### NEUROSCIENCE

#### 1. Fundamentals of Neuroscience

FLOYD E. BLOOM

A Brief History of Neuroscience 3  
The Terminology of Nervous Systems Is Hierarchical,  
Distributed, Descriptive, and Historically Based 3  
Neurons and Glia Are Cellular Building Blocks of the  
Nervous System 4  
The Operative Processes of Nervous Systems Are also  
Hierarchical 5  
Cellular Organization of the Brain 6  
Organization of this Text 7  
This Book Is Intended for a Broad Range of Scholars of  
the Neurosciences 8  
Clinical Issues in the Neurosciences 8  
The Spirit of Exploration Continues 9  
The Genomic Inventory Is a Giant Step Forward 9  
Neuroscience Today: A Communal Endeavor 10  
The Creation of Knowledge 10  
Responsible Conduct 11  
Summary 13  
References 13

#### 2. Basic Plan of the Nervous System

LARRY W. SWANSON

Introduction 15  
Evolution Highlights: General Organizing Principles 15

Development Reveals Basic Vertebrate Parts 22  
The Basic Plan of Nervous System Connectivity 27  
Overview of the Adult Mammalian Nervous  
System 31  
References 37  
Suggested Readings 38

## II

---

### CELLULAR AND MOLECULAR NEUROSCIENCE

#### 3. Cellular Components of Nervous Tissue

PATRICK R. HOF, JEAN DE VELLIS, ESTHER A. NIMCHINSKY,  
GRAHAME KIDD, LUZ CLAUDIO, AND BRUCE D. TRAPP

Neurons 41  
Specific Examples of Different Neuronal Types 45  
Neuroglia 47  
Cerebral Vasculature 54  
References 57  
Suggested Readings 58

#### 4. Subcellular Organization of the Nervous System: Organelles and Their Functions

SCOTT T. BRADY, DAVID R. COLMAN, AND PETER J. BROPHY

Axons and Dendrites: Unique Structural Components of  
Neurons 59  
Protein Synthesis in Nervous Tissue 63  
Cytoskeletons of Neurons and Glial Cells 70  
Molecular Motors in the Nervous System 77  
Building and Maintaining Nervous System Cells 80  
References 85

## 5. Electrotonic Properties of Axons and Dendrites

GORDON M. SHEPHERD

- Toward a Theory of Neuronal Information Processing 87
- Basic Tools: Cable Theory and Compartmental Models 88
- Spread of Steady-State Signals 88
- Spread of Transient Signals 93
- Electrotonic Properties Underlying Propagation in Axons 95
- Electrotonic Spread in Dendrites 98
- Dynamic Properties of Passive Electrotonic Structure 101
- Relating Passive to Active Potentials 106
- References 108

## 6. Membrane Potential and Action Potential

DAVID A. MCCORMICK

- Membrane Potential 112
- Action Potential 117
- References 131
- Suggested Readings 132

## 7. Neurotransmitters

ARIEL Y. DEUTCH AND ROBERT H. ROTH

- Several Modes of Neuronal Communication Exist 133
- Chemical Transmission 134
- Classical Neurotransmitters 136
- Nonclassical Neurotransmitters 147
- Peptide Transmitters 148
- Unconventional Transmitters 149
- Synaptic Transmission in Perspective 154
- References 154

## 8. Release of Neurotransmitters

THOMAS L. SCHWARZ

- Transmitter Release Is Quantal 157
- Excitation–Secretion Coupling 160
- Molecular Mechanisms of the Nerve Terminal 163
- Quantal Analysis: Probing Synaptic Physiology 173
- Short-Term Synaptic Plasticity 176
- References 180
- Suggested Readings 180

## 9. Neurotransmitter Receptors

M. NEAL WAXHAM

- Ionotropic Receptors 181
- G-Protein Coupled Receptors 193
- References 203

## 10. Intracellular Signaling

HOWARD SCHULMAN AND JAMES L. ROBERTS

- Signaling Through G-Protein-Linked Receptors 205
- Modulation of Neuronal Function by Protein Kinases and Phosphatases 214
- Intracellular Signaling Affects Nuclear Gene Expression 222
- References 226
- Suggested Readings 226

## 11. Postsynaptic Potentials and Synaptic Integration

JOHN H. BYRNE

- Ionotropic Receptors: Mediators of Fast Excitatory and Inhibitory Synaptic Potentials 227
- Metabotropic Receptors: Mediators of Slow Synaptic Potentials 239
- Integration of Synaptic Potentials 242
- References 245
- Suggested Readings 245

## 12. Complex Information Processing in Dendrites

GORDON M. SHEPHERD

- Strategies for Studying Complex Dendrites 247
- Building Principles Step by Step 248
- An Axon Places Constraints on Dendritic Processing 249
- Dendrodendritic Interactions between Axonal Cells 250
- Passive Dendritic Trees Can Perform Complex Computations 251
- Separation of Dendritic Fields Enhances Complex Information Processing 252
- Distal Dendrites Can be Closely Linked to Axonal Output 253
- Depolarizing and Hyperpolarizing Dendritic Conductances Interact Dynamically 255
- The Axon Hillock-Initial Segment Encodes Global Output 256
- Multiple Impulse Initiation Sites Are under Dynamic Control 256
- Retrograde Impulse Spread into Dendrites Can have Many Functions 258

- Examples of How Voltage-gated Channels Enhance  
Dendritic Information Processing 261  
Dendritic Spines Are Multifunctional Microintegrative  
Units 263  
Summary: The Dendritic Tree as a Complex Information  
Processing System 266  
References 268

### 13. Brain Energy Metabolism

PIERRE J. MAGISTRETTI

- Energy Metabolism of the Brain as a Whole Organ 271  
Tight Coupling of Neuronal Activity, Blood Flow, and  
Energy Metabolism 274  
Energy-Producing and Energy-Consuming Processes in the  
Brain 277  
Brain Energy Metabolism at the Cellular Level 282  
Glutamate and Nitrogen Metabolism: a Coordinated  
Shuttle Between Astrocytes and Neurons 289  
The Astrocyte-Neuron Metabolic Unit 292  
References 292

## III

### NERVOUS SYSTEM DEVELOPMENT

#### 14. Neural Induction and Pattern Formation

ANDREW LUMSDEN AND CHRIS KINTNER

- Neural Induction 297  
Early Neural Patterning 303  
Regionalization of the Central Nervous System 307  
Conclusions 318  
References 319

#### 15. Cellular Determination

WILLIAM A. HARRIS AND VOLKER HARTENSTEIN

- Origins and Generation of Neuronal Progenitors 321  
Spatial and Temporal Coordinates of Neuronal  
Specification 323  
The Proneural and Neurogenic Genes 326  
Asymmetric Cell Division and Cell Fate 328  
Central Neurons and Glia 330  
Sensory Neurons of the Peripheral Nervous System 330  
The Retina: a Collaboration of Intrinsic and Extrinsic  
Cues 336  
Combinatorial Coding in Motor Neurons  
Determination 342  
Cells of the Cerebral Cortex 344  
Conclusions 348  
References 348

#### 16. Neurogenesis and Migration

MARIANNE BRONNER-FRASER AND MARY E. HATTEN

- Introduction 351  
Development of the Peripheral Nervous System 352  
Cell Migration in the CNS 361  
References 372  
Suggested Readings 375

#### 17. Growth Cones and Axon Pathfinding

ALEX L. KOLODKIN AND MARC TESSIER-LAVIGNE

- Growth Cones Are Actively Guided 377  
Guidance Cues for Developing Axons 380  
Guidance Cues and the Control of Cytoskeletal  
Dynamics 391  
Guidance at the Midline: Changing Responses to  
Multiple Cues 395  
References 399

#### 18. Target Selection, Topographic Maps, and Synapse Formation

STEVEN J. BURDEN, DENNIS D.M. O'LEARY, AND  
PETER SCHEIFFELE

- Target Selection 401  
Development of the Neuromuscular Synapse 416  
Synapse Formation in the Central Nervous System 426  
References 434  
Suggested Readings 435

#### 19. Programmed Cell Death and Neurotrophic Factors

RONALD W. OPPENHEIM AND  
CHRISTOPHER S. VON BARTHELD

- Cell Death and the Neurotrophic Hypothesis 438  
The Origins of Programmed Cell Death and its  
Widespread Occurrence in the Developing Nervous  
System 438  
Functions of Neuronal Programmed Cell Death 444  
Modes of Cell Death in Developing Neurons 445  
The Mode of Neuronal Cell Death Reflects the  
Activation of Distinct Biochemical and Molecular  
Mechanisms 447  
Nerve Growth Factor: The Prototype Target-Derived  
Neuronal Survival Factor 450  
The Neurotrophin Family 452  
Neurotrophin Receptors 453  
Secretion and Axonal Transport of Neurotrophins and  
Pro-Neurotrophins 455  
Signal Transduction Through TRK Receptors 457  
Cytokines and Growth Factors have Multiple  
Activities 458

Programmed Cell Death Is Regulated by Interactions with  
Targets, Afferents, and Nonneuronal Cells 463  
The Role of Programmed Cell Death in  
Neuropathology 464  
References 466  
Suggested Readings 467

## 20. Synapse Elimination

JUAN C. TAPIA AND JEFF W. LICHTMAN

Overview 469  
The Purpose of Synapse Elimination 472  
A Structural Analysis of Synapse Elimination at The  
Neuromuscular Junction 475  
A Role for Interaxonal Competition and Activity 478  
Is Synapse Elimination Strictly A Developmental  
Phenomenon? 488  
Summary 488  
References 489

## 21. Dendritic Development

HOLLIS CLINE, ANIRVAN GHOSH, AND YUH-NUNG JAN

Dynamics of Dendritic Arbor Development 491  
Genetic Control of Dendrite Development in  
*Drosophila* 492  
Extracellular Regulation of Dendritic Development in  
The Mammalian Brain 496  
Effect of Experience on Dendritic Development 504  
Mechanisms that Mediate Activity-Dependent Dendritic  
Growth 507  
Convergence and Divergence 508  
Conclusion 510  
References 510

## 22. Early Experience and Sensitive Periods

ERIC I. KNUDSEN

Birdsong: Learned by Experience 517  
Sound Localization: Calibrated by Early Experience in the  
Owl 520  
Principles of Developmental Learning 529  
References 532

# IV

## SENSORY SYSTEMS

### 23. Fundamentals of Sensory Systems

STEWART H. HENDRY, STEVEN S. HSIAO, AND  
M. CHRISTIAN BROWN

Sensation and Perception 535  
Receptors 537

Peripheral Organization and Processing 540  
Central Pathways and Processing 542  
Sensory Cortex 544  
Summary 548  
References 548  
Suggested Readings 548

### 24. Chemical Senses: Taste and Olfaction

KRISTIN SCOTT

Taste 549  
Olfaction 560  
Pheromone Detection 576  
References 578  
Suggested Readings 579

### 25. Somatosensory System

STEWART HENDRY AND STEVEN HSIAO

Peripheral Mechanisms of Somatic  
Sensation 581  
Nociception, Thermoreception, and  
Itch 589  
Cns Components of Somatic Sensation 592  
Thalamic Mechanisms of Somatic  
Sensation 598  
The Path From Nociception to Pain 598  
The Trigeminal System 602  
Cortical Representation of Touch 604  
References 607  
Suggested Readings 608

### 26. Audition

M. CHRISTIAN BROWN AND JOSEPH SANTOS-SACCHI

External and Middle Ear 609  
The Cochlea 610  
The Auditory Nerve 618  
Central Nervous System 624  
References 635  
Suggested Readings 636

### 27. Vision

R. CLAY REID AND W. MARTIN USREY

Overview 637  
The Eye and the Retina 639  
The Retinogeniculocortical Pathway 649  
References 658  
Suggested Readings 659

## V

---

# MOTOR SYSTEMS

### 28. Fundamentals of Motor Systems

STEN GRILLNER

- Basic Components of the Motor System 665
- Motor Programs Coordinate Basic Motor Patterns 667
- Roles of Different Parts of the Nervous System in the Control of Movement 668
- Conclusion 676
- References 676

### 29. The Spinal and Peripheral Motor System

MARY KAY FLOETER AND GEORGE Z. MENTIS

- Locomotion is a Cycle 677
- Connecting the Spinal Cord to the Periphery 680
- Spinal Interneuron Networks 686
- Descending Control of Spinal Circuits 693
- Sensory Modulation 693
- References 697
- Suggested Readings 697

### 30. Descending Control of Movement

MARC H. SCHIEBER AND JAMES F. BAKER

- The Medial Postural System 699
- The Lateral Voluntary System 710
- Summary 723
- References 724

### 31. The Basal Ganglia

JONATHAN W. MINK

- Basal Ganglia Anatomy 725
- Signaling in Basal Ganglia 734
- The Effect of Basal Ganglia Damage on Movement 737
- Fundamental Principles of Basal Ganglia Operation for Motor Control 742
- Basal Ganglia Participation in Nonmotor Functions 744
- References 749
- Suggested Readings 750

### 32. Cerebellum

MICHAEL D. MAUK AND W. THOMAS THACH

- Anatomy and Phylogenetic Development of the Cerebellum 751
- Assessing Cerebellar Function 758
- References 770

### 33. Eye Movements

RICHARD J. KRAUZLIS

- Eye Movements are Used to Stabilize Gaze or to Shift Gaze 775
- The Mechanics of Moving the Eyes 778
- The Fundamental Circuits for Stabilizing Gaze 780
- The Commands for Shifting Gaze are Formed in the Brain Stem 782
- Gaze Shifts are Controlled by the Midbrain and Forebrain 785
- The Control of Gaze Shifts Involves Higher-Order Processes 788
- The Control of Eye Movements Changes Over Time 790
- Conclusions 791
- References 792
- Suggested Readings 792

## VI

---

# REGULATORY SYSTEMS

### 34. The Hypothalamus: An Overview of Regulatory Systems

J. PATRICK CARD, LARRY W. SWANSON, AND  
ROBERT Y. MOORE

- Historical Perspective 795
- Hypothalamic Cytoarchitecture 796
- Functional Organization of the Hypothalamus 797
- Effector Systems of the Hypothalamus are Hormonal and Synaptic 800
- References 805
- Suggested Readings 806

### 35. Central Control of Autonomic Functions: Organization of the Autonomic Nervous System

TERRY L. POWLEY

- Sympathetic Division: Organized to Mobilize the Body for Activity 809
- Parasympathetic Division: Organized for Energy Conservation 812
- The Enteric Division of the ANS: The Nerve Net Found in the Walls of Visceral Organs 816
- Ans Pharmacology: Transmitter and Receptor Coding 816
- Autonomic Coordination of Homeostasis 819
- Hierarchically Organized ANS Circuits in the CNS 823
- Perspective: Future of the Autonomic Nervous System 825
- Summary and General Conclusions 827

References 827  
Suggested Readings 828

### 36. Neural Regulation of the Cardiovascular System

JOHN LONGHURST

An Anatomical Framework 829  
Anatomy and Chemical Properties of Autonomic Pathways 834  
Network Generators 837  
Short-Term Control Mechanisms 838  
Reflex Control of the Cardiovascular System 838  
Arterial Baroreceptors 838  
Peripheral Arterial Chemoreceptors 844  
Cardiac Receptors 847  
Abdominal Visceral Reflexes 849  
References 852

### 37. Neural Control of Breathing

JACK L. FELDMAN AND DONALD R. MCCRIMMON

Early Neuroscience and the Brain Stem 855  
Central Nervous System and Breathing 856  
Where are the Neurons Generating Respiratory Pattern? 857  
Discharge Patterns of Respiratory Neurons 859  
Where are the Neurons that Generate the Breathing Rhythm? 862  
Sensory Inputs and Altered Breathing 865  
Mechanoreceptors in the Lungs Adjust Breathing Pattern and Initiate Protective Reflexes 867  
Modulation and Plasticity of Respiratory Motor Output 868  
Suprapontine Structures and Breathing 870  
References 872

### 38. Food Intake and Metabolism

STEPHEN C. WOODS AND EDWARD M. STRICKER

Caloric Homeostasis 873  
Role of Caloric Homeostasis in Control of Food Intake 875  
Central Control of Food Intake 882  
Neuropeptides and the Control of Food Intake 884  
References 888  
Suggested Readings 888

### 39. Water Intake and Body Fluids

EDWARD M. STRICKER AND JOSEPH G. VERBALIS

Body Fluid Physiology 889  
Osmotic Homeostasis 890  
Volume Homeostasis 898

References 902  
Suggested Readings 903

### 40. Neuroendocrine Systems

ANDREA C. GORE

The Hypothalamus Is a Neuroendocrine Organ 905  
Hypothalamic Releasing/Inhibiting Hormones and their Targets 906  
The Hypothalamic–Adenohypophysial Neuroendocrine Systems 909  
The Hypothalamic-Neurohypophysial Systems 925  
Hormones and the Brain 926  
References 929

### 41. Circadian Timekeeping

DAVID R. WEAVER AND STEVEN M. REPERT

Overview of the Mammalian Circadian Timing System 931  
The Suprachiasmatic Nuclei Are the Site of the Primary Circadian Pacemaker in Mammals 933  
A Hierarchy of Cell-Autonomous Circadian Oscillators 934  
The Molecular Basis for Circadian Oscillation Is a Transcriptional Feedback Loop 936  
Circadian Photoreception 943  
Circadian Output Mechanisms 949  
Diversity of Output Pathways Leading to Physiological Rhythms 950  
General Summary 955  
References 956  
Suggested Readings 957

