is common to such disparate conscious states as seeing a red sunset, the red flag of China, arterial blood, or a ruby gemstone. All four subjective states share “redness.” There are countless qualia (the plural of qualia): the ways things look, sound, and smell, the way it feels to have a pain, the way it feels to have thoughts and desires and so on. To have an experience means to have qualia, and the qualia of an experience is what specifies it and makes it different from other experiences.

A science of consciousness must explain the exact relationship between phenomenal, mental states, and brain states. This is the heart of the classical mind-body problem: *What is the nature of the relationship between the immaterial, conscious mind and its physical basis in the electrochemical interactions in the body?* This problem can be divided into several subproblems:

1. Why is there any experience at all? Or, put differently, why does a brain state feel like anything? In philosophy, this is referred to by some as the *Hard Problem* (note the capitalization), or as the explanatory gap between the material, objective world and the subjective, phenomenal world (Chalmers, 1996). Many scholars have argued that the exact nature of this relationship will forever remain a central puzzle of human existence, without an adequate reductionistic, scientific explanation. However, as similar sentiments have been expressed in the past for the problem of seeking to understand life or to determine what material the stars are made of, it is best to put this question aside for the moment and not be taken in by defeatist arguments.
2. Why is the relationship among different experiences the way it is? For instance, red, yellow, green, cyan, blue, magenta are all colors

that can be mapped onto the topology of a circle. Why? Furthermore, as a group, these color percepts share certain communalities that make them different from other percepts, such as seeing motion or smelling a rose.

3. Why are feelings private? As expressed by poets and novelists, we cannot communicate an experience to somebody else except by way of example.
4. How do feelings acquire meaning? Subjective states are not abstract states but have an immense amount of associated explicit and implicit feelings. Think of the unmistakable smell of dogs coming in from the rain or the crunchy texture of potato chips.
5. Why are only some behaviors associated with conscious states? Much brain activity and associated behavior occur without any conscious sensation.

## The Neurobiology of Free Will

A further aspect of the mind-body problem is the question of free will, a vast topic. Answering this question goes to the heart of the way people think of themselves. The spectrum of views ranges from the traditional and deeply embedded belief that we are free, autonomous, and conscious actors to the view that we are biological machines driven by needs and desires beyond conscious access and without willful control.

Of great relevance are the classical findings by Libet and colleagues (1983) of brain events that precede the conscious initiation of a voluntary action. In this elegant experiment, subjects were sitting in front of an oscilloscope, tracking a spot of light moving every 2.56 sec around a circle. Every now and then, “spontaneously,” subjects had to carry out a specific voluntary action, here flexing their wrist. If this action is repeated sufficiently often while electrical activity around the vertex of the head is recorded, a *readiness potential* (*Bereitschaftspotential*) in the form of a sustained scalp negativity can be recorded long before the muscle starts to move. Libet asked subjects to silently note the position of the spot of light when they first “felt the urge” to flex their wrist and to report this location afterward. This temporal marker for the awareness of willing an action occurs on average 200 msec before initiation of muscular action (with a standard error of about 20 msec), in accordance with commonsense notions of the causal action of free will. However, the readiness potential can be detected at least 350 msec before awareness of the action. In other words, the subject’s brain signals the action at least half a second before the subject feels that he or she has initiated it!

This simple result has been replicated but, because of its counterintuitive implication that conscious will has no causal role, continues to be vigorously debated (Haggard and Eimer, 1999).

Psychological work in both normal individuals as well as in patients reveals further dissociations between the conscious perception of a willed action and its actual execution: subjects believe that they perform actions that they did not do while, under different circumstances, subjects feel that they are not responsible for actions that are, demonstrably, their own (Wegner, 2002).

Yet whether volition is illusory or is free in some libertarian sense does not answer the question of how subjective states relate to brain states. The perception of free will, what psychologists call the *feeling of agency* or *authorship* (e.g., “I decided to lift my finger”), is certainly a subjective state with an associated quale no different in kind from the quale of a toothache or seeing marine blue. So even if free will is a complete chimera, the subjective feeling of willing an action must have some neuronal correlate.

Direct electrical brain stimulation during neurosurgery as well as fMRI experiments implicate medial premotor and anterior cingulate cortices in generating the subjective feeling of triggering an action (Lau *et al.*, 2004). In other words, the neural correlate for the feeling of apparent causation involves activity in these regions.