### 42. Sleep, Dreaming, and Wakefulness

EDWARD F. PACE-SCHOTT, J. ALLAN HOBSON AND ROBERT STICKGOLD

The Two States of Sleep: Rapid Eye Movement and Nonrapid Eye Movement 959  
Sleep in the Modern Era of Neuroscience 962  
Anatomy and Physiology of Brain Stem Regulatory Systems 965  
Modeling the Control of Behavioral State 975  
Sleep has Multiple Functions 980  
References 982  
Suggested Readings 985

### 43. Reward, Motivation, and Addiction

GEORGE F. KOOB, BARRY J. EVERITT, AND TREVOR W. ROBBINS

Reward and Motivation 987  
Addiction 999  
References 1014

# VII

## BEHAVIORAL and COGNITIVE NEUROSCIENCE

### 44. Human Brain Evolution

JON H. KAAS AND TODD M. PREUSS

- Evolutionary and Comparative Principles 1019
- Evolution of Primate Brains 1027
- Why Brain Size Is Important 1034
- Conclusions 1036
- References 1037
- Suggested Readings 1037

### 45. Cognitive Development and Aging

PETER R. RAPP AND JOCELYNE BACHEVALIER

- Brain Development 1039
- Cognitive Development and Aging: A Life Span Perspective 1043
- Pathological Processes In Cognitive Development and Aging 1055
- References 1065
- Suggested Readings 1066

### 46. Visual Perception of Objects

LUIZ PESSOA, ROGER B. H. TOOTELL, AND  
LESLIE G. UNGERLEIDER

- The Problem of Object Recognition 1067
- Substrates for Object Perception and Recognition: Early Evidence from Brain Damage 1068
- Visual Pathways for Object Processing in Nonhuman Primates 1071
- Neuronal Properties Within the Object Recognition Pathway 1074
- Functional Neuroimaging and Electrophysiology of Object Recognition in Humans 1080
- Perception and Recognition of Specific Classes of Objects 1083
- Overall Summary 1088
- References 1088
- Suggested Readings 1089

### 47. Spatial Cognition

CAROL L. COLBY AND CARL R. OLSON

- Neural Systems for Spatial Cognition 1091
- Parietal Cortex 1092
- Frontal Cortex 1102
- Hippocampus and Adjacent Cortex 1107
- Spatial Cognition and Spatial Action 1109

- References 1110
- Suggested Readings 1111

### 48. Attention

JOHN H. REYNOLDS, JACQUELINE P. GOTTLIEB,  
AND SABINE KASTNER

- Introduction 1113
- Varieties of Attention 1113
- Neglect Syndrome: A Deficit of Spatial Attention 1114
- Single Unit Recording Studies in Nonhuman Primates Provide Convergent Evidence for A Fronto-Parietal Attentional Control System 1116
- Attention Affects Neural Activity in the Human Visual Cortex in the Presence and Absence of Visual Stimulation 1121
- Attention Increases Sensitivity and Boosts the Clarity of Signals Generated by Neurons in Parts of the Visual System Devoted to Processing Information about Objects 1122
- Attention Modulates Neural Responses in the Human Lateral Geniculate Nucleus 1123
- The Visual Search Paradigm has been Used to Study the Role of Attention in Selecting Relevant Stimuli from Within a Cluttered Visual Environment 1124
- Where Is the Computational Bottleneck as Revealed by Search Tasks? 1126
- Neuronal Receptive Fields Are a Possible Neural Correlate of Limited Capacity 1126
- Competition Can Be Biased by Nonspatial Feedback 1127
- Filtering of Unwanted Information in Humans 1129
- Conclusions 1130
- References 1131
- Suggested Readings 1131

### 49. Learning and Memory: Basic Mechanisms

JOHN H. BYRNE

- Paradigms have been Developed to Study Associative and Nonassociative Learning 1133
- Invertebrate Studies: Key Insights From *Aplysia* Into Basic Mechanisms of Learning 1134
- Vertebrate Studies: Long-Term Potentiation 1140
- Long-Term Depression 1148
- How Does a Change in Synaptic Strength Store a Complex Memory? 1149
- References 1151
- Suggested Readings 1152

### 50. Learning and Memory: Brain Systems

JOSEPH R. MANNS AND HOWARD EICHENBAUM

- Introduction 1153
- History of Memory Systems 1153

Major Memory Systems of the Mammalian Brain 1156  
Behavior Supported by Multiple Memory Systems 1174  
Conclusion 1175

## Preface to the Third Edition

---

In this third edition of *Fundamental Neuroscience*, we have tried to improve on the second edition with a volume that effectively introduces students to the full range of contemporary neuroscience. Neuroscience is a large field founded on the premise that all of behavior and all of mental life have their origin in the structure and function of the nervous system. Today, the need for a single-volume introduction to neuroscience is greater than ever. Towards the end of the 20<sup>th</sup> century, the study of the brain moved from a peripheral position within both the biological and psychological sciences to become an interdisciplinary field that is now central within each discipline. The maturation of neuroscience has meant that individuals from diverse backgrounds—including molecular biologists, computer scientists, and psychologists—are interested in learning about the structure and function of the brain and about how the brain works. In addition, new techniques and tools have become available to study the brain in increasing detail. In the last 15 years new genetic methods have been introduced to delete or over-express single genes with spatial and temporal specificity. Neuroimaging techniques such as functional magnetic resonance imaging (fMRI) have been developed that allow study of the living human brain while it is engaged in cognition.

This third edition attempts to capture the promise and excitement of this fast-moving discipline. All the chapters have been rewritten to make them more concise. As a result the new edition is about 30% shorter than previous editions but still covers the same comprehensive range of topics. The volume begins with an opening chapter that provides an overview of the discipline. A second chapter presents fundamental information about the architecture and anatomy of

nervous systems. The remainder of the volume (Sections II–VII) presents the major topics of neuroscience. The second section (Cellular and Molecular Neuroscience) considers the cellular and subcellular organization of neurons, the physiology of nerve cells, and how signaling occurs between neurons. The third section (Nervous System Development) includes discussion of neural induction, cell fate, migration, process outgrowth, development of dendrites, synapse formation, programmed cell death, synapse elimination, and early experience including critical periods. The fourth and fifth sections (Sensory Systems and Motor Systems) describe the neural organization of each sensory modality and the organization of the brain pathways and systems important for locomotion, voluntary action, and eye movements. The sixth section (Regulatory Systems) describes the variety of hypothalamic and extra-hypothalamic systems that support motivation, reward, and internal regulation, including cardiovascular function, respiration, food and water intake, neuroendocrine function, circadian rhythms, and sleep and dreaming. The final section (Behavioral and Cognitive Neuroscience) describes the neural foundations of the so-called higher mental functions including perception, attention, memory, language, spatial cognition, and executive function. Additional chapters cover human brain evolution, cognitive development and aging, and consciousness. The volume will be accompanied by an easily accessible companion website, which will present all the figures and increase the flexibility with which the material can be used.

The authors listed at the ends of the chapters and boxes are working scientists, experts in the topics they cover. The Editors edited the chapters to achieve consistency of style and content. At Academic Press/Elsevier Science, the project was coordinated

by Hilary Rowe and Nikki Levy (Publishing Editors), and we are grateful to them for their leadership and advice throughout the project. In addition, Meg Day (Developmental Editor) very capably coordinated the production of the book with the help of Sarah Hajduk (Publishing Services Manager) and Christie Jozwiak (Project Manager).

The Editors of *Fundamental Neuroscience* hope that users of this book, and especially the students who will become the next generation of neuroscientists, find the subject matter of neuroscience as interesting and exciting as we do.

*The Editors*

## About The Editors

---

Larry R. Squire is Distinguished Professor of Psychiatry, Neurosciences, and Psychology at the University of California School of Medicine, San Diego, and Research Career Scientist at the Veterans Affairs Medical Center, San Diego. He investigates the organization and neurological foundations of memory. He is a former President of the Society for Neuroscience and is a member of the National Academy of Sciences and the Institute of Medicine.

Darwin K. Berg is Distinguished Professor in the Division of Biological Sciences at the University of California, San Diego. He has been chairman of the Biology Department and currently serves as Councilor of the Society for Neuroscience and as a Board member of the Kavli Institute for Brain and Mind. His research is focused on the roles of nicotinic cholinergic signaling in the vertebrate nervous system.

Floyd Bloom is Professor Emeritus in the Molecular and Integrative Neuroscience Department (MIND) at The Scripps Research Institute. His recent awards include the Sarnat Award from the Institute of Medicine and the Salmon Medal of the New York Academy of Medicine. He is a former President of the Society for Neuroscience and is a member of the National Academy of Sciences and the Institute of Medicine.

Sascha du Lac is an Investigator of the Howard Hughes Medical Institute and an Associate Professor

of Systems Neurobiology at the Salk Institute for Biological Studies. Her research interests are in the neurobiology of resilience and learning, and her laboratory investigates behavioral, circuit, cellular, and molecular mechanisms in the sense of balance.

Anirvan Ghosh is Stephen Kuffler Professor in the Division of Biological Sciences at the University of California, San Diego and Director of the graduate program in Neurosciences. His research interests include the development of synaptic connections in the central nervous system and the role of activity-dependent gene expression in the cortical development. He is recipient of the Presidential Early Career Award for Scientists and Engineers and the Society for Neuroscience Young Investigator Award.

Nicholas C. Spitzer is Distinguished Professor in the Division of Biological Sciences at the University of California, San Diego. His research is focused on neuronal differentiation and the role of electrical activity and calcium signaling in the assembly of the nervous system. He has been chairman of the Biology Department and the Neurobiology Section, a trustee of the Grass Foundation, and served as Councilor of the Society for Neuroscience. He is a member of the American Academy of Arts and Sciences and Co-Director of the Kavli Institute for Brain and Mind.

# Fundamentals of Neuroscience

## A BRIEF HISTORY OF NEUROSCIENCE

The field of knowledge described in this book is *neuroscience*, the multidisciplinary sciences that analyze the nervous system to understand the biological basis for behavior. Modern studies of the nervous system have been ongoing since the middle of the nineteenth century. Neuroanatomists studied the brain's shape, its cellular structure, and its circuitry; neurochemists studied the brain's chemical composition, its lipids and proteins; neurophysiologists studied the brain's bioelectric properties; and psychologists and neuropsychologists investigated the organization and neural substrates of behavior and cognition.

The term neuroscience was introduced in the mid-1960s, to signal the beginning of an era in which each of these disciplines would work together cooperatively, sharing a common language, common concepts, and a common goal—to understand the structure and function of the normal and abnormal brain. Neuroscience today spans a wide range of research endeavors from the molecular biology of nerve cells (i.e., the genes encoding the proteins needed for nervous system function) to the biological basis of normal and disordered behavior, emotion, and cognition (i.e., the mental properties by which individuals interact with each other and with their environments). For a more complete, but concise, history of the neurosciences see Kandel and Squire (2000).

Neuroscience is currently one of the most rapidly growing areas of science. Indeed, the brain is sometimes referred to as the last frontier of biology. In 1971, 1100 scientists convened at the first annual meeting of the Society for Neuroscience. In 2006, 25,785 scientists

participated at the society's 36th annual meeting at which 14,268 research presentations were made.

## THE TERMINOLOGY OF NERVOUS SYSTEMS IS HIERARCHICAL, DISTRIBUTED, DESCRIPTIVE, AND HISTORICALLY BASED

Beginning students of neuroscience justifiably could find themselves confused. Nervous systems of many organisms have their cell assemblies and macroscopically visible components named by multiple overlapping and often synonymous terms. With a necessarily gracious view to the past, this confusing terminology could be viewed as the intellectual cost of focused discourse with predecessors in the enterprise. The nervous systems of invertebrate organisms often are designated for their spatially directed collections of neurons responsible for local control of operations, such as the thoracic or abdominal ganglia, which receive sensations and direct motoric responses for specific body segments, all under the general control of a cephalic ganglion whose role includes sensing the external environment.

In vertebrates, the components of the nervous system were named for both their appearance and their location. As noted by Swanson, and expanded upon in Chapter 2 of this volume, the names of the major parts of the brain were based on creative interpretations of early dissectors of the brain, attributing names to brain segments based on their appearance in the freshly dissected state: hippocampus (shaped like

the sea horse) or amygdala (shaped like the almond), cerebrum (the main brain), and cerebellum (a small brain).

## NEURONS AND GLIA ARE CELLULAR BUILDING BLOCKS OF THE NERVOUS SYSTEM

This book lays out our current understanding in each of the important domains that together define the full scope of modern neuroscience. The structure and function of the brain and spinal cord are most appropriately understood from the perspective of their highly specialized cells: the *neurons*, the interconnected, highly differentiated, bioelectrically driven, cellular units of the nervous system; and their more numerous support cells, the *glia*. Given the importance of these cellular building blocks in all that follows, a brief overview of their properties may be helpful.

### Neurons Are Heterogeneously Shaped, Highly Active Secretory Cells

Neurons are classified in many different ways, according to function (sensory, motor, or interneuron), location (cortical, spinal, etc.), the identity of the transmitter they synthesize and release (glutamatergic, cholinergic, etc.), and their shape (pyramidal, granule, mitral, etc.). Microscopic analysis focuses on their general shape and, in particular, the number of extensions from the cell body. Most neurons have one *axon*, often branched, to transmit signals to interconnected target neurons. Other processes, termed *dendrites*, extend from the nerve cell body (also termed the perikaryon—the cytoplasm surrounding the nucleus of the neuron) to receive synaptic contacts from other neurons; dendrites may branch in extremely complex patterns, and may possess multiple short protrusions called dendritic *spines*. Neurons exhibit the cytological characteristics of highly active secretory cells with large nuclei; large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi apparatus), in which secretory products of the cell are packaged into membrane-bound organelles for transport out of the cell body proper to the axon or dendrites. Neurons and their cellular extensions are rich in microtubules—elongated tubules approximately 24 nm in diameter. Microtubules support the elongated axons and dendrites and assist in the reciprocal transport of essential macromolecules and organelles between the cell body and the distant axon or dendrites.

### Neurons Communicate Chemically through Specialized Contact Zones

The sites of interneuronal communication in the central nervous system (CNS) are termed *synapses* in the CNS and *junctions* in somatic, motor, and autonomic nervous systems. Paramembranous deposits of specific proteins essential for transmitter release, response, and catabolism characterize synapses and junctions morphologically. These specialized sites are presumed to be the active zone for transmitter release and response. Paramembranous proteins constitute a specialized junctional adherence zone, termed the synaptolemma. Like peripheral junctions, central synapses also are denoted by accumulations of tiny (500 to 1500 Å) organelles, termed synaptic vesicles. The proteins of these vesicles have been shown to have specific roles in transmitter storage; vesicle docking onto presynaptic membranes, voltage- and  $\text{Ca}^{2+}$ -dependent secretion, and the recycling and restorage of previously released transmitter molecules.

### Synaptic Relationships Fall into Several Structural Categories

Synaptic arrangements in the CNS fall into a wide variety of morphological and functional forms that are specific for the neurons involved. The most common arrangement, typical of hierarchical pathways, is either the axodendritic or the axosomatic synapse, in which the axons of the cell of origin make their functional contact with the dendrites or cell body of the target neuron, respectively. A second category of synaptic arrangement is more rare—forms of functional contact between adjacent cell bodies (somasomatic) and overlapping dendrites (dendrodendritic). Within the spinal cord and some other fields of neuropil (relatively acellular areas of synaptic connections), serial axoaxonic synapses are relatively frequent. Here, the axon of an interneuron ends on the terminal of a long-distance neuron as that terminal contacts a dendrite, or on the segment of the axon that is immediately distal to the soma, termed the initial segment, where action potentials arise. Many presynaptic axons contain local collections of typical synaptic vesicles with no opposed specialized synaptolemma. These are termed *boutons en passant*. The release of a transmitter may not always occur at such sites.

### Synaptic Relationships Also Belong to Diverse Functional Categories

As with their structural representations, the qualities of synaptic transmission can also be functionally

categorized in terms of the nature of the neurotransmitter that provides the signaling; the nature of the receptor molecule on the postsynaptic neuron, gland, or muscle; and the mechanisms by which the postsynaptic cell transduces the neurotransmitter signal into transmembrane changes. So-called “fast” or “classical” neurotransmission is the functional variety seen at the vast majority of synaptic and junctional sites, with a rapid onset and a rapid ending, generally employing excitatory amino acids (glutamate or aspartate) or inhibitory amino acids ( $\gamma$ -aminobutyrate, GABA, or glycine) as the transmitter. The effects of those signals are largely attributable to changes in postsynaptic membrane permeability to specific cations or anions and the resulting depolarization or hyperpolarization, respectively. Other neurotransmitters, such as the monoamines (dopamine, norepinephrine, serotonin) and many neuropeptides, produce changes in excitability that are much more enduring. Here the receptors activate metabolic processes within the postsynaptic cells—frequently to add or remove phosphate groups from key intracellular proteins; multiple complex forms of enduring postsynaptic metabolic actions are under investigation. The brain’s richness of signaling possibilities comes from the interplay on common postsynaptic neurons of these multiple chemical signals.

### THE OPERATIVE PROCESSES OF NERVOUS SYSTEMS ARE ALSO HIERARCHICAL

As research progressed, it became clear that neuronal functions could best be fitted into nervous system function by considering their operations at four fundamental hierarchical levels: molecular, cellular, systems, and behavioral. These levels rest on the fundamental principle that neurons communicate chemically, by the activity-dependent secretion of *neurotransmitters*, at specialized points of contact named *synapses*.

At the *molecular level* of operations, the emphasis is on the interaction of molecules—typically proteins that regulate transcription of genes, their translation into proteins, and their posttranslational processing. Proteins that mediate the intracellular processes of transmitter synthesis, storage, and release, or the intracellular consequences of intercellular synaptic signaling are essential neuronal molecular functions. Such transductive molecular mechanisms include the neurotransmitters’ receptors, as well as the auxiliary molecules that allow these receptors to influence the short-term biology of responsive neurons (through regulation of ion channels) and their longer-term regu-

lation (through alterations in gene expression). Completion of the human, chimpanzee, rat, and mouse genomes can be viewed as an extensive inventory of these molecular elements, more than half of which are thought to be either highly enriched in the brain or even exclusively expressed there.