## Consciousness in Other Species

Data about subjective states come not only from people that can talk about their subjective experiences but also from nonlinguistic competent individuals—newborn babies or patients with complete paralysis of nearly all voluntary muscles (locked-in syndrome)—and, most importantly, from animals other than humans. There are three reasons to assume that many species, in particular those with complex behaviors such as mammals, share at least some aspects of consciousness with humans:

- **Similar neuronal architectures.** Except for size, there are no large-scale, dramatic differences between the cerebral cortex and thalamus of mice, monkey, humans, and whales. In particular, the macaque monkey is a powerful model organism to study visual perception because it shares with the human visual system three distinct cone photopigments, binocular stereoscopic vision, a foveated retina and similar eye movements.
- **Similar behavior.** Almost all human behaviors have precursors in the animal literature. Take the case of pain. The behaviors seen in humans when

they experience pain and distress—facial contortions, moaning, yelping, or other forms of vocalization; motor activity such as writhing, avoidance behaviors at the prospect of a repetition of the painful stimulus—can be observed in all mammals and in many other species. Likewise for the physiological signals that attend pain—activation of the sympathetic autonomous nervous system resulting in change in blood pressure, dilated pupils, sweating, increased heart rate, release of stress hormones, and so on. The discovery of cortical pain responses in premature babies shows the fallacy of relying on language as sole criteria for consciousness (Slater *et al.*, 2006).

- **Evolutionary continuity.** The first true mammals appeared at the end of the Triassic period, about 220 million years ago, with primates proliferating following the Cretaceous-Tertiary extinction event, about 60 million years ago, whereas humans and macaque monkeys did not diverge until 30 million years ago (Allman, 1999). *Homo sapiens* is part of an evolutionary continuum with its implied structural and behavioral continuity, rather than an independently developed organism.

Although certain aspects of consciousness, in particular those relating to the recursive notion of self and to abstract, culturally transmitted knowledge, are not widespread in nonhuman animals, there is little reason to doubt that other mammals share conscious feelings—sentience—with humans. To believe that humans are special, are singled out by the gift of consciousness above all other species, is a remnant of humanity’s atavistic, deeply held belief that *homo sapiens* occupies a privileged place in the universe, a belief with no empirical basis.

The extent to which nonmammalian vertebrates, such as tuna, cichlid and other fish, crows, ravens, magpies, parrots and other birds, or even invertebrates, such as squids, or bees, with complex, non-stereotyped behaviors including delayed-matching, nonmatching-to-sample and other forms of learning (Giurfa *et al.*, 2001) are conscious is difficult to answer at this point in time. Without a sounder understanding of the neuronal architecture necessary to support consciousness, it is unclear where in the animal kingdom to draw the Rubicon that separates species with at least some conscious percepts from those that never experience anything and that are nothing but pure automata (Griffin, 2001).

## Arousal and States of Consciousness

There are two common, but quite distinct, usages of the term consciousness, one revolving around *arousal*

and *states of consciousness* and another one around *the content of consciousness* and *conscious states*.

To be conscious of anything, the brain must be in a relatively high state of arousal (sometimes also referred to as *vigilance*). This is as true of wakefulness as it is of REM sleep that is vividly, consciously experienced—though usually not remembered—in dreams (see Chapter 42). The level of brain arousal, measured by electrical or metabolic brain activity, fluctuates in a circadian manner, and is influenced by lack of sleep, drugs and alcohol, physical exertion, and so on in a predictable manner. High arousal states are always associated with some conscious state—a percept, thought or memory—that has a specific *content*. We see a face, hear music, remember an incident, plan an experiment, or fantasize about sex. Indeed, it is unlikely that one can be awake without being conscious of something. Referring to such conscious states is conceptually quite distinct from referring to states of consciousness that fluctuate with different levels of arousal. Arousal can be measured behaviorally by the signal amplitude that triggers some criterion reaction (for instance, the sound level necessary to evoke an eye movement or a head turn toward the sound source).

Different levels or states of consciousness are associated with different kinds of conscious experiences. The awake state in a normal functioning individual is quite different from the dreaming state (for instance, the latter has little or no self-reflection) or from the state of deep sleep. In all three cases, the basic physiology of the brain is changed, affecting the space of possible conscious experiences. Physiology is also different in *altered states of consciousness*, for instance after taking psychedelic drugs when events often have a stronger emotional connotation than in normal life. Yet another state of consciousness can occur during certain meditative practices, when conscious perception and insight may be enhanced compared to the normal waking state.

In some obvious but difficult to rigorously define manner, the *richness of conscious experience* increases as an individual transitions from deep sleep to drowsiness to full wakefulness. This richness of possible conscious experience could be quantified using notions from complexity theory that incorporate both the dimensionality as well as the granularity of conscious experience (e.g., Tononi, 2004). For example, inactivating all of visual cortex in an otherwise normal individual would significantly reduce the dimensionality of conscious experience since no color, shape, motion, texture, or depth could be perceived or imagined. As behavioral arousal increases, so does the range and complexity of behaviors of which an individual is capable. A singular exception to this progression is

REM sleep where most motor activity is shut down in the *atonia* that is characteristic of this phase of sleep, and the person is difficult to wake up. Yet this low level of behavioral arousal goes, paradoxically, hand in hand with high metabolic and electrical brain activity and conscious, vivid states.