At the *cellular level* of neuroscience, the emphasis is on interactions between neurons through their synaptic transactions and between neurons and glia. Much current cellular level research focuses on the biochemical systems within specific cells that mediate such phenomena as pacemakers for the generation of circadian rhythms or that can account for activity-dependent adaptation. Research at the cellular level strives to determine which specific neurons and which of their most proximate synaptic connections may mediate a behavior or the behavioral effects of a given experimental perturbation.

At the *systems level*, emphasis is on the spatially distributed sensors and effectors that integrate the body’s response to environmental challenges. There are sensory systems, which include specialized senses for hearing, seeing, feeling, tasting, and balancing the body. Similarly, there are motor systems for trunk, limb, and fine finger motions and internal regulatory systems for visceral regulation (e.g., control of body temperature, cardiovascular function, appetite, salt and water balance). These systems operate through relatively sequential linkages, and interruption of any link can destroy the function of the system.

Systems level research also includes research into cellular systems that innervate the widely distributed neuronal elements of the sensory, motor, or visceral systems, such as the pontine neurons with highly branched axons that innervate diencephalic, cortical, and spinal neurons. Among the best studied of these divergent systems are the monoaminergic neurons, which have been linked to the regulation of many behavioral outputs of the brain, ranging from feeding, drinking, thermoregulation, and sexual behavior. Monoaminergic neurons also have been linked to such higher functions as pleasure, reinforcement, attention, motivation, memory, and learning. Dysfunctions of these systems have been hypothesized as the basis for some psychiatric and neurological diseases, supported by evidence that medications aimed at presumed monoamine regulation provide useful therapy.

At the *behavioral level* of neuroscience research, emphasis is on the interactions between individuals and their collective environment. Research at the behavioral level centers on the integrative phenomena that link populations of neurons (often operationally or empirically defined) into extended specialized circuits, ensembles, or more pervasively distributed

“systems” that integrate the physiological expression of a learned, reflexive, or spontaneously generated behavioral response. Behavioral research also includes the operations of higher mental activity, such as memory, learning, speech, abstract reasoning, and consciousness. Conceptually, “animal models” of human psychiatric diseases are based on the assumption that scientists can appropriately infer from observations of behavior and physiology (heart rate, respiration, locomotion, etc.) that the states experienced by animals are equivalent to the emotional states experienced by humans expressing these same sorts of physiological changes.

As the neuroscientific bases for some elemental behaviors have become better understood, new aspects of neuroscience applied to problems of daily life have begun to emerge. Methods for the noninvasive detection of activity in certain small brain regions have improved such that it is now possible to link these changes in activity with discrete forms of mental activity. These advances have given rise to the concept that it is possible to understand where in the brain the decision-making process occurs, or to identify the kinds of information necessary to decide whether to act or not. The detailed quantitative data that now exist on the details of neuronal structure, function, and behavior have driven the development of computational neurosciences. This new branch of neuroscience research seeks to predict the performance of neurons, neuronal properties, and neural networks based on their discernible quantitative properties.

### Some Principles of Brain Organization and Function

The central nervous system is most commonly divided into major structural units, consisting of the major physical subdivisions of the brain. Thus, mammalian neuroscientists divide the central nervous system into the brain and spinal cord and further divide the brain into regions readily seen by the simplest of dissections. Based on research that has demonstrated that these large spatial elements derive from independent structures in the developing brain, these subdivisions are well accepted. Mammalian brain thusly is divided into hindbrain, midbrain, and forebrain, each of which has multiple highly specialized regions within it. In deference to the major differences in body structure, invertebrate nervous systems most often are organized by body segment (cephalic, thoracic, abdominal) and by anterior-posterior placement.

Neurons within the vertebrate CNS operate either within layered structures (such as the olfactory bulb,

cerebral cortex, hippocampal formation, and cerebellum) or in clustered groupings (the defined collections of central neurons, which aggregate into “nuclei” in the central nervous system and into “ganglia” in the peripheral nervous system, and in invertebrate nervous systems). The specific connections between neurons within or across the macro-divisions of the brain are essential to the brain’s functions. It is through their patterns of neuronal circuitry that individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain.

## CELLULAR ORGANIZATION OF THE BRAIN

Present understanding of the cellular organization of the CNS can be viewed simplistically according to three main patterns of neuronal connectivity.

### Three Basic Patterns of Neuronal Circuitry Exist

*Long hierarchical neuronal connections* typically are found in the primary sensory and motor pathways. Here the transmission of information is highly sequential, and interconnected neurons are related to each other in a hierarchical fashion. Primary receptors (in the retina, inner ear, olfactory epithelium, tongue, or skin) transmit first to primary relay cells, then to secondary relay cells, and finally to the primary sensory fields of the cerebral cortex. For motor output systems, the reverse sequence exists with impulses descending hierarchically from the motor cortex to the spinal motoneuron. It is at the level of the motor and sensory systems that beginning scholars of the nervous system will begin to appreciate the complexities of neuronal circuitry by which widely separated neurons communicate selectively. This hierarchical scheme of organization provides for a precise flow of information, but such organization suffers the disadvantage that destruction of any link incapacitates the entire system.

*Local circuit neurons* establish their connections mainly within their immediate vicinity. Such local circuit neurons frequently are small and may have relatively few processes. Interneurons expand or constrain the flow of information within their small spatial domain and may do so without generating action potentials, given their short axons.

*Single-source divergent circuitry* is utilized by certain neurons of the hypothalamus, pons, and medulla. From their clustered anatomical location, these neurons extend multiple branched and divergent connections

to many target cells, almost all of which lie outside the brain region in which the neurons of origin are located. Neurons with divergent circuitry could be considered more as interregional interneurons rather than as sequential elements within any known hierarchical system. For example, different neurons of the noradrenergic nucleus, the locus coeruleus (named for its blue pigmented color in primate brains) project from the pons to either the cerebellum, spinal cord, hypothalamus, or several cortical zones to modulate synaptic operations within those regions.

## Glia Are Supportive Cells to Neurons

Neurons are not the only cells in the CNS. According to most estimates, neurons are outnumbered, perhaps by an order of magnitude, by the various non-neuronal supportive cellular elements. Nonneuronal cells include macroglia, microglia, and cells of the brain's blood vessels, cells of the choroid plexus that secrete the cerebrospinal fluid, and *meninges*, sheets of connective tissue that cover the surface of the brain and comprise the cerebrospinal fluid-containing envelope that protects the brain within the skull.

Macroglia are the most abundant supportive cells; some are categorized as astrocytes (nonneuronal cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes). Astrocytes play a variety of metabolic support roles, including furnishing energy intermediates and providing for the supplementary removal of excessive extracellular neurotransmitter secretions (see Chapter 13). A second prominent category of macroglia is the myelin-producing cells, the oligodendroglia. Myelin, made up of multiple layers of their compacted membranes, insulates segments of long axons bioelectrically and accelerates action potential conduction velocity. Microglia are relatively uncharacterized supportive cells believed to be of mesodermal origin and related to the macrophage/monocyte lineage. Some microglia reside quiescently within the brain. During periods of intracerebral inflammation (e.g., infection, certain degenerative diseases, or traumatic injury), circulating macrophages and other white blood cells are recruited into the brain by endothelial signals to remove necrotic tissue or to defend against the microbial infection.

## The Blood–Brain Barrier Protects Against Inappropriate Signals

The blood–brain barrier is an important permeability barrier to selected molecules between the bloodstream and the CNS. Evidence of a barrier is provided

by the greatly diminished rate of access of most lipophobic chemicals between plasma and brain; specific energy-dependent transporter systems permit selected access. Diffusional barriers retard the movement of substances from brain to blood as well as from blood to brain. The brain clears metabolites of transmitters into the cerebrospinal fluid by excretion through the acid transport system of the choroid plexus. The blood–brain barrier is much less prominent in the hypothalamus and in several small, specialized organs (termed *circumventricular organs*; see Chapters 34 and 39) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. The peripheral nervous system (e.g., sensory and autonomic nerves and ganglia) has no such diffusional barrier.

## The Central Nervous System Can Initiate Limited Responses to Damage

Because neurons of the CNS are terminally differentiated cells, they cannot undergo proliferative responses to damage, as can cells of skin, muscle, bone, and blood vessels. Nevertheless, previously unrecognized neural stem cells can undergo regulated proliferation and provide a natural means for selected neuronal replacement in some regions of the nervous system. As a result, neurons have evolved other adaptive mechanisms to provide for the maintenance of function following injury. These adaptive mechanisms range from activity dependent regulation of gene expression, to modification of synaptic structure, function, and can include actual localized axonal sprouting and new synapse creation. These adaptive mechanisms endow the brain with considerable capacity for structural and functional modification well into adulthood. This plasticity is not only considered to be activity dependent, but also to be reversible with disuse. Plasticity is pronounced within the sensory systems (see Chapter 23), and is quite prominent in the motor systems as well. The molecular mechanisms employed in memory and learning may rely upon very similar processes as those involved in structural and functional plasticity.

## ORGANIZATION OF THIS TEXT

With these overview principles in place, which are detailed more extensively in Section II, we can resume our preview of this book. Another major domain of our field is nervous system development (Section III).

How does a simple epithelium differentiate into specialized collections of cells and ultimately into distinct brain structures? How do neurons grow processes that find appropriate targets some distance away? How do nascent neuronal activity and embryonic experience shape activity?

Sensory systems and motor systems (Sections IV and V) encompass how the nervous system receives information from the external world and how movements and actions are produced (e.g., eye movements and limb movements). These questions range from the molecular level (how are odorants, photons, and sounds transduced into informative patterns of neural activity?) to the systems and behavioral level (which brain structures control eye movements and what are the computations required by each structure?).

An evolutionarily old function of the nervous system is to regulate respiration, heart rate, sleep and waking cycles, food and water intake, and hormones to maintain internal homeostasis and to permit daily and longer reproductive cycles. In this area of regulatory systems (Section VI), we explore how organisms remain in balance with their environment, ensuring that they obtain the energy resources needed to survive and reproduce. At the level of cells and molecules, the study of regulatory systems concerns the receptors and signaling pathways by which particular hormones or neurotransmitters prepare the organism to sleep, to cope with acute stress, or to seek food or reproduce. At the level of brain systems, we ask such questions as what occurs in brain circuitry to produce thirst or to create a self-destructive problem such as drug abuse?

In recent years, the disciplines of psychology and biology have increasingly found common ground, and this convergence of psychology and biology defines the modern topics of behavioral and cognitive neuroscience (Section VII). These topics concern the so-called higher mental functions: perception, attention, language, memory, thinking, and the ability to navigate in space. Work on these problems traditionally has drawn on the techniques of neuroanatomy, neurophysiology, neuropharmacology, and behavioral analysis. More recently, behavioral and cognitive neuroscience has benefited from several new approaches: the use of computers to perform detailed formal analyses of how brain systems operate and how cognition is organized; noninvasive neuroimaging techniques, such as positron emission tomography and functional magnetic resonance imaging, to obtain pictures of the living human brain in action; and molecular biological methods, such as single gene knockouts in mice, which can relate genes to brain systems and to behavior.

## **THIS BOOK IS INTENDED FOR A BROAD RANGE OF SCHOLARS OF THE NEUROSCIENCES**

---

This textbook is for anyone interested in neuroscience. In preparing it we have focused primarily on graduate students just entering the field, understanding that some of you will have majored in biology, some in psychology, some in mathematics or engineering, and even some like me, in German literature. It is hoped that through the text, the explanatory boxes, and, in some cases, the supplementary readings, you will find the book to be both understandable and enlightening. In many cases, advanced undergraduate students will find this book useful as well.

Medical students may find that they need additional clinical correlations that are not provided here. However, it is hoped that most medical scholars at least will be able to use our textbook in conjunction with more clinically oriented material. Finally, to those who have completed their formal education, it is hoped that this text can provide you with some useful information and challenging perspectives, whether you are active neuroscientists wishing to learn about areas of the field other than your own or individuals who wish to enter neuroscience from a different area of inquiry. We invite all of you to join us in the adventure of studying the nervous system.

## **CLINICAL ISSUES IN THE NEUROSCIENCES**

---

Many fields of clinical medicine are directly concerned with the brain. The branches of medicine tied most closely to neuroscience are neurology (the study of the diseases of the brain), neurosurgery (the study of the surgical treatment of neurological disease), and psychiatry (the study of behavioral, emotional, and mental diseases). Other fields of medicine also make important contributions, including radiology (the use of radiation for such purposes as imaging the brain—initially with X rays and, more recently, with positron emitters and magnetic waves) and pathology (the study of pathological tissue). To make connections to the many facets of medicine that are relevant to neuroscience, this book includes discussion of a limited number of clinical conditions in the context of basic knowledge in neuroscience.

## THE SPIRIT OF EXPLORATION CONTINUES

Less than a decade into the twenty-first century, the Hubble space telescope continues to transmit information about the uncharted regions of the universe and clues to the origin of the cosmos. This same spirit of adventure also is being directed to the most complex structure that exists in the universe—the human brain. The complexity of the human brain is enormous, describable only in astronomical terms. For example, the number of neurons in the human brain (about  $10^{12}$  or 1000 billion) is approximately equal to the number of stars in our Milky Way galaxy. Whereas the possibility of understanding such a complex device is certainly daunting, it is nevertheless true that an enormous amount has already been learned. The promise and excitement of research on the nervous system have captured the attention of thousands of students and working scientists. What is at stake is not only the possibility of discovering how the brain works. It is estimated that diseases of the brain, including both neurological and psychiatric illnesses, affect as many as 50 million individuals annually in the United States alone, at an estimated societal cost of hundreds of billions of dollars in clinical care and lost productivity. The prevention, treatment, and cure of these diseases will ultimately be found through neuroscience research. Moreover, many of the issues currently challenging societies globally—instability within the family, illiteracy, poverty, and violence, as well as improved individualized programs of education—could be illuminated by a better understanding of the brain.

## THE GENOMIC INVENTORY IS A GIANT STEP FORWARD

Possibly the single largest event in the history of biomedical research was publicly proclaimed in June 2000 and was presented in published form in February 2001: the initial inventory of the human genome. By using advanced versions of the powerful methods of molecular biology, several large scientific teams have been able to take apart all of an individual's human DNA in very refined ways, amplify the amounts of the pieces, determine the order of the nucleic acid bases in each of the fragments, and then put those fragments back together again across the 23 pairs of human chromosomes.

Having determined the sequences of the nucleic acids, it was possible to train computers to read the

sequence information and spot the specific signals that identify the beginning and ending of sequences likely to encode proteins. Furthermore, the computer systems could then sort those proteins by similarity of sequences (motifs) within their amino acid building blocks. After sorting, the computers could next assign the genes and gene products to families of similar proteins whose functions had already been established. In this way, scientists were rapidly able to predict approximately how many proteins could be encoded by the genome (all of the genes an individual has). Whole genome data are now available for humans, for some non-human primates, for rats, and for mice.

Scientifically, this state of information has been termed a “draft” because it is based on a very dense, but not quite complete, sample of the whole genome. What has been determined still contains a very large number of interruptions and gaps. Some of the smaller genes, whose beginning and ending are most certain, could be thought of as parts in a reassembled Greek urn, held in place by bits of blank clay until further excavation is done. However, having even this draft has provided some important realities.

Similar routines allowed these genomic scholars to determine how many of those mammalian genes were like genes we have already recognized in the smaller genomes of other organisms mapped out previously (yeast, worm (*Caenorhabditis elegans*), and fruitfly (*Drosophila melanogaster*)) and how many other gene forms may not have been encountered previously. Based on current estimates, it would appear that despite the very large number of nucleotides in the human and other mammalian genomes, about 30 times the length of the worms and more like 15 times the fruitfly, mammals may have only twice as many genes—perhaps some 30,000 to 40,000 altogether. Compared to other completed genomes, the human genome has greatly increased its representation of genes related to nervous system function, tissue-specific developmental mechanisms, and immune function and blood coagulation. Importantly for diseases of the nervous system that are characterized by the premature death of neurons, there appears to have been a major expansion in the numbers of genes related to initiating the process of intentional cell death, or *apoptosis*. Although still controversial, genes regulating primate brain size have been reported, but links to intellectual capacity remain unproven.

Two major future vistas can be imagined. To create organisms as complex as humans from relatively so few genes probably means that the richness of the required proteins is based on their modifications, either during transcription of the gene or after translation of the intermediate messenger RNA into the

protein. These essential aspects of certain proteins account for a small number of brain diseases that can be linked to mutations in a single gene, such as Huntington's Disease (see Chapter 31). Second, though compiling this draft inventory represents a stunning technical achievement, there remains the enormously daunting task of determining, for example, where in the brain's circuits specific genes normally are expressed, and how that expression pattern may be altered by the demands of illness or an unfriendly environment. That task, at present, is one for which there are as yet no tools equivalently as powerful as those used to acquire the flood of sequence data with which we are now faced. This stage has been referred to as the end of "naïve reductionism."

In the fall of 2005, a six-nation consortium of molecular biologists announced the next phase of genomic research. The new focus will be toward refining the initial inventories to compare whole genomes of healthy and affected individuals for a variety of complex genetic illnesses (the HapMap project). Complex genetic diseases, such as diabetes mellitus, hypertension, asthma, depression, schizophrenia, and alcoholism, arise through the interactions of multiple short gene mutations that can increase or decrease one's vulnerability to a specific disease depending on individual life experiences. Ultimately, as the speeds of genome sequencing improve still further and the cost is reduced, it may be possible to predict what diseases will be more likely to affect a given person, and predict the lifestyle changes that person could undertake to improve his or her opportunities to remain healthy.