These observations suggest a two-dimensional graph (Fig. 53.1) in which the richness of conscious experience (its representational capacity) is plotted as a function of levels of behavioral arousal or responsiveness.

Global disorders of consciousness can likewise be mapped onto this plane. Clinicians speak of impaired states of consciousness as in “the comatose state,” “the persistent vegetative state” (PVS), and the “minimal conscious state” (MCS). Here, state refers to different levels of consciousness, from a total absence in the case of coma, PVS or (hopefully) general anesthesia, to a fluctuating and limited form of conscious sensation in MCS, sleep walking or during a complex partial epileptic seizure (Schiff, 2004).

The repertoire of distinct conscious states or experiences that are accessible to a patient in MCS is presumably minimal (possibly including pain, discomfort, and sporadic sensory percepts), immeasurably smaller than the possible conscious states that can be experienced by a healthy brain. In the limit of brain death, the origin of this space has been reached with no experience at all (Fig. 53.1). More relevant to clinical practice is the case of global anesthesia, during which the patient should not experience anything so as to avoid traumatic memories and their undesirable sequelae.

Given the absence of any accepted theory for the minimal neuronal criteria necessary for consciousness, the distinction between a PVS patient—who shows regular sleep-wave transitions and who may be able to move eyes or limbs or smile in a reflexive manner as in the widely publicized 2005 case of Terri Schiavo in Florida—and a MCS patient who can communicate (on occasion) in a meaningful manner (for instance, by differential eye movements) and who shows some signs of consciousness, is often difficult in a clinical setting. Functional brain imaging may prove immensely useful here.

Blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) demonstrated that a patient in a vegetative state following a severe traumatic brain injury exhibited the same pattern of brain activity as normal individuals when asked to imagine playing tennis or to imagine visiting all the rooms in her house (Owen *et al.*, 2006). Differential brain imaging of patients with such global disturbances of consciousness (including akinetic mutism) reveal that dysfunction in a widespread cortical network including medial

**FIGURE 53.1** Normal and pathological brain states can be situated in a two-dimensional graph. Here increasing levels of behaviorally determined arousal is plotted on the x-axis and the “richness” or “representational capacity of consciousness” is plotted on the y-axis. Increasing arousal can be measured by the threshold to obtain some specific behavior (for instance, spatial orientation to a sound). Healthy subjects cycle during a 24-hour period from deep sleep with low arousal and very little conscious experience to increasing levels of arousal and conscious sensation. In REM sleep, low levels of behavioral arousal go hand-in-hand with vivid consciousness. Conversely, various pathologies of clinical relevance are associated with little to no conscious content. Modified from Laureys (2005).

and lateral prefrontal cortex and parietal associative areas is associated with a global loss of consciousness (Laureys, 2005).

In contrast to diffuse cortical damage, relatively discrete bilateral injuries to midline (paramedian) subcortical structures can also cause a complete loss of consciousness. These structures are therefore part of the *enabling* factors that control the level of brain arousal (as determined by metabolic or electrical activity) and that are needed for any form of consciousness to occur. For an example, consider the heterogeneous collection of more than two dozen (on each side) of nuclei in the upper brain stem (pons, midbrain, and in the posterior hypothalamus), collectively referred to as the *reticular activating system*. These nuclei—three-dimensional collections of neurons with their own cytoarchitecture and neurochemical identity—release distinct neuromodulators such as acetylcholine, noradrenaline/norepinephrine, serotonin, histamine, and orexin/hypocretin. Their axons project widely throughout the brain (Fig. 53.2). These neuromodulators control the excitability of thalamus and forebrain, mediate the alternation between wakefulness and sleep, as well as the general level of both behavioral and brain arousal. Acute lesions in the reticular activating system can result in loss of consciousness and coma. However, eventually the excitability of thala-

mus and forebrain can recover and consciousness can return (Villablanca, 2004).

Other enabling factors for consciousness are the five or more *intralaminar nuclei of the thalamus* (ILN). These receive input from many brain stem nuclei and from frontal cortex and project strongly to the basal ganglia and, in a more distributed manner, into layer I of much of neocortex. Comparatively small (1 cm<sup>3</sup> or less), bilateral lesions in the ILN can completely eliminate awareness (Bogen, 1995). Thus, the ILN are necessary for an organism to be conscious at all but do not appear to be responsible for mediating specific conscious percepts or memories.

If a single substance is critical for consciousness, then acetylcholine is the most likely candidate. Two major cholinergic pathways originate in the brain stem and in the basal forebrain (Fig. 53.2). Brain stem cells send an ascending projection to the thalamus, where release of acetylcholine facilitates thalamo-cortical relay cells and suppresses inhibitory interneurons. Cholinergic cells are therefore well positioned to influence all of cortex by controlling the thalamus. In contrast, cholinergic basal forebrain neurons send their axons to a much wider array of target structures. Collectively, brain stem and basal forebrain cholinergic cells innervate the thalamus, hippocampus, amygdala, and neocortex.