In order to benefit from the enormously rich potential mother lode of genetic information, next we must determine where these genes are expressed, what functions they can control, and what sorts of controls other gene products can exert over them. In the nervous system, where cell-cell interaction is the main operating system in relating molecular events to functional behavioral events, discovering the still-murky properties of activity-dependent gene expression will require enormous investment.

### NEUROSCIENCE TODAY: A COMMUNAL ENDEAVOR

As scientists, we draw from the work of those who came before us, using other scientists' work as a foundation for our own. We build on and extend previous observations and, it is hoped, contribute something to those who will come after us. The information pre-

sented in this book is the culmination of hundreds of years of research. To help acquaint you with some of this work, we have described many of the key experiments of neuroscience throughout the book. We also have listed some of the classic papers of neuroscience and related fields at the end of each chapter, and invite you to read some of them for yourselves.

The pursuit of science has not always been a communal endeavor. Initially, research was conducted in relative isolation. The scientific "community" that existed at the time consisted of intellectuals who shared the same general interests, terminology, and paradigms. For the most part, scientists were reluctant to collaborate or share their ideas broadly, because an adequate system for establishing priority for discoveries did not exist. However, with the emergence of scientific journals in 1665, scientists began disseminating their results and ideas more broadly because the publication record could be used as proof of priority. Science then began to progress much more rapidly, as each layer of new information provided a higher foundation on which new studies could be built.

Gradually, an interactive community of scientists evolved, providing many of the benefits that contemporary scientists enjoy: Working as part of a community allows for greater specialization and efficiency of effort. This not only allows scientists to study a topic in greater depth but also enables teams of researchers to attack problems from multidisciplinary perspectives. The rapid feedback and support provided by the community help scientists refine their ideas and maintain their motivation. It is this interdependence across space and time that gives science much of its power.

With interdependence, however, comes vulnerability. In science, as in most communities, codes of acceptable conduct have evolved in an attempt to protect the rights of individuals while maximizing the benefits they receive. Some of these guidelines are concerned with the manner in which research is conducted, and other guidelines refer to the conduct of scientists and their interactions within the scientific community. Let us begin by examining how new knowledge is created.

### THE CREATION OF KNOWLEDGE

Over the years, a generally accepted procedure for conducting research has evolved. This process involves examining the existing literature, identifying an important question, and formulating a research plan. Often, new experimental pathways are launched when one

scientist reads with skepticism the observations and interpretations of another and decides to test their validity. Sometimes, especially at the beginning of a new series of experiments, the research plan is purely “descriptive,” for example, determining the structure of a protein or the distribution of a neurotransmitter in brain. Descriptive initial research is essential to the subsequent inductive phase of experimentation, the movement from observations to theory, seasoned with wisdom and curiosity. Descriptive experiments are valuable both because of the questions that they attempt to answer and because of the questions that their results allow us to ask. Information obtained from descriptive experiments provides a base of knowledge on which a scientist may draw to develop hypotheses about cause and effect in the phenomenon under investigation. For example, once we identify the distribution of a particular transmitter within the brain or the course of a pathway of connections through descriptive work, we may then be able to develop a theory about what function that transmitter or pathway serves.

Once a hypothesis has been developed, the researcher then has the task of designing and performing experiments that are likely to disprove that hypothesis if it is incorrect. This is referred to as the deductive phase of experimentation, the movement from theory to observation. Through this paradigm the neuroscientist seeks to narrow down the vast range of alternative explanations for a given phenomenon. Only after attempting to disprove the hypothesis as thoroughly as possible may scientists be adequately assured that their hypothesis is a plausible explanation for the phenomenon under investigation.

A key point in this argument is that data may only lend support to a hypothesis rather than provide absolute proof of its validity. In part, this is because the constraints of time, money, and technology allow a scientist to test a particular hypothesis only under a limited set of conditions. Variability and random chance may also contribute to the experimental results. Consequently, at the end of an experiment, scientists generally report only that there is a statistical probability that the effect measured was due to intervention rather than to chance or variability.

Given that one can never prove a hypothesis, how do “facts” arise? At the conclusion of their experiments, the researchers’ first task is to report their findings to the scientific community. The dissemination of research findings often begins with an informal presentation at a laboratory or departmental meeting, eventually followed by presentation at a scientific meeting that permits the rapid exchange of information more broadly. One or more research articles pub-

lished in peer-reviewed journals ultimately follow the verbal communications. Such publications are not simply a means to allow the authors to advance as professionals (although they are important in that respect as well). Publication is an essential component of the advancement of science. As we have already stated, science depends on sharing information, replicating and thereby validating experiments, and then moving forward to solve the next problem. Indeed, a scientific experiment, no matter how spectacular the results, is not completed until the results are published. More likely, publication of “spectacular” results will provoke a skeptical scientist into doing an even more telling experiment, and knowledge will evolve.

## RESPONSIBLE CONDUCT

Although individuals or small groups may perform experiments, new knowledge is ultimately the product of the larger community. Inherent in such a system is the need to be able to trust the work of other scientists—to trust their integrity in conducting and reporting research. Thus, it is not surprising that much emphasis is placed on the responsible conduct of research.

Research ethics encompasses a broad spectrum of behaviors. Where one draws the line between sloppy science and unethical conduct is a source of much debate within the scientific community. Some acts are considered to be so egregious that despite personal differences in defining what constitutes ethical behavior, the community generally recognizes certain research practices as behaviors that are unethical. These unambiguously improper activities consist of *fabrication*, *falsification*, and *plagiarism*: Fabrication refers to making up data, falsification is defined as altering data, and plagiarism consists of using another person’s ideas, words, or data without attribution. Each of these acts significantly harms the scientific community.

Fabrication and falsification in a research paper taint the published literature by undermining its integrity. Not only is the information contained in such papers misleading in itself, but other scientists may unwittingly use that information as the foundation for new research. If, when reported, these subsequent studies cite the previous, fraudulent publication, the literature is further corrupted. Thus, through a domino-like effect one paper may have a broad negative impact on the scientific literature. Moreover, when fraud is discovered, a retraction of the paper

provides only a limited solution, as there is no guarantee that individuals who read the original article will see the retraction. Given the impact that just one fraudulent paper may have, it is not surprising that the integrity of published literature is a primary ethical concern for scientists.

Plagiarism is also a major ethical infraction. Scientific publications provide a mechanism for establishing priority for a discovery. As such, they form the currency by which scientists earn academic positions, gain research grants to support their research, attract students, and receive promotions. Plagiarism denies the original author of credit for his or her work. This hurts everyone: The creative scientist is robbed of credit, the scientific community is hurt by the disincentive to share ideas and research results, and the individual who has plagiarized—like the person who has fabricated or falsified data—may well find his or her career ruined.

In addition to the serious improprieties just described, which are in fact extremely rare, a variety of much more frequently committed “misdemeanors” in the conduct of research can also affect the scientific community. Like fabrication, falsification, and plagiarism, some of these actions are considered to be unethical because they violate a fundamental value, such as honesty. For example, most active scientists believe that honorary authorship—listing as an author someone who did not make an intellectual contribution to the work—is unethical because it misrepresents the origin of the research. In contrast, other unethical behaviors violate standards that the scientific community has adopted. For example, although it is generally understood that material submitted to a peer-reviewed journal as part of a research manuscript has never been published previously and is not under consideration by another journal, instances of retraction for dual publications can be found on occasion.

### Scientific Misconduct Has Been Formally Defined by U.S. Governmental Agencies

The serious misdeeds of fabrication, falsification, and plagiarism generally are recognized throughout the scientific community. These were broadly recognized by federal regulations in 1999 as a uniform standard of scientific misconduct by all agencies funding research. What constitutes a misdemeanor is less clear, however, because variations in the definitions of accepted practices are common. There are several sources of this variation. Because responsible conduct is based in part on conventions adopted by a field, it follows that there are differences among disci-

plines with regard to what is considered to be appropriate behavior. For example, students in neuroscience usually coauthor papers with their advisor, who typically works closely with them on their research. In contrast, students in the humanities often publish papers on their own even if their advisor has made a substantial intellectual contribution to the work reported. Within a discipline, the definition of acceptable practices may also vary from country to country. Because of animal use regulations, neuroscientists in the United Kingdom do relatively little experimental work with animals on the important topic of stress, whereas in the United States this topic is seen as an appropriate area of study so long as guidelines are followed to ensure that discomfort to the animals is minimized.

The definition of responsible conduct may change over time. For example, some protocols that were once performed on human and animal subjects may no longer be considered ethical. Indeed, ethics evolve alongside knowledge. We may not currently be able to know all of the risks involved in a procedure, but as new risks are identified (or previously identified risks refuted), we must be willing to reconsider the facts and adjust our policies as necessary. In sum, what is considered to be ethical behavior may not always be obvious, and therefore we must actively examine what is expected of us as scientists.

Having determined what is acceptable practice, we then must be vigilant. Each day neuroscientists are faced with a number of decisions having ethical implications, most of them at the level of misdemeanors: Should a data point be excluded because the apparatus might have malfunctioned? Have all the appropriate references been cited and are all the authors appropriate? Might the graphic representation of data mislead the viewer? Are research funds being used efficiently? Although individually these decisions may not significantly affect the practice of science, cumulatively they can exert a great effect.

In addition to being concerned about the integrity of the published literature, we must be concerned with our public image. Despite concerns over the level of federal funding for research, neuroscientists are among the privileged few who have much of their work funded by taxpayer dollars. Highly publicized scandals damage the public image of our profession and hurt all of us who are dependent on continued public support for our work. They also reduce the public credibility of science and thereby lessen the impact that we can expect our findings to have. Thus, for our own good and that of our colleagues, the scientific community, and the public at large, we must strive to act with integrity.

## SUMMARY

You are about to embark on a tour of fundamental neuroscience. Enjoy the descriptions of the current state of knowledge, read the summaries of some of the classic experiments on which that information is based, and consult the references that the authors have drawn on to prepare their chapters. Think also about the ethical dimensions of the science you are studying—your success as a professional and the future of our field depend on it.

## Basic Plan of the Nervous System

### INTRODUCTION

The brain often is compared with a computer these days. True, the brain is a computer, but it is a very special kind of computer—a biological computer that has evolved by natural selection over hundreds of millions of years and countless generations. Furthermore, it has no obvious design features in common with human-engineered computers. Instead, the brain is a unique organ that thinks and feels, generates behavioral interactions with the environment, keeps bodily physiology relatively stable, and enables reproduction of the species—its most important role from evolution's grand perspective. And for strictly personal reasons the brain is the most precious thing we have simply because it is the organ of consciousness, as reflected in René Descartes's famous seventeenth century aphorism, "I think therefore I am."

Aristotle first emphasized that structure and function are inextricably intertwined, two sides of the same coin, with structure providing obvious physical constraints on function. Just think about the difference between a hammer and a saw. Unfortunately, as knowledge becomes more and more specialized, there is a tendency to analyze the structure, function, and chemistry of the nervous system from different, sometimes even isolated, perspectives. The main theme of this chapter is the basic structure-function organization of the nervous system: what are the parts and how are they interconnected into functional systems? In other words, what are the organizing principles—the basic design features—of its circuitry?

Evolution and development are two approaches often used to understand biological complexity—

because they start with the simplest condition—and the human brain is far and away the most complex object we know of, with its roughly 100 billion neurons and 100 trillion axonal connections between them. One remarkable conclusion emerging from these two perspectives is that nerve cells in all animals—from jellyfish to humans—are basically the same in terms of cell biology; what changes most during ontogeny and phylogeny is the *arrangement* of nerve cells into functional circuits: the architecture of the nervous system. The "bricks" or "legos" are similar, but the "buildings" constructed with them can vary tremendously in size and functionality. An ultimate goal of neuroscience may be to understand the human brain, but remarkable progress can nevertheless be made through analyzing "lower" animals and early embryos. The other equally remarkable conclusion is that all vertebrates, from fish to humans, share a common basic plan of the nervous system, with the same major parts and functional systems.

### EVOLUTION HIGHLIGHTS: GENERAL ORGANIZING PRINCIPLES

Protists and the simplest multicellular animals (sponges) display ingestive, defensive, reproductive, and other behaviors without any nervous system whatsoever, raising the question: what is the adaptive value of adding a nervous system to an organism? We will now examine key structure-function correlates of nervous system organization in animals with relatively simple body plans and behaviors.

## The Nerve Net Is the Simplest Type of Nervous System

In his provocative 1919 book, *The Elementary Nervous System*, George Parker outlined a reasonable scenario for how nervous systems evolved. An updated version begins with the first multicellular animals—similar to modern-day sponges—that emerged over half a billion years ago. They are seemingly amorphous animals that spend their adult lives immobile, submerged in water. Their relatively simple behavior is mediated largely by a set of primitive smooth muscle cell (myocyte) sphincters allowing water flow through

body wall pores. These specialized cells are called *independent effectors* because their contraction is evoked by stimuli like stretch or environmental chemicals acting directly on the plasma membrane of individual cells.

The first animal phylum with a nervous system was the Cnidaria, which includes jellyfish, corals, anemones, and the elegantly simple hydra. In contrast to sponges, hydra locomote and show active feeding behavior (Fig. 2.1). These behaviors are coordinated and mediated by a nervous system, a network of specialized units or cells called nerve cells or *neurons* (Box 2.1).

**FIGURE 2.1** Locomotor behavior in hydra resembles a series of somersaults, as shown in the sequence beginning on the left. The tiny black dot in the region between the tentacles in the figure at the far right is the animal's mouth. Ingestive (feeding) behavior involves guiding food particles into the mouth with coordinated tentacle movements.

### BOX 2.1

## THE NEURON DOCTRINE

The cell theory, which states that all organisms are composed of individual cells, was developed around the middle of the nineteenth century by Matthias Schleiden and Theodor Schwann. However, this unitary vision of the cellular nature of life was not immediately applied to the nervous system, as most biologists at the time believed in the cytoplasmic continuity of nervous system cells. Later in the century the most prominent advocate of this **reticularist** view was Camillo Golgi, who proposed that axons entering the spinal cord actually fuse with other axons (Fig. 2.2A). The reticularist view was challenged most thoroughly by Santiago Ramón y Cajal, a founder of contemporary neuroscience and without doubt the greatest observer of neuronal architecture. In beautifully written and carefully reasoned deductive arguments, Cajal presented us with what is now known as the **neuron doctrine**. This great concept in essence states that the cell theory applies to the nervous system: each neuron is an individual entity, the basic unit of neural circuitry (Fig. 2.2B). The acrimonious debate between reticularists and

proponents of the neuron doctrine raged for decades. Over the years, the validity of the neuron doctrine has been supported by a wealth of accumulated data. Nevertheless, the reticularist view is not entirely incorrect, because some neurons do act syncytially via specialized intercellular gap junctions, a feature that is more prominent during embryogenesis.

In 1897, Charles Sherrington postulated that neurons establish functional contact with each other and with other cell types via a theoretical structure he called the synapse (Greek *synaptein*, to fasten together). It was not until 50 years later that the structural existence of synapses was demonstrated by electron microscopy (see Fig. 3.3). The synaptic complex is built around an *adhesive junction*, and in this and other respects the complex is quite similar to the desmosome and the adherens junctions of epithelia. In fact, similarities in ultrastructure between the adherens junction and the synaptic complex of central nervous tissue were noted even in early electron microscopic studies (see Peters *et al.*, 1991).

### Sensory Neurons

Hydra's body wall is simple, with an outer *ectoderm* layer contacting the external environment, an inner *endoderm* layer facing the body cavity's internal environment and promoting digestion and waste elimination, and a vague middle or *meso* layer in between. Neurons probably differentiated initially from the

ectoderm, and perhaps the first to evolve were *sensory neurons*. One cytoplasmic extension of these bipolar cells facing the external environment became specialized to detect stimuli much weaker than those activating independent effectors, whereas the other pole became specialized to transmit information about these stimuli to a *group* of independent effectors (Fig. 2.3). Experimental evidence indicates that sensory neurons provide four major selective advantages in evolution:

- Increased stimulus sensitivity
- Faster effector cell responses
- Stronger behavioral responses because multiple effector cells are influenced
- Sensory neurons responding to different stimulus modalities can be distributed strategically in different body regions

The bipolar shape of sensory neurons is fundamentally important. The prototypical theory about neural circuit organization was presented by Santiago Ramón y Cajal in his classic "bible" of structural neuroscience, *The Histology of the Nervous System in Man and Vertebrates* (1909–1911). According to the cornerstone *functional polarity theory*, information normally flows in one direction through most neurons, and thus through most neural circuits—from *dendrites* and *cell body*, the input or receptive parts of the neuron, to a single *axon*, the output or effector part. In other words, most neurons have two classes of processes: one or more dendrites detecting inputs, and a single axon conducting an output that can influence multiple cells through branching or *collateralization*. At least in early developmental stages, all sensory neurons have this fundamental bipolar shape, and over the course of evolution they have become specialized to detect a remarkable

**FIGURE 2.2** Two competing views: The nervous system as a reticulum or the neuron doctrine. (A) Proponents of the reticular theory believed that neurons are physically continuous with one another, forming an uninterrupted network. (B) In contrast, the neuron doctrine regards each neuron an individual entity communicating with target cells by way of contiguity rather than continuity, across an appropriate intercellular gap. Adapted from Cajal (1909–1911).