**FIGURE 53.2** Midline structures in the brainstem and thalamus necessary to regulate the level of brain arousal include the intralaminar nuclei of the thalamus (ILN), the thalamic reticular nucleus (NRT) encapsulating the dorsal thalamus, and the midbrain reticular formation (MRF) that encompasses the reticular activating system. Small, bilateral lesions in many of these nuclei can cause a global loss of consciousness.

Cholinergic activity fluctuates with the sleep–wake cycle. In general, increasing levels of spiking activity in cholinergic neurons is associated with wakefulness or REM sleep, and decreasing levels occur during non-REM or slow-wave sleep. Lastly, many neurological pathologies whose symptoms include disturbances of consciousness, such as Parkinson’s disease, Alzheimer’s disease, and other forms of dementia, are associated with a selective loss of cholinergic neurons.

In summary, a plethora of nuclei with distinct chemical signatures in the thalamus, midbrain, and pons must function for the brain of an individual to be sufficiently aroused to experience anything at all. These nuclei belong to the enabling factors for consciousness. It is likely that the specific content of any one conscious sensation is mediated by neurons in cortex and their associated satellite structures, including the amygdala, thalamus, claustrum, and the basal ganglia.

### The Neuronal Correlates of Consciousness

Progress in addressing the mind–body problem has come from focusing on empirically accessible questions rather than on eristic philosophical arguments with no clear resolution. One key objective has been to search for the neuronal correlates—and ultimately the causes—of consciousness. As defined by Crick and Koch (2003), the neuronal correlates of consciousness (NCC) are the *minimal neuronal mecha-*

*nisms jointly sufficient for any one specific conscious percept* (Fig. 53.3).

This definition of the NCC stresses the word “minimal,” because the question of interest is which subcomponents of the brain actually are needed. For instance, it is likely that neural activity in the cerebellum does not underlie any conscious perception, and thus is not part of the NCC. That is, trains of spikes in Purkinje cells (or their absence) will not induce a sensory percept although they may ultimately affect some behaviors (such as eye movements).

This definition does not focus on the necessary conditions for consciousness, because of the great redundancy and parallelism found in neurobiological networks. While activity in some population of neurons may underpin a percept in one case, a different population might mediate a related percept if the former population is lost or inactivated.

Every phenomenal, subjective state will have associated NCC: one for seeing a red patch, another one for seeing grandmother, yet a third one for hearing a siren, and so on. Perturbing or inactivating the NCC for any one specific conscious experience will affect the percept or cause it to disappear respectively. If the NCC could be induced artificially, for instance by cortical microstimulation in a prosthetic device or during neurosurgery, the subject will experience the associated percept.

What characterizes the NCC? What are the commonalities between the NCC for seeing and for

**FIGURE 53.3** The neuronal correlates of consciousness (NCC) are the minimal set of neural events and structures—here synchronized action potentials in neocortical pyramidal neurons—sufficient for a specific conscious percept or memory. From Koch (2004).

hearing? Will the NCC involve all pyramidal neurons in cortex at any given point in time? Or only a subset of long-range projection cells in the frontal lobes that project to the sensory cortices in the back? Only layer 5 cortical cells? Neurons that fire in a rhythmic manner? Neurons that fire in a synchronous manner? These are some of the proposals that have been advanced over the years (Chalmers, 2000).

It is implicitly assumed by most neurobiologists that the relevant variables giving rise to consciousness are to be found at the neuronal level, among the synaptic release or the action potentials in one or more population of cells, rather than at the molecular level. A few scholars have proposed that macroscopic quantum behaviors underlie consciousness. Of particular interest here is *entanglement*, the observation that the quantum states of multiple objects, such as two coupled electrons, may be highly correlated even though they are spatially separated, violating our intuition about locality (entanglement is also the key feature of quantum mechanics that is exploited in quantum computers). The role of quantum mechanics for the photons received by the eye and for the molecules of life is not controversial. But there is no evidence that any components of the nervous system—a 37°C wet and warm tissue strongly coupled to its environment—display quantum entanglement. And even if quantum entanglement were to occur inside individual cells, diffusion and action potential generation and propagation, the principal mechanism for getting information into and out of neurons, would destroy superposition. At the cellular level, the interaction of neurons is governed by classical physics (Koch and Hepp, 2006).

Thus, the vast majority of experiments concerned with the NCC refer to either electrophysiological

recordings in monkeys or functional brain imaging data in humans.

## The Neuronal Basis of Perceptual Illusions

The possibility of precisely manipulating visual percepts in time and space has made vision a preferred modality for seeking the NCC. Psychologists have perfected a number of techniques—masking, binocular rivalry, continuous flash suppression, motion-induced blindness, change blindness, inattention blindness—in which the seemingly simple and unambiguous relationship between a physical stimulus in the world and its associated percept in the privacy of the subject's mind is disrupted (Kim and Blake, 2005). With such techniques, a stimulus can be perceptually suppressed for seconds or even minutes at a time: the image is projected into one of the observer's eyes but it is invisible, not seen. In this manner the neural mechanisms that respond to the subjective percept rather than the physical stimulus can be isolated, permitting the footprints of visual consciousness to be tracked in the brain. In a *perceptual illusion*, the physical stimulus remains fixed while the percept fluctuates. The best known example is the *Necker cube*, whose 12 lines can be perceived in one of two different ways in depth (Fig. 53.4).

A perceptual illusion that can be precisely controlled is *binocular rivalry* (Blake and Logothetis, 2002). Here, a small image (e.g., a horizontal grating) is presented to the left eye and another image (e.g., a vertical grating) is shown to the corresponding location in the right eye. In spite of the constant visual stimulus, observers consciously see the horizontal grating alternate every few seconds with the vertical one. The brain

does not allow for the simultaneous perception of both images.

Macaque monkeys can be trained to report whether they see the left or the right image. The distribution of the switching times and the way in which changing the contrast in one eye affects the reports, leaves little doubt that monkeys and humans experience the same

**FIGURE 53.4** The left line drawing can be perceived in one of two distinct depth configurations shown on the right. Without any other cue, the visual system flips back and forth between these two interpretations of the Necker cube. From Koch (2004).

basic phenomenon. In a series of elegant experiments, Logothetis and colleagues (Logothetis, 1998) recorded from a variety of visual cortical areas in the awake macaque monkey while the animal performed a binocular rivalry task. In primary visual cortex (V1), only a small fraction of cells weakly modulate their response as a function of the percept of the monkey. The majority of cells responded to one or the other retinal stimulus with little regard to what the animal perceived at the time. In contrast, in a high-level cortical area such as the inferior temporal (IT) cortex along the ventral pathway, almost all neurons responded only to the perceptual dominant stimulus, that is, to the stimulus that was being reported. For example, when a face and a more abstract design were presented, one of these to each eye, a “face” cell fired only when the animal indicated by its performance that it saw the face and not the design presented to the other eye (Fig. 53.5). This result implies that the NCC involves activity in neurons in inferior temporal cortex.

Does this mean that the NCC is local to IT? At this point, this is not clear. However, given known anatomical connections, it is possible that specific reciprocal interactions between IT cells and neurons in parts of the prefrontal cortex are necessary for the NCC. This is compatible with the broadly accepted notion that the NCC must involve positive feedback to insure that neural activity is persistent and strong enough to exceed some threshold and to be broadly distributed to multiple cognitive systems, including working memory, planning, and language.

**FIGURE 53.5** A fraction of a minute in the life of a typical IT cell while a monkey experiences binocular rivalry. The upper row indicates the visual input, with dotted vertical boundaries marking stimulus transitions. The second row shows the individual spikes, the third the smoothed firing rate, and the bottom row the monkey's behavior. The animal was taught to press a lever when it saw either one or the other image, but not both. The cell responded only weakly to either the sunburst design or to its optical superposition with the image of a monkey's face. During binocular rivalry (gray central zone) between 5 and 18 seconds, the monkey's perception vacillated back and forth between seeing the face and seeing the bursting sun. Perception of the face was consistently accompanied (and preceded) by a strong increase in firing rate. From N. Logothetis (private communication) as modified by Koch (2004).

In a related perceptual phenomena, *flash suppression*, the percept associated with an image projected into one eye is suppressed by flashing another image into the other eye (while the original image remains). Its methodological advantage over binocular rivalry is that the timing of the perceptual transition is determined by an external trigger rather than by an internal event. The majority of responsive cells in inferior temporal cortex and in the superior temporal sulcus follow the monkey's behavior, and therefore its percept. That is, when the animal perceives a cell's preferred stimulus, the neuron fires; when the stimulus is present on the retina but is perceptually suppressed, the cell falls silent, even though legions of V1 neurons fire vigorously to the same stimulus (Sheinberg and Logothetis, 1997). Single neuron recordings in the medial temporal lobe of epileptic patients during flash suppression likewise demonstrate abolition of neuronal responses when the cells preferred stimulus is present on the retina but is not seen (Kreiman, Fried, and Koch, 2002).

A number of fMRI experiments have exploited binocular rivalry and related illusions to identify the hemodynamic activity underlying visual consciousness in humans. They demonstrate quite conclusively that BOLD activity in the upper stages of the ventral pathway (e.g., the fusiform face area and the parahippocampal place area) follow the percept and not simply the retinal stimulus (Rees and Frith, 2007).