**FIGURE 2.3** Activation of effector cells (e) in simple animals. (A) Sponges lack a nervous system; stimuli act directly on effector cells, which are thus called independent effectors. (B) In cnidarians, bipolar sensory neurons (s) differentiate in the ectoderm. The sensory neuron outer process detects stimuli and is thus a dendrite. The inner process of some sensory neurons transmits information directly to effector cells and is thus an axon. Because this type of sensory neuron innervates effector cells directly, it is actually a sensorimotor neuron. (C) Most cnidarian sensory neurons send their axon to motoneurons (m), which in turn send an axon to effector cells. Cnidarian motoneurons may also have lateral processes with other motoneurons, and these processes typically conduct information in either direction (and are thus amacrine processes). Arrows show the direction of information flow.

variety of stimuli from light, temperature, and a wide range of chemicals and ions, to vibration and other mechanical deformations.

### Motor Neurons

A second stage of differentiation or complexity in hydra's nervous system was the addition of neurons between sensory and effector. They are defined as motor neurons (*motoneurons*) because they directly innervate effector cells (usually muscle or gland cells), which in turn receive their inputs from sensory neurons (Figs. 2.2B, 2.3C). Conceptually, this provides a *two-layered nervous system*: the first or top layer having sensory neurons and the second or bottom layer having motor neurons. In this prototypical network sensory neurons project (send axon collaterals) to multiple motoneurons, and then each motoneuron innervates a set of effector cells (with a motoneuron and its effector cell set defined as a *motor unit*). During an animal's normal behavior, information flow is unidirectional or polarized from one cell type, sensory neuron, to another cell type, motoneuron, to a third cell type, effector. This is the basic definition of a simple reflex, as defined by Charles Sherrington in his cornerstone of systems neuroscience, *The Integrative Action of the Nervous System* (1906).

In this hypothetical scenario (Fig. 2.3) an environmental stimulus detected by a sensory neuron's dendrite is transmitted by its axon to the dendrites of a motoneuron population. Then the axon of each motoneuron innervates an effector cell population. This is the functional polarity rule applied to a simple two-layer, sensory-motor network mediating reflex behavior.

Another general feature of the hydra two-layered nervous system has been observed: sensory neurons do not innervate each other, whereas motoneurons do interact directly. Here, motoneurons have two projection classes: one to effector cells and another to other motoneurons. Structurally and functionally, many of these hydra motoneurons also have two types of output processes. One is a typical axon innervating an effector cell population. However, the other is a process that contacts homologous processes from other motoneurons. Interestingly, many of these "horizontal" processes between motoneurons transmit information in either direction—either motoneuron can transmit information to the other via these processes. This is an exception to the functional polarity rule and is mediated by reciprocal rather than the more common unidirectional synapses. Cajal (1909–1911) described several examples of neurons that lack a clear axon (in retina, olfactory bulb, and intestine) and called them amacrine cells. As an extension of this it is useful to

divide neuronal processes into three types: dendritic (input), axonal (output), or amacrine (bidirectional).

Adding a second layer to the nervous system has obvious adaptive advantages related to increased capacity for response complexity and integration. Consider a stimulus to one specific part of the animal or even one sensory neuron. Its influence may radiate to distant parts of the animal because one sensory neuron innervates multiple motoneurons, those motoneurons innervate additional motoneurons, and each motoneuron innervates multiple effector cells—an example of what Cajal called avalanche conduction. There may be great *divergence* between stimulus and effector cells producing a response, with the actual divergence pattern shaped by the structure–function architecture of the nervous system: how the neurons and their interconnections are arranged in the body. It is easy to imagine how this arrangement in hydra might coordinate the tentacles to bring a food morsel detected by just one of them to the mouth, or how it might coordinate locomotion (Fig. 2.1).

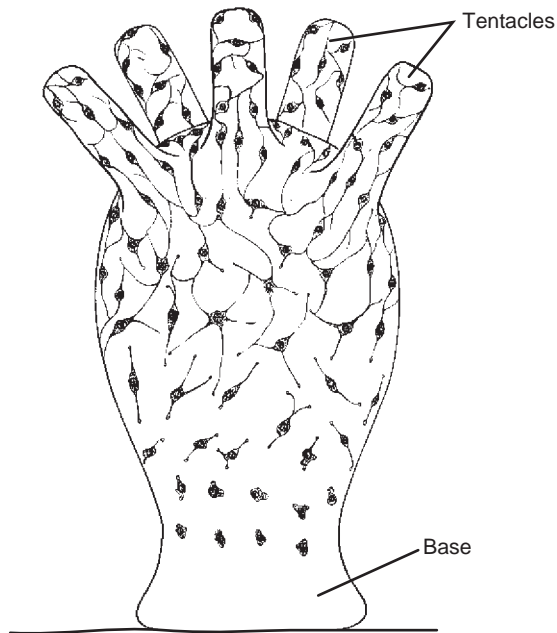

A second basic consequence of this structural arrangement is information *convergence* in the nervous system. Just consider a particular motoneuron: it can receive inputs from more than one sensory neuron and from other motoneurons as well.

### Nerve Nets

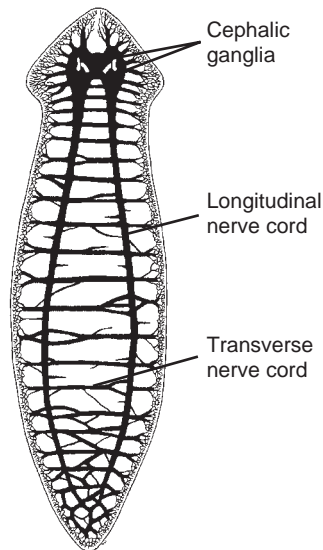

At first glance hydra's nervous system is distributed fairly uniformly around the radially symmetrical body wall and tentacles (Fig. 2.4). Its essentially double-layered arrangement of distributed sensory and motor neurons is called a *nerve net*. However, in certain regions of the body with specialized function, like around the mouth and base of the tentacles, neurons tend to aggregate—a tendency toward *centralization* that will now be examined more carefully.

## Bilateral Symmetry, Centralization, and Cephalization Emerge in Flatworms

In contrast to cnidarians, flatworms are bilaterally symmetrical predators with rostral (head) and caudal (tail) ends, and dorsal and ventral surfaces. These changes in body plan and behavior are accompanied by equally important changes in nervous system organization. Many flatworm neurons are clustered into distinct ganglia interconnected by longitudinal and transverse axon bundles called *nerve cords* (Fig. 2.5). This condensation of neural elements, or centralization, allows faster and thus more efficient communication between neurons because cellular material is conserved and conduction times are reduced. The largest, most complex ganglia (*cephalic ganglia*) are

**FIGURE 2.4** The nerve net of hydra, a simple cnidarian, is spread diffusely throughout the body wall of the animal. This drawing shows maturation of the nerve net in a hydra bud, starting near the base and finishing near the tentacles. Refer to McConnell (1932) and Koizumi (2002).

**FIGURE 2.5** The nervous system of the planarian, a flatworm, includes longitudinal and transverse nerve cords associated with centralization, and two fused cephalic ganglia in the rostral end associated with cephalization. Centralization and cephalization probably are related to the flatworm's bilateral symmetry and ability to swim forward rapidly. Refer to Lentz (1968). Reproduced with permission from Yale University Press.

localized rostrally where they receive information from specialized sensory receptors in the front of the animal as it swims. Bilateral symmetry, centralization, and cephalization are three cardinal organizational trends in nervous system evolution.

### Interneurons

Flatworms are the simplest animals with an abundant, clearly distinct third neuron division, *interneurons*, which are interpolated between sensory and motor neurons (Fig. 2.6). As already noted, Cajal recognized some atypical interneurons that apparently lack distinguishable dendrites and axon (amacrine neurons, or more precisely, amacrine interneurons). However, most interneurons have recognizable dendrites and axon and so presumably transmit information down the axon in only one direction, toward its terminals. They are *typical neurons* conforming to the functional polarity rule.

One consequence of adding a third "layer" of neurons to the nervous system is simply to increase convergence and divergence of information processing, and thus the capacity for response complexity. There are, however, three other critical functions interneurons subserv. They can act as *excitatory* or *inhibitory "switches"* in neuronal networks, assemblies of them can act as *pattern detectors* and *generators* between sensory and motor neurons, and they can be *pacemakers* if they generate intrinsic rhythmical activity patterns.

**FIGURE 2.6** Invertebrate ganglia (G) usually display two neuron classes: motor neurons (m) and interneurons (i), both typically unipolar, with dendrites arising from a single axon. Here neuronal cell bodies are arranged peripherally and synapses occur in a central region called the neuropil. Sensory neurons (s) usually innervate motoneurons and interneurons but not effectors (e). Arrows show the usual direction of information flow.

## BOX 2.2

## CAJAL: ICONOCLAST TO ICON

Santiago Ramón y Cajal (1852–1934) is considered by many people to be the founder of modern neuroscience—a peer of Darwin and Pasteur in nineteenth-century biology. He was born in the tiny Spanish village of Petilla de Aragon on May 1, 1852, and as related in his delightful autobiography, he was somewhat mischievous as a child and determined to become an artist, much to the consternation of his father, a respected local physician. However, he eventually entered the University of Zaragoza and received a medical degree in 1873. As a professor of anatomy at Zaragoza his interests were mostly in bacteriology (the nineteenth-century equivalent of molecular biology today in terms of an exciting biological frontier) until 1887, when he visited Madrid at age 35 and first saw through the microscope histological sections of brain tissue treated with the Golgi method, which had been introduced in 1873. Although very few workers had used this technique, Cajal saw immediately that it offered great hope in solving the most vexing problem of nineteenth-century neuroscience: how do nerve cells interact with each other? This realization galvanized and directed the rest of his scientific life, which was extremely productive in terms of originality, scope, and accuracy.

Shortly after Jacob Schleiden, Theodor Schwann, and Rudolf Virchow proposed the cell theory in the late 1830s, Joseph von Gerlach, Sr. and Otto Deiters suggested that nerve tissue was special in the sense that nerve cells are not independent units but instead form a continuous syncytium or reticular net (Fig. 2.2A). This concept was later refined by Camillo Golgi who, based on the use of his silver chromate method, concluded that axons of nerve cells form a continuous reticular net, whereas in contrast dendrites do not anastomose but instead serve a nutritive role, much like the roots of a tree. Using the same technique, Cajal almost immediately arrived at the opposite conclusion, based first on his examination of the cerebellum, and later of virtually all other parts of the nervous system. In short, he proposed that neurons interact by way of contact or contiguity rather than by continuity,

and are thus structurally independent units, which was finally proven when the electron microscope was used in the 1950s. This concept became known as the **neuron doctrine**.

Cajal's second major conceptual achievement was the theory of **functional polarity**, which stated that the dendrites and cell bodies of neurons receive information, whereas the single axon with its collaterals transmits information to the other cells. This rule allows prediction of information flow direction through neural circuits based on the morphology or shape of individual neurons forming them, and it was the cornerstone of Charles Sherrington's (1906) revolutionary physiological analysis of mammalian reflex organization. Recent evidence that many dendrites transmit an action potential or graded potential in the retrograde direction would not violate the tenants of the functional polarity theory unless the potential led to altered membrane potentials in the associated presynaptic axon—and if this were the case the “dendrite” would be classed instead as an amacrine process (see text).

Around the close of the nineteenth century, Cajal made a remarkable series of discoveries at the cellular level. In addition to the two concepts outlined earlier, they include (1) the mode of axon termination in the adult CNS (1888), (2) the dendritic spine (1888), (3) the first diagrams of reflex pathways based on the neuron doctrine and functional polarity (1890), (4) the axonal growth cone (1890), (5) the chemotactic theory of synapse specificity (1892), and (6) the hypothesis that learning could be based on the selective strengthening of synapses (1895).

In one of the great ironies in the history of neuroscience, Cajal and Golgi shared the Nobel Prize for Medicine in 1906 though they had used the same technique to elaborate fundamentally different views on nervous system organization! The meeting in Stockholm may not have diminished the great personal friction between them. In 1931 Cajal wrote: “What a cruel irony of fate to pair like Siamese twins united by the shoulders, scientific adversaries of such contrasting characters.”

By this definition the vast majority of vertebrate brain neurons are interneurons. So it is useful at the outset to recognize two broad interneuron categories: local and projection. *Local interneurons*, or *local circuit neurons*, have an axon that remains confined to a distinguishable gray matter region or ganglion, whereas

*projection interneurons* send a longer axon to a different gray matter region or ganglion, although it may also generate local axon collaterals.

The omnidirectional information flow typical of cnidarian nerve nets is unusual in the rest of the animal kingdom, where most neurons are functionally polar-

ized with information flowing through neural circuits sequentially from dendrites and cell body to axon and axon terminals. However, most invertebrate motoneurons and interneurons are unipolar: a single process, the axon, extends from the cell body. Dendrites branch from the axons in the center of a ganglion—entering the *neuropil*—where most synapses are formed (Fig. 2.6). In vertebrates most neurons are multipolar, with several dendrites, plus an axon extending from the cell body or a dendrite.

Features of simple nervous systems are preserved throughout evolution. For example, the part of nervous system in the wall of the human gastrointestinal tract (the enteric nervous system) has many features of a highly refined nerve net, and a “layer” of amacrine interneurons is found in the human retina and olfactory bulb.

### A Segmented Ventral Nerve Cord Typifies Annelids and Arthropods

Annelid worms and arthropods have even more complex body plans and behaviors than flatworms, partly because of *segmentation*. Body segments (*metameres*) are repeated serially along the body’s rostrocaudal axis, and presumably share a common underlying genetic developmental program, although terminal differentiation (adult structure) may vary. This strategy allows for more complex body plans (including the nervous system) to evolve without a linear or exponential increase in genetic material. Annelids and all the more complex invertebrates share another characteristic feature, a *ventral nerve cord* with a pair of ganglia (or a single fused ganglion) in each segment, and longitudinal axon bundles between ganglia in adjacent segments (Fig. 2.7). Transverse *nerves* also extend from each ganglion to sensory structures and muscles in the same segment.

### The Basic Plan of the Vertebrate Nervous System Is Found in Lancelets

Vertebrates are a subphylum of the Chordates and are the most complex of all animals in terms of structure and behavior. They share a basic body plan where common organ systems are arranged in a relatively strict anatomical relationship with one another (Box 2.3 and Figs. 2.8, 2.9). Like other chordates, vertebrates display two key features during some part of their life: a cartilaginous rod, the *notochord*, extending dorsally along the body, and above it a hollow *dorsal nerve cord*. In most vertebrates the notochord’s body stiffening and protective functions are supplanted by the verte-

**FIGURE 2.7** Nervous system organization in the rostral end of an annelid worm. A ventral nerve cord with more or less distinct ganglia connects with a fused pair of cerebral ganglia (brain) dorsal to the pharynx (part of the digestive tract). Note nerves extending from ventral nerve cord and cerebral ganglia. Refer to Brusca and Brusca (1990).

bral column and bony skull, with the notochord reduced to a series of cartilaginous cushions (discs) between or within the vertebrae. The vertebrate nerve cord is tremendously expanded, thickened, and folded to form the brain and spinal cord (the central nervous system, CNS).

The vertebrate nervous system’s basic parts are revealed in the lancelet (amphioxus), a simple, nonvertebrate chordate (subphylum Cephalochordata). The lancelet is a slender, fish-like filter-feeder living half buried in the sand of shallow, tropical marine waters (Fig. 2.9). The body is stiffened by a notochord, and a dorsal nerve cord runs the length of the body, generating segmental nerves innervating muscles and organs. Locomotor behavior (swimming) is produced by alternately contracting right and left segmental muscles (myotomes). Without a notochord these contractions would shorten the animal rather than generate forward propulsive force.

Although typical vertebrate brain regions are not obvious rostrally in the lancelet nerve cord, genes specifying early vertebrate head embryogenesis also are expressed rostrally in the lancelet body. Thus, some components of the molecular program specifying modern vertebrate head development apparently were present early in chordate evolution (Holland and Takahashi, 2005).

### Summary

The cnidarian nerve net displays most of the basic cellular features of nervous system organization, including convergence and divergence of sensory and

## BOX 2.3

## ANATOMICAL RELATIONSHIPS IN THE VERTEBRATE BODY

To describe the physical relationships between structures in the nervous system and the rest of the vertebrate body it is best to use terms that accurately and unambiguously describe the position of a given structure in three dimensions. The major axis of the body is the **rostrocaudal axis**, which extends along the length of the animal from the *rostrum* (beak) to the *cauda* (tail) (Fig. 2.8) as well as the length of the embryonic neural plate and neural tube (see Figs. 2.10 and 2.12). A second axis, the orthogonal **dorsoventral axis**, is vertical and runs from the *dorsum* (back) to the *ventrum* (belly). Finally, the third perpendicular axis, the **mediolateral axis**, is horizontal and runs from the midline (medial) to the lateral margin of the animal (lateral). Unfortunately, the rostrocaudal axis undergoes complex bending during embryogenesis, and the bending pattern is unique to each species. It would be ideal if the three cardinal axes were used in a topologically accurate way, say with reference to the body as it might appear with a “straightened out” rostrocaudal axis. In practice,

however, this is rarely the case, which leads to a certain degree of ambiguity, as is obvious when looking at the fish, frog, cat, and human bodies shown in Fig. 2.8.