There is a lively debate about the extent to which neurons in primary visual cortex simply encode the visual stimulus or are directly responsible for expressing the subject's conscious percept. That is, is V1 part of the NCC (Crick and Koch, 1995)? It is clear that retinal neurons are not part of the NCC for visual experiences. While retinal neurons often correlate with visual experience, the spiking activity of retinal ganglion cells does not accord with visual experience (for example, there are no photoreceptors at the blind spot; yet no hole in the field of view is apparent; in dreams vivid imagery occurs despite closed eyes, and so on). A number of compelling observations link perception with fMRI BOLD activity in human V1 and even LGN (Tong *et al.*, 1998; Lee, Blake, and Heeger, 2005). These data are at odds with single neuron recordings from the monkey. What explains this discrepancy? Most notably, the two methods operate at quite distinct spatial and temporal scales, recording with high granularity and millisecond resolution individual action potentials in monkeys versus measuring hemodynamic activity at the time scale of seconds in people. Clearly, firing rates and fMRI activity are linked but how they are linked is a very active area of research. It is, of course, always possible that the fine structure of visual cortex differs between these two primate species. These questions have yet to

be resolved, particularly in light of more recent experiments that compellingly demonstrate that V1 BOLD activity and conscious perception can be dissociated.

Haynes and Rees (2005) exploited multivariate decoding techniques to read out perceptually suppressed information (the orientation of a masked stimulus) from V1 BOLD activity, even though the stimulus orientation was so efficiently masked that subjects performed at chance levels when trying to guess the orientation. That is, although subjects did not give any behavioral indication that they saw the orientation of the stimulus, its slant could be predicted on a single trial basis with better than chance odds from the V1 (but not from V2 or V3) BOLD signal. This finding supports the hypothesis that information present in V1 may not be accessible to behavior or to consciousness.

In a powerful combination of binocular rivalry and flash suppression, a stationary image in one eye can be suppressed for minutes on end by continuously flashing different images into the other eye (*continuous flash suppression*; Tsuchiya and Koch, 2005). This paradigm lends itself naturally to further investigate the relationship between neural activity—whether assayed at the single neuron or at the brain voxel level—and conscious perception.

### Other Perceptual Puzzles of Contemporary Interest

The attributes of even simple percepts seem to vary along a continuum. For instance, a patch of color has a brightness and a hue that are variable, just as a simple tone has an associated loudness and pitch. However, is it possible that each particular, consciously experienced, percept is all-or-none? Might a pure tone of a particular pitch and loudness be experienced as an atom of perception, either heard or not, rather than gradually emerging from the noisy background? The perception of the world around us would then be a superposition of many elementary, binary percepts (Sergent and Dehaene, 2004).

Is perception continuous, like a river, or does it consist of series of discontinuous batches, rather like the discrete frames in a movie (Purves, Paydarfar, and Andrews, 1996; VanRullen and Koch, 2003a). In *cinematographic vision* (Sacks, 2004), a rare form of visual migraine, the subject sees the movement of objects as fractured in time, as a succession of different configurations and positions, without any movement in between. The hypothesis that visual perception is quantized in discrete batches of variable duration, most often related to EEG rhythms in various frequency ranges (from theta to beta), is an old one. This idea is being revisited in light of the discrepancies of timing of perceptual

events within and across different sensory modalities. For instance, even though a change in the color of an object occurs simultaneously with a change in its direction of motion, it may not be perceived that way (Zeki, 1998; Bartels and Zeki, 2006; Stetson *et al.*, 2006).

What is the relationship between endogenous, top-down attention and consciousness? Although these are frequently coextensive—subjects are usually conscious of what they attend to—there is a considerable tradition in psychology that argues that these are distinct neurobiological processes (Koch and Tsuchiya, 2007). This question is receiving renewed attention due to the development of ever more refined and powerful visual masking techniques (Kim and Blake, 2005) that independently manipulate attention and consciousness. Indeed, it has been shown that attention can be allocated to a perceptually invisible stimulus (Naccache, Blandin, and Dehaene, 2002) and that subjects can be conscious of a stimulus without attending to it. When exploring the neural basis of these processes, it is therefore critical to not confound attention with consciousness and vice versa.

### Forward versus Feedback Projections

Many actions in response to sensory inputs are rapid, transient, stereotyped, and unconscious (Milner and Goodale, 1995). They can be thought of as cortical reflexes and are characterized by rapid and somewhat stereotyped responses sometimes called *zombie behaviors* (Koch and Crick, 2001), in addition to a slower, all-purpose conscious mode. The latter, conscious mode deals more slowly with broader, less stereotyped and more complex aspects of the sensory input (or a reflection of these, as in imagery) and takes time to decide on appropriate thoughts and responses. A consciousness mode is needed because otherwise a vast number of different zombie modes would be required to react to unusual events. The conscious system may interfere somewhat with the concurrent zombie systems (Beilock *et al.*, 2002): focusing consciousness onto the smooth execution of a complex, rapid, and highly trained sensory-motor task—dribbling a soccer ball, to give one example—can interfere with its smooth execution, something well known to athletes and their trainers. Having both a zombie mode that responds in a well-rehearsed and stereotyped manner as well as a slower system that allows time for thinking and planning more complex behavior is a great evolutionary discovery. This latter aspect, planning, may be one of the principal functions of consciousness.