The problem is especially difficult in human anatomy where use of an idiosyncratic terminology has a long, ingrained tradition. The basic principles are much easier to illustrate than to describe in writing (see Fig. 2.8), but one major source of confusion in the human brain is related to the fact that the rostrocaudal axis makes a 90 degree bend in the midbrain region (unlike in rodents and carnivores, for example, where the axis is relatively straight). The other source of confusion is simply the different names that are used. For example, in human anatomy the spinal cord has anterior and posterior horns, and posterior root ganglia, whereas in other mammals they usually are referred to as ventral and dorsal horns, and dorsal root ganglia. The merits of a uniformly applied nomenclature based on comparative structural principles seem obvious.

motor information. In more complex bilaterally symmetrical invertebrates, neurons and axons tend to aggregate in ganglia, nerve cords, and nerves (centralization), and there is a greater concentration of neurons and sensory organs in the body's rostral end (cephalization). Segmented invertebrates have a ventral nerve cord that includes a bilateral pair of ganglia (or single fused ganglion) in each segment. The primitive chordate, lancelet, displays the basic nervous system organization characteristic of vertebrates, including mammals and humans.

### DEVELOPMENT REVEALS BASIC VERTEBRATE PARTS

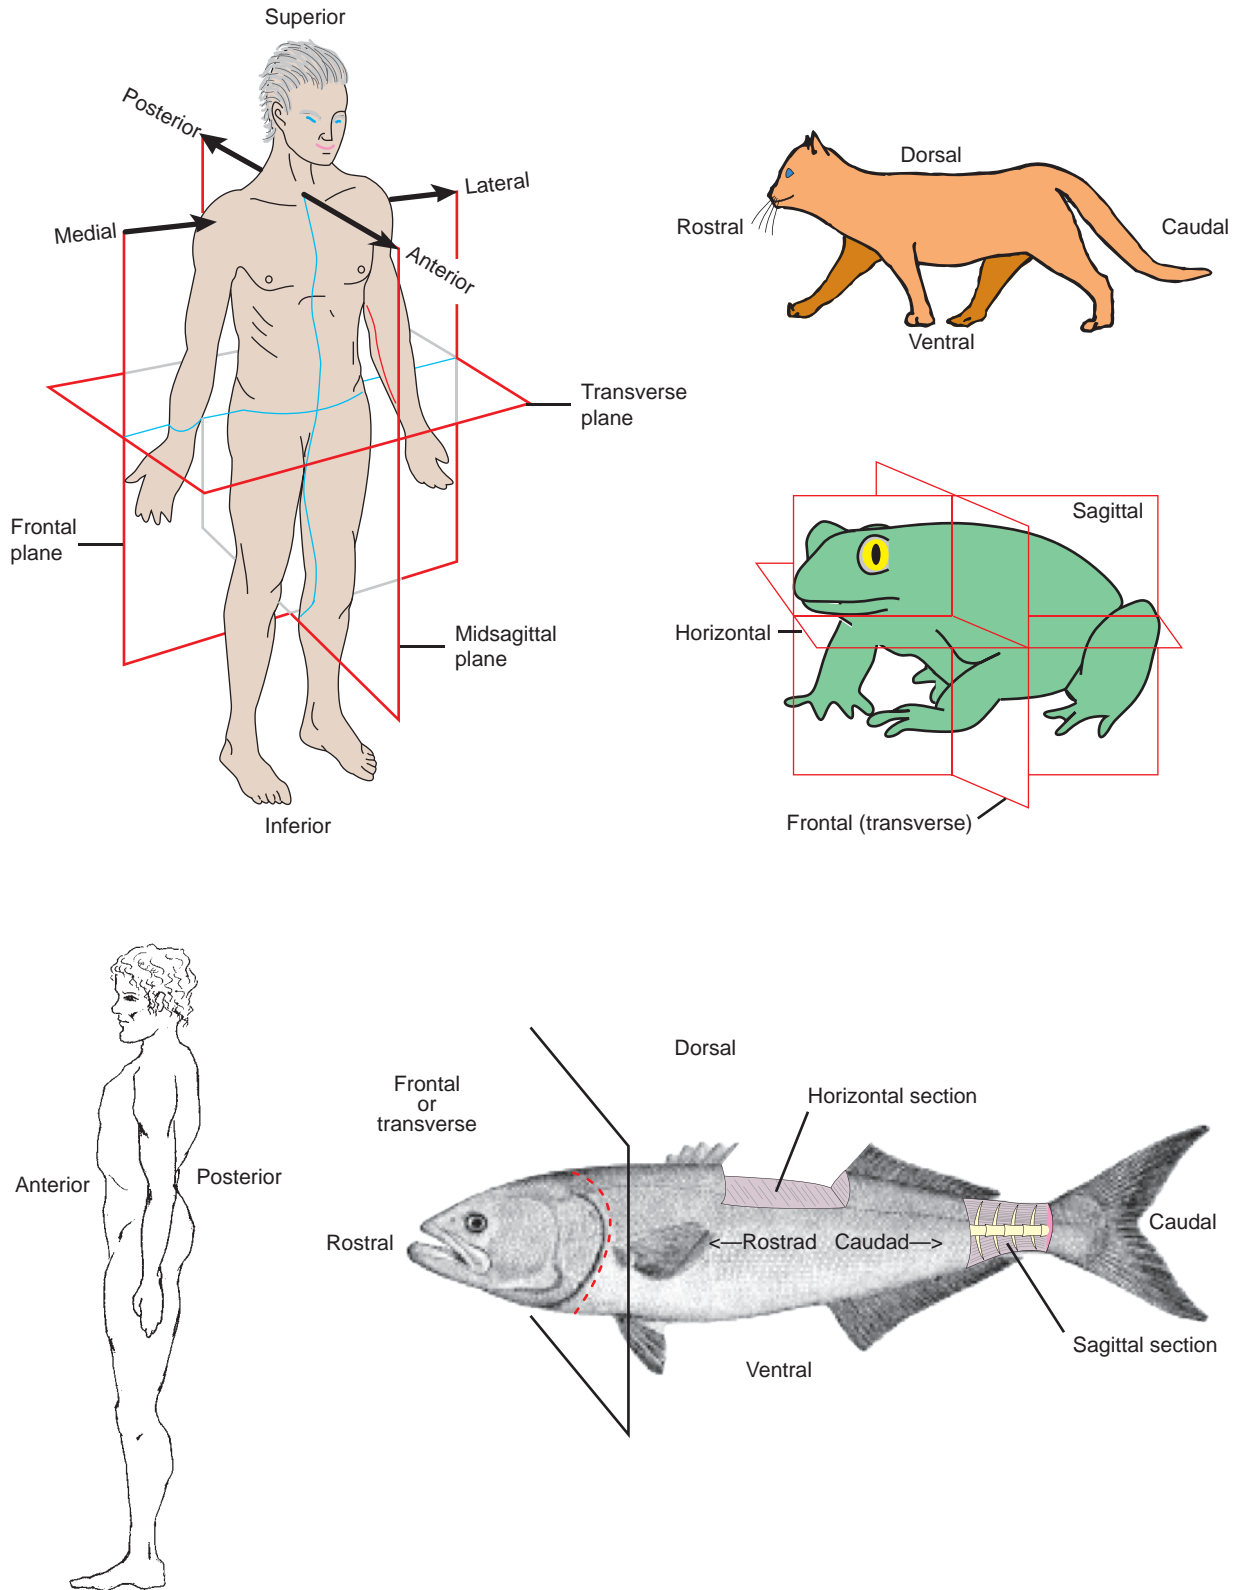

One nineteenth century biology triumph was the demonstration that early stages of embryogenesis are fundamentally the same in all vertebrates. The CNS and heart are the first organs to differentiate in the embryo, and the basic CNS divisions differentiating early in development are also common to all vertebrates. The names and arrangement of these divisions are the starting point for regional or topo-

graphic neuroanatomical nomenclature (Swanson, 2000a).

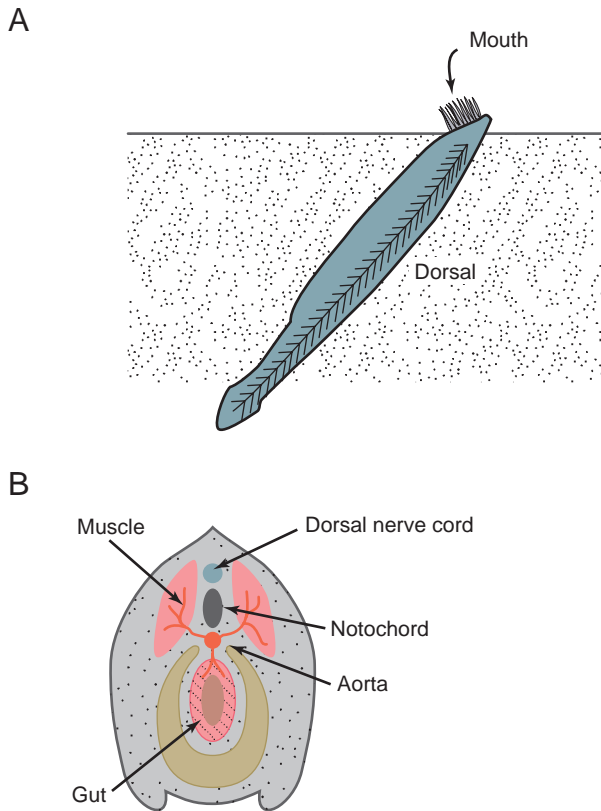

### Nervous System Regionalization Begins in the Neural Plate

During embryogenesis the CNS develops as a hollow cylinder (*neural tube*) from a topologically flat sheet of cells (*neural plate*), by a process of *neurulation* (Chapter 14). Here we simply consider macroscopic structural changes during the transformation.

The neural plate is a spoon-shaped differentiation of the trilaminar embryonic disc's one-cell-thick ectodermal layer (Fig. 2.10). Its wide end lies rostrally and becomes the brain, whereas the narrow end lies caudally and becomes the spinal cord—the two major CNS divisions. A midline *neural groove* divides the neural plate into right and left halves, so the plate displays three cardinal morphogenetic features: *polarity*, *bilateral symmetry*, and *regionalization*. Furthermore, the neural plate differentiates from rostral to caudal, so the brain plate regionalizes first. Signs of this include appearance of the *optic vesicles*, evaginating near the rostral end of the neural plate (in the presumptive hypothalamus); a midline *infundibulum* evaginating

**FIGURE 2.8** Orientation of the vertebrate body. Orientation planes for fish, quadrupeds, and bipeds are depicted. Associated with the three cardinal planes (rostrocaudal, dorsoventral, and mediolateral) are three orthogonal planes: horizontal, sagittal, and transverse (or frontal), which are the same in all early vertebrate embryos. For more explanation, see Williams (1995).

**FIGURE 2.9** The lancelet (amphioxus) is a forerunner of the vertebrates. (A) Lateral view of the animal in its native habitat under the ocean floor, with its mouth protruding above the sand. (B) A cross-section of the lancelet body showing relationships between gut, aorta, notochord, and dorsal nerve cord. Adapted from Cartmill *et al.* (1987).

between optic vesicles and rostral end of the notochord, and indicating the presumptive pituitary stalk (again in presumptive hypothalamus); and the *otic rhombomere* (presumptive rhombomere 4), a swelling near the center of what will become the hindbrain (Fig. 2.11, left).

At the junction between neural plate and remaining ectoderm (later forming the skin's epidermal layer) lies a narrow strip of transitional ectoderm, the *neural crest*, a distinctive vertebrate feature (Fig. 2.10). It generates a variety of adult structures, including most neurons of the peripheral nervous system (PNS).

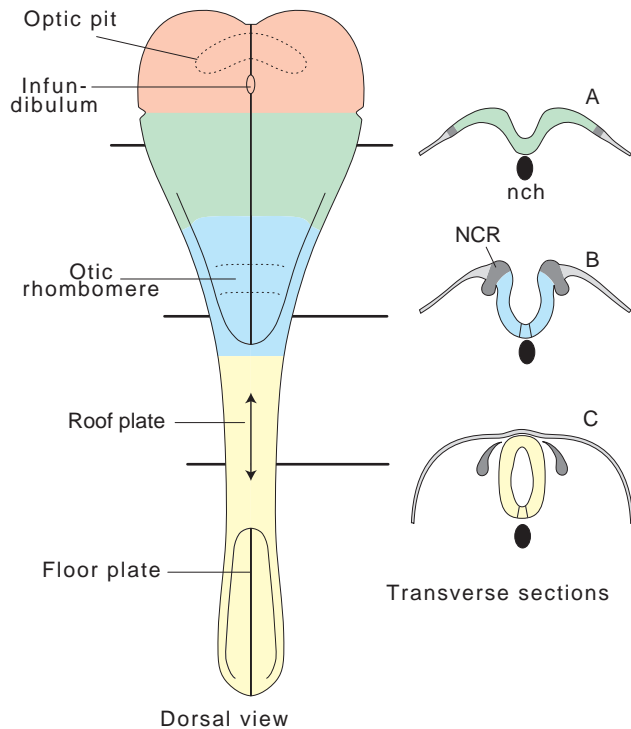

In summary, the CNS and PNS divisions are represented by the neural plate and neural crest, respectively, during the neural plate stage of vertebrate development. The two major CNS divisions, brain and spinal cord, are also indicated in the neural plate, which at this developmental stage is topologically simple: a bilaterally symmetrical, flat sheet that is one cell thick.

**FIGURE 2.10** The neural plate is a spoon-shaped region of ectoderm (neural ectoderm) forming the CNS; surrounding it is somatic ectoderm. The neural plate is polarized (wider rostrally than caudally), bilaterally symmetrical (divided by the midline neural groove), and regionalized (brain plate rostrally, spinal plate caudally). The neural crest is a zone between neural and somatic ectoderm, and a series of placodes develops as “islands” within the somatic ectoderm. The neural crest and placodes generate PNS neurons. The approximate location of future CNS divisions in the neural plate is shown in color on the left. The same color scheme is used in Figs. 2.11, 2.12, and 2.14. Refer to Swanson (1992).

### Further Regionalization Occurs in the Neural Tube

As neurulation progresses, the neural plate becomes U-shaped as the two halves (*neural folds*) become vertically oriented (Fig. 2.11, right). Then the dorsal tips of the folds fuse, forming an open tube—and finally the tube's ends (*neuropores*) also fuse, producing a completely closed neural tube with a one-cell-thick wall (*neuroepithelium*).

**FIGURE 2.11** Optic pits, infundibulum, and otic rhombomere (dorsal view on left) are the earliest clear structural differentiations of the neural plate, other than the neural groove. The neural tube forms by neuroectoderm invagination (transverse sections A and B), followed by fusion of the lateral edges of the neural plate (roughly in the neck region of humans), and proceeds both rostrally and caudally (double arrows in roof plate). Note how the neural crest (NCR) pinches off in the process. Also observe notochord (nch) position ventral to neural groove. Refer to Swanson (1992).

Marcello Malpighi, the great seventeenth century founder of histology who also discovered the capillary network between arteries and veins postulated by William Harvey in 1628, recognized that the early chick neural tube displays three rostrocaudally arranged swellings now called primary brain vesicles. They include the *forebrain* (prosencephalic) vesicle, with the optic stalks and infundibulum; the *midbrain* (mesencephalic) vesicle; and the *hindbrain* (rhombencephalic) vesicle, with the otic rhombomere (Fig. 2.12A).

These vesicles are the fundamental structural or regional brain divisions. Transitory rhombomeres are the most characteristic hindbrain vesicle feature at this stage, and they develop in association with the pharyngeal pouches (Chapter 14). As embryogenesis continues, the forebrain vesicle divides into *endbrain* (telencephalic) and *interbrain* (diencephalic) vesicles, whereas the hindbrain vesicle differentiates vaguely into rostral *pontine* (metencephalic) and caudal *medullary* (myelencephalic) regions (Fig. 2.12B). These divi-

sions transform the “three primary vesicle stage” into the “five secondary vesicle stage.”

The neural tube lumen becomes the adult CNS *ventricular system* (Fig. 2.12B, left), and its adult shape conforms to extensive differential regionalization of the neural tube wall. Each endbrain vesicle contains a *lateral ventricle*, which communicates through an *inter-ventricular foramen* with the *third ventricle* in the inter-brain vesicle’s center. The third ventricle continues into the midbrain’s *cerebral aqueduct*, which becomes the hindbrain’s *fourth ventricle* and then the spinal cord’s *central canal*. In older embryos and adults, the ventricular system contains *cerebrospinal fluid* (CSF), much of which is elaborated by specialized, highly vascular regions of *choroid plexus* in the roof of the lateral, third, and fourth ventricles.

### Migrating Neurons Form the Mantle Layer’s Gray Matter

In the early five secondary vesicle neural tube, cells divide repeatedly although the neural tube remains one cell thick, a *pseudostratified epithelium* of stem cells for neurons and glia. Shortly thereafter many of these cells begin a terminal differentiation into young neurons migrating from the luminal proliferation zone to form a new, more superficial *mantle layer* (Chapter 16). In some CNS regions mantle layer neurons segregate into layers parallel to the surface, whereas in others neurons cluster in nuclei, relatively uniform neuron populations (usually multiple types) that are structurally distinct from surrounding nuclear or layered regions.

Mantle layer formation leads to further CNS regionalization (Fig. 2.12B). In hindbrain and spinal cord, it emerges because motoneurons are generated earliest and ventrally (corresponding to medial neural plate regions). This correlates with observations that gross, relatively uncoordinated embryonic motor behavior starts before reflex pathways become functional—and implying that such behavior is generated endogenously in the CNS itself (Hamburger, 1975).

Ventral mantle layer formation accompanies the transient appearance of a longitudinal groove (*limiting sulcus*) on the neural tube’s inner surface. The leading nineteenth century Swiss embryologist Wilhelm His noted that the limiting sulcus divides much of the neural tube into dorsal or *alar plate* and ventral or *basal plate*, with predominantly sensory and motor functions, respectively (Fig. 2.13). This observation complemented the earlier fundamental discovery of François Magendie that spinal sensory and motor fibers are completely segregated in spinal roots: sensory axons enter through dorsal roots whereas motor axons leave

through ventral roots. It is now clear that alar and basal plates are not purely sensory or motor because each contains projection interneurons. Nevertheless, it is helpful to view the hindbrain and spinal cord as having three longitudinal zones: sensory, integrative (reticular formation), and motor. Regionalization of midbrain and forebrain does not fit this scheme neatly and is relatively poorly understood conceptually.

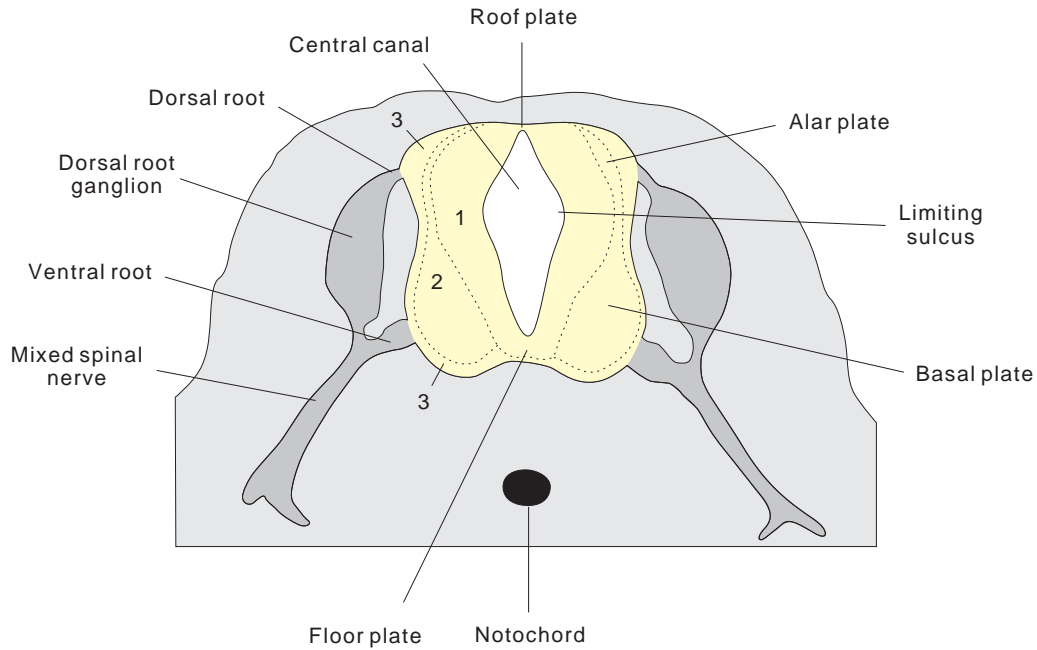

Dorsal regions of the hindbrain's alar plate form a unique structure, the *rhombic lip*. In the pons it generates cerebellar granule cells, whereas more caudally it produces neuron populations like the precerebellar and vestibulocochlear nuclei. Many rhombic lip neuron populations are interesting because they migrate parallel to the neural tube's surface to reach their final destinations, instead of radially like most CNS neurons (Chapter 16).

This differentiation continues until the adult CNS configuration is achieved (Figs. 2.14 and 2.15). The most obvious late-developing structures are the cerebral cortex and cerebellar cortex.

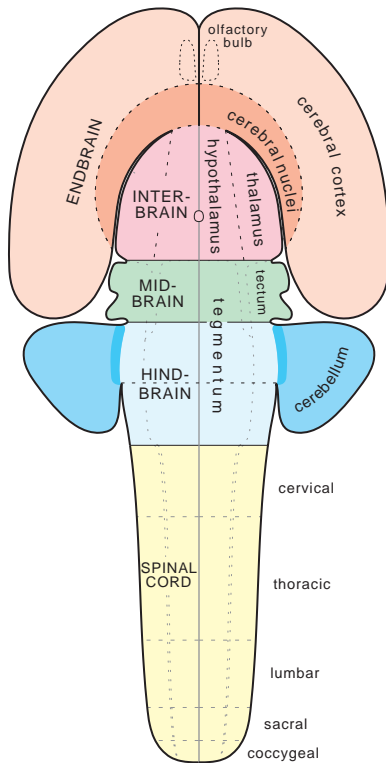

**Summary**

The vertebrate CNS develops from a sheet of cells called the neural plate that invaginates to form the neural tube. The tube's rostral end differentiates a series of vesicles that constitute the major brain regions, and the caudal end forms the simpler spinal cord. Most PNS neurons differentiate from the neural crest, with the rest arising from nearby somatic ectodermal placodes.

**FIGURE 2.12** Formation and regionalization of the neural tube. (A) The early neural tube brain region develops three swellings: forebrain, midbrain, and hindbrain vesicles. The hindbrain vesicle then differentiates a series of transverse swellings called rhombomeres. (B) As differentiation continues, the forebrain vesicle displays right and left endbrain (cerebral hemisphere) vesicles and a medial interbrain vesicle, and the hindbrain vesicle shows vague pontine and medullary regions. This is the five-vesicle stage of neural tube transverse regionalization. Then longitudinal, dorsoventral, regionalization begins. The endbrain vesicle divides into cerebral cortex (including olfactory bulb) and cerebral nuclei (basal ganglia), the interbrain vesicle divides into thalamus and hypothalamus, the midbrain vesicle divides into tectum and tegmentum, the hindbrain vesicle divides into rhombic lip, alar plate, and basal plate, and the spinal cord divides into alar and basal plates. Whether the pretegmental region (sometimes called synencephalon) is part of interbrain or midbrain is controversial. At this developmental stage major components of the adult ventricular system are seen in the neural tube lumen. Refer to Swanson (1992) and Alvarez-Bolado and Swanson (1996).

**FIGURE 2.13** The early spinal cord and hindbrain are divided into dorsal (alar) and ventral (basal) plates by the limiting sulcus. This morphology reflects earlier ventral differentiation of the mantle layer (2), accompanied by earlier ventral thinning of the neuroepithelial or ventricular layer (1) of the neural tube, which remains as the adult ependymal lining of the ventricular system. The mantle layer develops into adult gray matter. This schematic drawing of a transverse spinal cord histological section also shows dorsal (sensory) and ventral (motor) spinal cord roots, dorsal root ganglia containing sensory neurons derived from the neural crest, and mixed (sensory and motor) spinal nerves distal to the ganglia. The peripheral area (3) is called the marginal zone and develops into the spinal cord white matter or funiculi containing ascending and descending axonal fiber tracts.

**FIGURE 2.14** Major divisions of the adult mammalian CNS are derived from neural plate and neural tube regionalization illustrated in Figs. 2.10–2.12. Modified from Swanson (1992).

## THE BASIC PLAN OF NERVOUS SYSTEM CONNECTIVITY

### Functional Systems Consist of Interconnected Gray Matter Regions

The nervous system’s wiring diagram can be described in terms of the neuronal cell types in each of its distinct gray matter regions and their stereotyped pattern of axonal projections to cell types both locally (within the region) and in other gray matter regions or other tissues (like muscle or gland). A long-term goal of systems neuroscience is to provide a global wiring diagram for the nervous system that systematically accounts for its various functional subsystems—analogue to the circulatory system model provided by Harvey. Little work has been done on this synthetic problem, although interest is accelerating with the development of online neuroinformatics workbenches for connectional information (Bota and Swanson, 2007).

The high-level model of nervous system information processing shown in Figure 2.16 synthesizes basic neurobiological concepts pioneered by Cajal and Sherrington with basic cybernetic principles pioneered by

◀ **FIGURE 2.15** Mini atlases to compare major adult brain regions in humans and mice. The brains are cut approximately transversely to the CNS longitudinal axis and illustrate five major levels, arranged from rostral to caudal: a, endbrain; b, interbrain; c, midbrain; d, pons; and e, medulla. The color scheme follows that in Figs. 2.10–2.12 and 2.14, with the choroid plexus of the lateral, third, and fourth ventricles shown in red. Adapted from Nieuwenhuys *et al.* (1988) and Sidman *et al.* (1971).

Norbert Wiener (1948) and John von Neumann (1958). In essence, the model postulates that behavior is determined by CNS motor system output, and that this output is a function of three inputs: sensory system (reflexive), cognitive system (voluntary), and intrinsic behavioral state system. The relative importance of each input in controlling motor output (behavior) varies qualitatively in different species and quantitatively in different individuals. Note that behavior elicits sensory feedback from the external and internal environments that helps determine future motor activity and thus behavior. Each component is now considered further without trying to place all nervous system parts within the global model.

**Motor Systems Are Organized Hierarchically**

There are three different motor systems: skeletal, autonomic, and neuroendocrine. The first controls striated muscles responsible for voluntary behavior; the

**FIGURE 2.16** A model of the nervous system’s basic wiring diagram. The model of information flow through the nervous system (yellow box) postulates that behavior (B) is determined by the motor system (M), which is influenced by three classes of neural input: sensory (S), intrinsic behavioral state (I), and cognitive (C). Sensory inputs lead directly to reflex responses (r), cognitive inputs mediate voluntary responses (v), and intrinsic inputs act as control signals (c) to regulate behavioral state. Motor system inputs (1) produce behaviors whose consequences are monitored by sensory feedback (2). Sensory feedback may be used by the cognitive system for perception and by the intrinsic system to generate affect (e.g., positive and negative reinforcement/pleasure and pain). The cognitive, sensory, and intrinsic systems are all interconnected, hence the arrowheads at the ends of each dashed line within the nervous system box. Refer to Swanson (2003).

second controls smooth and cardiac muscle, and many glands; and the third controls pituitary gland hormone secretion. The skeletal motor system is understood best and thus serves as a prototype for examining basic organizing principles presumably similar for all three.

The skeletal motor system is arranged hierarchically (Fig. 2.17), the lowest level consisting of brainstem-spinal cord  $\alpha$ -motoneurons whose axons synapse directly on striated muscle fibers. The next higher level consists of motor pattern generators (MPGs), and the highest level has motor pattern initiators (MPIs) that “recognize” or alter their output in response to specific input patterns, and project to unique sets of MPGs. Ethologists refer to MPIs as “innate releasing mechanisms.” One reason central neural circuitry is so complex is that each of the three input types (sensory, intrinsic, cognitive) may go directly to each general level of the motor system hierarchy.

The MPGs and MPIs themselves are hierarchically arranged. This organization is particularly easy to see conceptually for the MPGs subserving locomotor behavior. In the spinal cord, simple MPGs coordinate

**FIGURE 2.17** Hierarchical organization of the skeletal motor system. At the simplest level (1), motoneuron pools (MN) innervate individual muscles generating individual components of behavior. At the next higher level (2), additional interconnected interneuron pools, called motor pattern generators (MPG), innervate specific motoneuron pool sets. At the highest level (3), additional interconnected interneuron pools, called motor pattern initiators (MPI), innervate specific MPG sets. MPIs can activate complex, stereotyped behaviors when activated (or inhibited) by specific patterns of sensory, intrinsic, and/or cognitive inputs. Note that MPGs and MPIs themselves may be organized hierarchically (dashed lines) and that sensory, intrinsic, and cognitive inputs may go directly to any level of the motor system hierarchy. Refer to Swanson (2003).

the reciprocal innervation of muscle pair antagonists across individual joints, more complex MPGs coordinate activity in the set of simpler MPGs for all the joints in a limb, and still more complex MPGs coordinate activity in MPGs for all four limbs. At the next higher level there is a brain hierarchy of MPGs for locomotion that is activated by specific input patterns and projects to the spinal locomotor pattern generator network.

### *Multiple Sensory Systems Function in Parallel*

A set of sensory systems provides information to the CNS from various receptor types, and all the systems can function simultaneously. Cajal noted that unimodal sensory pathways generally branch with some information going directly to the motor system and some going to the cerebral cortex for sensation and perception. The former typically evokes reflex behavior and the latter potentially reaches consciousness and plays an important role in cognition.

Several general features characterize the sensory system (Section IV covers subsystems in detail). First, the CNS receives a wide range of information about the external environment and about the body's internal state. Thus, sensory receptors lie near the body's surface (e.g., touch and olfactory receptors), deep within the body (e.g., aortic stretch receptors), and even within the brain itself (e.g., hypothalamic insulin receptors). Second, each of the three motor systems receives a broad range of sensory inputs. Third, the range of sensory modalities is remarkably similar (though not identical) across vertebrate classes, and information about specific modalities enters the CNS through homologous cranial and spinal nerves in all vertebrates. And fourth, the number of synapses between sensory receptor and cerebral cortex varies in different systems. There is one synapse in the olfactory system, and at least four in the visual system.

### *The Cognitive System Generates Anticipatory Behavior*

It is very likely that the cerebral cortex—along with its cerebral nuclei (basal ganglia)—is the most important, if not sole, part of the cognitive system and that the cerebral cortex is responsible for planning, prioritizing, initiating, and evaluating the consequences of voluntary behavior (Section VII). The fundamental nature of voluntary behavior is obviously a difficult problem to address, but one useful approach is simply to compare it with reflexive behavior. Interestingly, most if not all behaviors mediated by skeletal muscle can be initiated either reflexively or voluntarily, as Descartes pointed out long ago. What seems to distinguish reflexive and voluntary behaviors most clearly

is that the former involves a stereotyped response to a defined stimulus, whereas the latter is anticipatory, with a duration and content impossible to predict with anywhere near the same degree of certainty.

### *Intrinsic Systems Control Behavioral State*

The CNS generates considerable endogenous activity (action potential patterns)—it is definitely not just a passive system waiting to respond to sensory input, as the behaviorist approach a century ago assumed. All CNS parts apparently have a basal activity level that can be either increased or decreased. In many cases, it is still not established whether particular neuronal cell types generate intrinsic activity patterns. It is clear, however, that motoneurons and related MPGs do generate intrinsic activity; as already noted, the embryonic spinal cord produces motor output before sensory circuits develop. Thus, in addition to the three extrinsic input types to the motor system illustrated in Figure 2.16, intrinsic activity within the motor system itself can produce behavior that is neither reflexive nor voluntary.

Certain CNS regions generate intrinsic rhythmic activity patterns. The most important rhythmic behavioral pattern is the sleep–wake cycle that is entrained to the day–night cycle by an endogenous circadian clock, the hypothalamic suprachiasmatic nucleus (Chapters 41 and 42). The sleep–wake cycle is profoundly important because during sleep the body is maintained entirely by ongoing intrinsic and reflexive systems controlling behaviors like respiration and sustained sphincter contractions. In contrast, voluntary mechanisms dominate in wakefulness though reflexive and intrinsic mechanisms are also vitally important then.

Behavioral state control is thus a fundamental intrinsic brain activity. Another aspect of behavioral state—arousal—is especially important during wakefulness. Arousal level generally is correlated with an animal's motivational state or drive level (Chapter 43). The neural system mediating drive is not fully elucidated but is critically dependent on the hypothalamus, and attainment of specific goal objects (foraging behavior) depends on the cognitive system. Arousal and drive may be controlled by subcortical systems but behavior's actual direction and prioritization mainly is determined cortically.

The full identity of neural systems elaborating pleasure and pain is one of neuroscience's deep mysteries. Many regard pleasure and pain as conscious expressions of positive and negative reinforcement, influencing how likely a particular voluntary behavior will be repeated or avoided in the future. Here, reinforcement depends on sensory feedback about a particular behav-

ior's consequences (Fig. 2.16), and one suggestion is that pleasurable and painful sensations, like those associated with drive, are elaborated subcortically within intrinsic control systems. According to this view, thinking or cognition arises in cerebral cortex whereas feeling or affect arises subcortically. It is also possible that all aspects of consciousness (thinking and feeling) arise only from cortical neural activity (Chapter 53).

### How Pharmacological and Genetic Networks Relate to Functional Systems

Specific neurotransmitter systems have been incorporated into models of CNS function since the 1950s. Two examples are cholinergic and noradrenergic systems, defined as the total sets of CNS neurons releasing acetylcholine or noradrenalin, respectively, as a neurotransmitter (Chapter 7). In general, these systems are not obviously correlated with traditional CNS functional systems or major topographic parts—typically they are not restricted to one functional system or one major CNS division, though some exceptions may exist. Thus, neurotransmitter systems are not functional systems in the traditional sense. However, they are conceptually or operationally important in helping define circuits or functional systems influenced by particular drug actions. For example, administering centrally acting acetylcholine receptor agonists influences synapses in a variety of traditional *functional systems*, and the set of these functional systems could be defined as a *pharmacological system* with a specific set of behavioral and other responses. If a drug targeted for therapeutic reasons to a specific neural system (e.g., a cholinergic agonist targeted to the cerebral cholinergic system in Alzheimer's disease; Chapter 45), it will also act on other functional systems with appropriate cholinergic receptors (e.g., in the thalamus and lower brainstem). Responses in these other systems produce "side effects" that may be good or bad.

Likewise, any gene product's distribution pattern can also be used to define a chemical, molecular, or neural *gene expression system*. For example, a system could be defined in terms of all neurons expressing the calbindin or  $\mu$ -opioid receptor gene, and expression of the corresponding gene might be prevented or altered in experimental knockout mice or natural mutations in genetic diseases. These alterations may produce an obvious and stereotyped phenotype or syndrome, but in most instances the gene normally is expressed in multiple functional systems and has complex (even if subtle) physiological and behavioral effects.

Finally, it is important to remember that a genetic program constructs the nervous system's basic *macrocircuits* during embryogenesis. Determining the correspondence between gene expression networks and neural networks may be the ultimate achievement of systems neuroscience. The nervous system's *microcircuits*—quantitative aspects of synapse number and strength associated with individual neurons—may be sculpted by experience throughout life.