It seems possible that visual zombie modes in the cortex mainly use the dorsal stream in the parietal region (Milner and Goodale, 1995). However, parietal

activity can affect consciousness by producing attentional effects on the ventral stream, at least under some circumstances. The basis of this inference are clinical case studies and fMRI experiments in normal subjects (Corbetta and Shulman, 2002). The conscious mode for vision depends largely on intermediate visual areas (beyond V1) and especially on the ventral “what” stream.

Seemingly complex visual processing (such as detecting animals in natural, cluttered images) can be accomplished by cortex within 130–150 msec (Thorpe, Fize, and Marlot, 1996; VanRullen and Koch, 2003b), far too slow for conscious perception to be involved in these tasks. It is quite plausible that such behaviors are mediated by a purely feed-forward moving wave of spiking activity that passes from the retina through V1, into V4, IT, and prefrontal cortex, until it affects motor neurons in the spinal cord that control the finger press (as in a typical laboratory experiment). The hypothesis that the basic processing of information is feed-forward is supported most directly by the short times required for a selective response to appear in IT cells. Indeed, Hung *et al.* (2005) were able to decode from the spiking activity of a couple of hundred neurons in monkey IT (over intervals as short as 12.5 msec and about 100 msec after image onset), the category, identity, and even position of a single image flashed onto the retina of the fixating animal. Such hierarchical, purely feed-forward models of visual perception for object recognition in the ventral stream—an outgrowth of the original Hubel and Wiesel scheme (1968)—has been formalized and performs as well as human observers (for masked natural images) and state-of-the-art machine vision categorization algorithms (Serre *et al.*, 2007). Coupled with a suitable motor output, such a feed-forward network implements a zombie behavior in the Koch and Crick (2001) sense—rapidly and efficiently subserving one task, here distinguishing animal from nonanimal pictures, in the absence of any conscious experience.

Contrariwise, conscious perception is believed to require more sustained, reverberatory neural activity, most likely via global feedback from frontal regions of neocortex back to sensory cortical areas in the back (Crick and Koch, 1995). These feedback loops would explain why in backward masking a second stimulus, flashed up to 80 msec after onset of a first image, can still interfere (mask) with the percept of the first image. The reverberatory activity builds up over time until it exceeds a critical threshold. At this point, the sustained neural activity rapidly propagates to parietal, prefrontal, and anterior cingulate cortical regions, thalamus, claustrum, and related structures that support short-term memory, multimodality integration, planning, speech, and other processes intimately related to con-

consciousness. Competition prevents more than one or a very small number of percepts to be simultaneously and actively represented. This is the hypothesis at the heart of the *global workspace* model of consciousness (Baars, 1977; Dehaene and Changeux, 2005). Sending visual information to more frontal structures would allow the associated visual events to be decoded and placed into context (for instance, by accessing various memory banks) and to have this interpretation feed back to the sensory representation in visual cortex (Jazayeri and Movshon, 2007).

In brief, while rapid but transient neural activity in the thalamo-cortical system can mediate complex behavior without conscious sensation it is surmised that consciousness requires sustained but well-organized neural activity dependent on long-range cortico-cortical feedback.

### An Information-Theoretical Theory of Consciousness

At present, it is not known to what extent animals whose nervous systems have an architecture considerably different from the mammalian neocortex are conscious. Furthermore, whether artificial systems, such as computers, robots, or the World Wide Web as a whole, which behave with considerable intelligence, are or can become conscious (as widely assumed in science fiction; e.g., the paranoid computer *HAL* in the film *2001*), remains completely speculative. What is needed is a theory of consciousness, which explains in quantitative terms what type of systems, with what architecture, can possess conscious states.

Progress in the study of the NCC on the one hand, and of the neural correlates of nonconscious zombie behaviors on the other, will hopefully lead to a better understanding of what distinguishes neural structures or processes that are associated with consciousness from those that are not. Yet such an opportunistic, data-driven approach will not lead to an understanding of why certain structures and processes have a privileged relationship with subjective experience. For example, why is it that neurons in corticothalamic circuits are essential for conscious experience, whereas cerebellar neurons, despite their huge numbers, are not? And what aspect of cortical zombie systems make them unsuitable to yield subjective experience? Or why is it that consciousness wanes during slow-wave sleep early in the night, despite levels of neural firing in the thalamocortical system that are comparable to the levels of firing in wakefulness?

Information theory may be such a theoretical approach that establishes at the fundamental level what consciousness is, how it can be measured, and

what requisites a physical system must satisfy in order to generate it (Chalmers, 1996; Tononi and Edelman, 1998).

The most promising candidate for such a theoretical framework is the *information integration theory of consciousness* (Tononi, 2004). It posits that the most important property of consciousness is that it is extraordinarily *informative*. Any one particular conscious state rules out a huge number of alternative experiences. Classically, the reduction of uncertainty among a number of alternatives constitutes information. For example, when a subject consciously experiences reading this particular phrase, a huge number of other possible experiences are ruled out (consider all possible written phrases that could have been written in this space, in all possible fonts, ink colors, and sizes, think of the same phrases spoken aloud, or read and spoken, and so on). Thus, every experience represents one particular conscious state out of a huge repertoire of possible conscious states.

Furthermore, information associated with the occurrence of a conscious state is *integrated* information. An experience of a particular conscious state is an integrated whole. It cannot be subdivided into components that are experienced independently (Tononi and Edelman, 1998). For example, the conscious experience of this particular phrase cannot be experienced as subdivided into, say, the conscious experience of how the words look independently of the conscious experience or how they sound in the reader's mind. Similarly, visual shapes cannot be experienced independently of their color, nor can the left half of the visual field of view be experienced independently of the right half.

Based on these and other considerations, the theory claims that *a physical system can generate consciousness to the extent that it can integrate information*. This idea requires that the system has a large repertoire of available states (information) yet cannot be decomposed into a collection of causally independent subsystems (integration).

Importantly, the theory introduces a measure of a system's capacity to integrate information. This measure, called  $\phi$ , is obtained by determining the minimum repertoire of different states that can be produced in one part of the system by perturbations of its other parts (Tononi, 2004).  $\phi$  can loosely be thought of as the representational capacity of the system (as in the  $y$ -axis of Fig. 53.1). Although  $\phi$  is not easy to calculate exactly for realistic systems, it can be estimated. Thus, by using simple computer simulations, it is possible to show that  $\phi$  is high for neural architectures that conjoin functional specialization with functional integration, like the mammalian thalamocortical system. Conversely,  $\phi$  is low for systems that are made up of small,

quasi-independent modules, like the cerebellum, or for networks of randomly or uniformly connected units (Tononi, 2004).

The notion that consciousness has to do with the brain's ability to integrate information has been tested directly by transcranial magnetic stimulation. In TMS a coil is placed above the skull and a brief and intense magnetic field generates a weak electrical current in the underlying gray matter in a noninvasive manner. Massimini *et al.* (2005) compared multichannel EEG of awake and conscious subjects in response to TMS pulses to the EEG when the same subjects were deeply asleep early in the night—a time during which consciousness is much reduced. During quiet wakefulness, an initial response at the stimulation site was followed by a sequence of waves that moved to connected cortical areas several centimeters away. During slow wave sleep, by contrast, the initial response was stronger but was rapidly extinguished and did not propagate beyond the stimulation site. Thus, the fading of consciousness during certain stages of sleep may be related, as predicted by the theory, to the breakdown of information integration among specialized thalamo-cortical modules.

## Conclusion

Ever since the Greeks first considered the mind-body problem more than two millennia ago, it has been the domain of armchair speculations and esoteric debates with no apparent resolution. Yet many aspects of this ancient set of questions now fall squarely within the domain of science.

In order to advance the resolution of these and similar questions, it will be imperative to record from a large number of neurons simultaneously at many locations throughout the cortico-thalamo system and related satellites such as the claustrum (Crick and Koch, 2005) in behaving subjects. Such experiments cannot, of course, be done in humans. Progress in understanding the circuitry of consciousness, therefore, demands a battery of behaviors (akin to but different from the well-known Turing test for intelligence) that the subject—a newborn infant, immobilized patient, or nonhuman animal—has to pass before considering him, her, or it to possess some measure of conscious perception. This is not an insurmountable step for mammals such as the monkey or the mouse that share many behaviors and brain structures with humans. For example, one particular mouse model of contingency awareness (Han *et al.*, 2003) is based on the differential requirement for awareness of trace versus delay associative eyeblink conditioning in humans (Clark and Squire, 1998).

The growing ability of neuroscientists to manipulate in a reversible, transient, deliberate, and delicate manner identified populations of neurons in the mouse, and thereby affecting its behavior, using combined genetic and optical tools (Adamantidis *et al.*, 2007) opens the possibility of moving from correlation—observing that a particular conscious state is associated with some neural or hemodynamic activity—to causation. For example, rather than just noting that motion perception is associated with an elevated firing rate in projection neurons in cortical area MT, we will be able to perturb the system by inactivating genetically distinct subpopulation of cells in a highly targeted manner. Exploiting these increasingly powerful tools depends on the simultaneous development of appropriate behavioral assays and model organisms amenable to large-scale genomic analysis and manipulation, particularly in mice (Lein *et al.*, 2007).

It is the combination of such fine-grained neuronal analysis in mice and monkeys, ever more sensitive psychophysical and brain imaging techniques in patients and healthy individuals, and the development of a robust theoretical framework that lend hope to the belief that human ingenuity can, ultimately, understand in a rational manner one of the central mysteries of life.