### Summary

There is no simple relationship between the CNS's topographic or regional differentiation and its functional organization. So it is mistaken to assume *a priori* that CNS information simply is processed hierarchically with the spinal cord at the lowest level and the cerebral cortex at the top. An alternative view is that the CNS displays a network rather than hierarchical organization scheme—a circuit where the motor system is driven by sensory, cognitive, and intrinsic behavioral state inputs, and future motor activity is determined partly by sensory feedback about the initial behavior's consequences.

Two major features complicate this simple network model. First, the motor system itself is organized hierarchically, whereas the sensory system transmits multiple modalities in parallel, and this sensory information can reach directly each level of the motor system hierarchy. And second, sensory information also reaches the intrinsic and cognitive systems. In fact, all three input systems are interconnected bidirectionally. The basic plan of neural circuit architecture must be understood on its own terms, not through simple preconceived ideas or superficial analogies with computers, the Internet, irrigation systems, or complicated robots. How traditional CNS functional systems relate to pharmacological systems and genetic networks remains to be determined.

## OVERVIEW OF THE ADULT MAMMALIAN NERVOUS SYSTEM

This section reviews structural neuroscience methods used to achieve our current—still very incomplete—understanding of nervous system architectural principles, and introduces the major nervous system components. Long experience teaches that nothing approaches actual dissection for gaining an appreciation of overall brain structure.

## A Brief History of Structural Neuroscience Methods

The human brain's macroscopic structure was observed by early Greek physician-philosophers and thoroughly understood by the early 1800s. However, its circuitry's astounding complexity was not appreciated until microscopy effectively identified individual pathways (axon bundles) and neuronal regions (distinguishable neuronal cell body aggregates) toward the end of the 1800s—applying to thin CNS tissue sections neurohistological reagents and reactions developed by the textile and photographic industries (Swanson, 2000b).

Perhaps the single most enduring contribution of nineteenth century neurohistology was Camillo Golgi's 1873 silver impregnation method. The full morphology of individual neurons was visible for the first time (Fig. 2.18; Boxes 2.1 and 2.2)—their dendritic tree, cell body shape, axon and all its collaterals, and points of presumed functional contact with other cells, which Sherrington named synapses in 1897. The Golgi method involves impregnating brain tissue

alternately in potassium dichromate and silver nitrate solutions over periods of weeks to years, and mysteriously (the reaction's chemistry remains elusive) about 1% of the neurons are filled (apparently randomly) with a dense precipitate. The Golgi stain thus reveals more by staining less. Today, selective labeling of individual neurons also is achieved by injecting markers directly into living neurons with micropipettes, allowing simultaneous electrophysiological and cytoplasm analysis.

Unfortunately, Golgi's method provided little information about longer CNS connections: axonal projections between nonadjacent regions. This was approached with methods selectively staining fibers degenerating from pathological or experimental lesions. Augustus Waller showed (1850) that nerve transection causes the nerve's distal segment to degenerate (Wallerian, anterograde degeneration), inspiring his proposal that the cell body is the nerve cell's "trophic center," which the axon depends on for survival. Thirty years later Bernard von Gudden showed that Wallerian degeneration may be accompanied by pathological changes in the cell body when its axon is

**FIGURE 2.18** Cajal's (1909–1911) neural architecture drawing based on the Golgi method. It shows the organization of four major retinal neuron types (right) and projections from retina to optic tectum (superior colliculus; left). Applying the neuron doctrine and functional polarity rule (Boxes 2.1 and 2.2) to the entire vertebrate nervous system by Cajal and many other researchers a century ago led to the "classical" way neuronal cell types have been described structurally ever since, a view beautifully illustrated here. Three major neuron types tend to populate specific retinal layers: photoreceptors (subtypes a, b, A, B), bipolar cells (subtypes c, d), and ganglion cells (subtypes e, D, E). A specific neuron type's cardinal feature is its axon's distribution—the neuron's function in terms of output. Photoreceptors detect light and their axon innervates bipolar cells. The latter in turn innervate ganglion cells whose axon projects through the optic nerve to the tectum. Photoreceptors are classical sensory neurons (Fig. 2.3), bipolar cells are local interneurons, and ganglion cells are projection interneurons. Also note a second retinal local interneuron class, amacrine cells (f). Cajal pointed out that retinal neuronal cell bodies aggregate in three layers with synaptic neuropil zones in between, and illustrated a clear structural gradient—reflecting a foveal region (F) with greater visual acuity because of multiple structural features, some of which are obvious in the drawing. The power of Cajal's functional polarity theory is evident: he drew arrows to indicate the presumed normal direction of information flow through the circuit, based on the sequential arrangement of dendrites and axons associated with each neuronal type.

cut, suggesting retrograde transport of “trophic factors” from axon to cell body.

Marchi and Algeri developed the first method to stain selectively central pathways (1885), revealing degenerating myelin sheaths of severed axons as black particles on a light background—effectively isolating degenerating from healthy sheaths in tissue sections. Anatomists could produce discrete CNS lesions in experimental animals and after several weeks trace the course of neural pathways arising in the lesioned region. The method was severely limited, however, because unmyelinated or thinly myelinated axons, and terminal fields, were unlabeled, and there were many “false-positive” results from transecting fibers simply passing through the lesion (the “fiber-of-passage” problem common to many experimental methods).

By the 1950s selective silver impregnation and degeneration methods were combined by Walle J.H. Nauta and colleagues to stain unmyelinated axons and their terminal fields. The CNS was remapped at finer resolution with these methods, which still suffered from the fiber-of-passage problem (false-positive results) and were not nearly as sensitive (false-negative results) as the next generation of methods developed around 1970. Instead of relying on lesion-induced pathology the latter (current) are based on a combination of (1) physiological mechanisms (anterograde and retrograde intraaxonal marker transport) in healthy neurons and (2) histochemical detection of antibodies and complementary nucleic acid strands.

Also in the 1950s, the electron microscope opened a whole world of ultrastructure previously only guessed at. It provided the first glimpses of synapse structure (with a typical cleft only about 20 nm wide, far below the 1  $\mu$ m resolution of light microscopes, and presynaptic vesicles), myelin sheath organization, and many cellular organelles. It also allowed biologists to examine in detail the biosynthetic apparatus residing within each cell.

These methods provide far more detail about CNS connectivity patterns or circuit organization than ever before in many species. As a result, comparative neuroanatomy has flourished and forms a solid structural foundation on which contemporary physiological and behavioral studies are based.

## The PNS Has Sensorimotor, Autonomic, and Enteric Divisions

Overall, the nervous system is divided into CNS (brain and spinal cord) and PNS (nerves, ganglia, and enteric nervous system). However, this CNS–PNS distinction is just a gross anatomical convenience that ignores circuit organization because nerves contain

axons from neuronal cell bodies in both CNS and peripheral ganglia.

Functionally, the PNS has (1) a sensory ganglion component with accompanying dorsal and ventral roots and functionally mixed nerves, (2) the autonomic nervous system’s (ANS) motor ganglia and communicating roots, and (3) the enteric nervous system (Furness, 2006). The sensory part has dorsal root ganglia sensory neurons with one process (embryologically and phylogenetically an axon) entering the CNS through dorsal roots and the other process (embryologically and phylogenetically a dendrite) traversing peripheral nerves to sites throughout the body. However, peripheral nerves also contain axons of skeletal motoneurons with cell bodies in spinal cord and brainstem; for spinal nerves the axon’s initial part traverses a ventral root. Thus, most peripheral nerves carry *afferent* (“sensory”) information toward the CNS and *efferent* (motor) information toward the body (Fig. 2.13). Sensory neurons carry afferent information from receptors in skin, skeletal muscles, tendons, joints, blood vessels, and deep viscera. The autonomic and enteric nervous systems have a network of efferent pathways, ganglia, and nerve nets controlling gut peristalsis, glandular secretions, blood vessel diameter, and other visceral functions—and their output is modulated by both somatic and visceral afferents. Thus, a typical peripheral nerve carries a mixture of afferents and efferents innervating body wall and deep organs.

Somatic afferents distribute near the body surface in a pattern reflecting the body wall’s segmental origins: each spinal nerve innervates a narrow medio-lateral band of skin called a *dermatome* (Fig. 25.9), although adjacent nerves innervate overlapping territories (otherwise single nerve interruption would produce complete sensation loss in a band of skin, which is not the case). The segmental dermatome pattern is obvious in the torso where very little differential body wall growth occurs, whereas limb dermatomes are distorted because they form before the limbs grow out fully in the embryo.

Peripheral nerves often ramify and join with nerves from other segments to form *plexi* (singular: plexus; literally a “braid”) that serve as crossroads and distribution centers for peripheral nerves, allowing axons to reorganize into complex nerve bundles innervating body structures. Brachial and lumbosacral plexi at the base of the upper and lower limbs, respectively, are the largest examples of these perplexing structures that also provide great mechanical strength to nerves passing through the shoulders and hips, which may undergo extreme rotation. The ANS also has a bewildering variety of plexi in the abdomen and pelvis,

where nerves converge and redistribute axons to their target organs.

The ANS has anatomically and functionally *sympathetic* and *parasympathetic* divisions (Chapter 35). The two divisions function in a kind of push-pull relationship with each other. One or the other is never completely on or off. Instead, there are degrees of sympathetic and parasympathetic tone. During sleep, certain involuntary functions like digestion are accelerated. Glands participating in digestion are activated parasympathetically and sympathetic tone is correspondingly decreased. In contrast, Walter B. Cannon noted almost a century ago that during the “fight or flight” reaction characterizing defensive behavior, sympathetic tone is markedly enhanced and parasympathetic tone is reduced sharply. Sympathetic outflow is vastly amplified and coordinated through a set of ganglia and the adrenal medulla, so that sympathetic function occurs relatively synchronously throughout the body. In contrast, parasympathetic system is relatively finely tuned.

### The Cerebrospinal Trunk Generates Cranial and Spinal Nerves

From a more systematic perspective on nervous system organization, the spinal cord and brainstem (together the cerebrospinal trunk) generate a continuous series of spinal and cranial nerves, respectively. The human spinal cord, roughly as thick as an adult’s little finger, is ultimately surrounded and protected by the vertebral column, whereas the skull protects the brain. In cross-section, the spinal cord’s two basic types of nervous tissue are obvious: *gray matter* and *white matter*. Gray matter forms an H-shaped region surrounding the central canal (the ventricular system’s spinal segment) and consists mainly of neuronal cell bodies and neuropil. White matter surrounds gray matter in the spinal cord and consists mostly of axons collected into overlapping fiber bundles. Many axons have a myelin sheath, a uniquely vertebrate feature allowing rapid nerve impulse conduction (Chapter 6) and giving white matter its pale appearance.

The spinal cord looks segmented because bilateral pairs of dorsal and ventral roots emerge regularly along its length. These pairs form five sets: cervical (in the neck above the rib cage), thoracic (associated with the rib cage), lumbar (near the abdomen), sacral (near the pelvis), and coccygeal (associated with tail vertebrae). In humans there are typically 31 spinal nerve pairs (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that are named according to the intervertebral foramen they pass through. This enumeration varies between species.

Based on human brain macroscopic dissection, Samuel Thomas von Sömmerring in 1778 recognized a sequence of 12 cranial nerve pairs, and this classification scheme remains traditional for vertebrates in general, although it is problematic in terms of completeness (e.g., not including the nasal cavity’s terminal nerve) and nonconformance with contemporary fate maps of cranial nerve nucleus development (e.g., motoneurons for nerve VII are generated rostral to those for nerve VI). In any event, cranial nerves are more heterogeneous functionally than spinal nerves, and indeed most cranial nerve pairs have distinct compositions in terms of fiber types.

In humans, seven cranial nerves transmit information about the so-called special senses associated with the head: olfaction (I, olfactory nerve—purely sensory, arising in nasal olfactory epithelium), vision (II, optic nerve from retina), hearing and balance (VIII, vestibuloacoustic nerve from inner ear), and taste (V, VII, IX, and X; parts of the trigeminal, facial, glossopharyngeal, and vagus nerves, respectively). Nerves III (oculomotor), IV (trochlear), and VI (abducens) primarily control conjugate eye movements, although the third nerve also mediates autonomic control of the pupillary light reflex and lens accommodation. Major parts of the trigeminal (V) nerve carry sensory axons from the face (a rostral extension of the spinal somatosensory system) and motor axons innervating the muscles of mastication (chewing). The facial (VII) nerve controls the muscles of facial expression and also innervates the salivary and lacrimal glands—its role in emotional expression is obvious. The glossopharyngeal (IX) nerve innervates the pharynx and mediates the swallowing reflex. The vagus (“wandering,” X) nerve has an exceptionally complex and widespread innervation pattern, including laryngeal muscles producing speech, and the parasympathetic innervation of most thoracic and abdominal viscera. The spinal accessory (XI) nerve innervates several muscles that stabilize the head and neck and the hypoglossal (XII) nerve innervates the tongue musculature.

### Cerebral Hemispheres and Cerebellum Are Divided into Cortex and Nuclei

Macroscopically the mammalian cerebrospinal trunk has two great expansions—the cerebral hemispheres and cerebellum—and both have an outer laminated cortex surrounding deep nonlaminated nuclei. The most extraordinary growth of the mammalian brain occurs in the endbrain or cerebral hemispheres (Fig. 2.19), which develop more or less as mirror images of one another and are separated in the dorsal midline by a deep interhemispheric (longitudinal) fissure. In

**FIGURE 2.19** Surface features of the human cerebral cortex, which is thrown into gyri separated by sulci. In the drawing on the right, the right and left hemispheres have been pulled apart at the interhemispheric or longitudinal fissure to reveal the corpus callosum (L) interconnecting the two hemispheres. The drawings are from perhaps the most important book in the history of medicine by Andreas Vesalius, *Fabric of the Human Body*, published in 1543. The drawings were probably executed by an artist from Titian's studio.

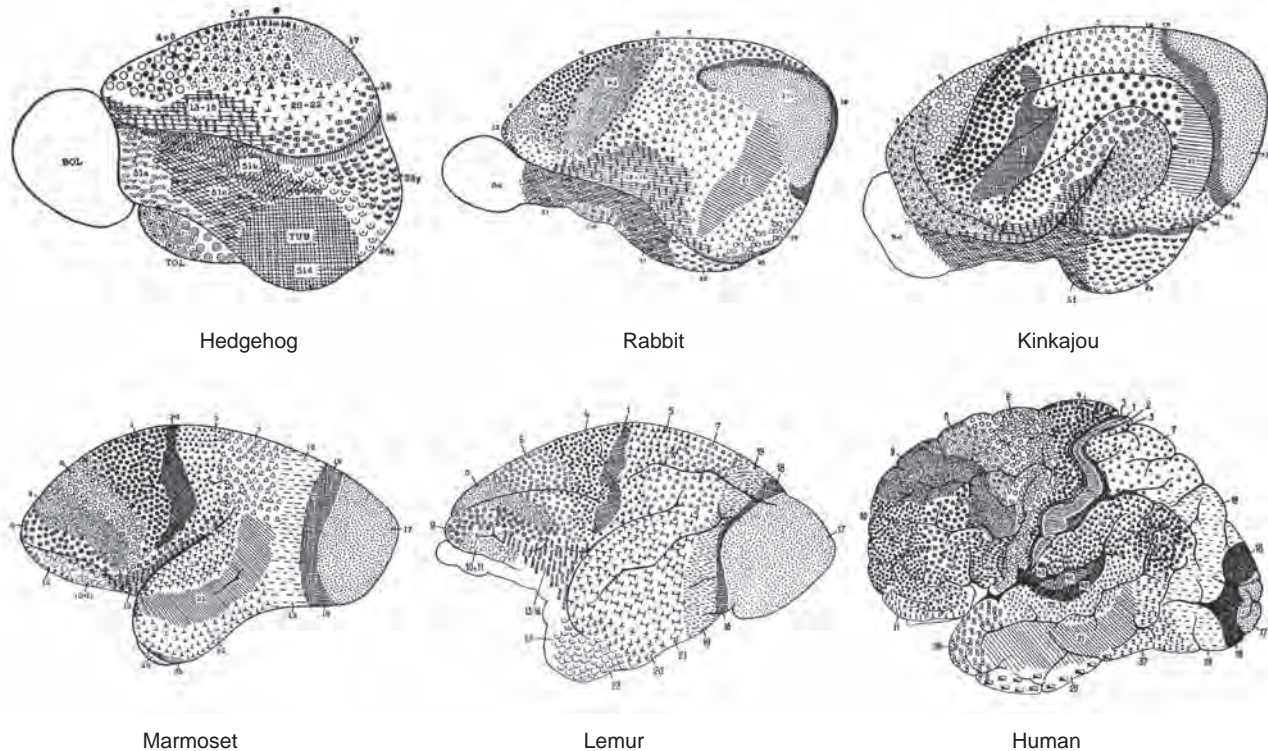

humans, the sulcal pattern is, however, asymmetric and unique in each person, and there are functional asymmetries as well; for example, the speech centers typically are lateralized (Chapter 51). Hemisphere volume is restricted by skull capacity, so as the hemispheres grow during embryogenesis they develop folds (*gyri*) separated by invaginations (*sulci*, and when deeper, *fissures*). This corrugation allows cerebral (and cerebellar) cortex to have a larger surface area. The extent and pattern of folding vary stereotypically with species, although like any trait there are quantitative differences between individuals of a particular species. Two major grooves, the central sulcus and lateral (Sylvian) fissure, are used as anatomical landmarks in the human cerebrum. The central sulcus extends more or less vertically along the hemisphere's lateral surface where it approaches the horizontally oriented lateral fissure. Together they divide arbitrarily the outer cerebral cortical surface into four lobes (*frontal*, *parietal*, *occipital*, and *temporal*), named for the overlying cranial bones. In addition, the *insular lobe* is folded completely inside the hemisphere, deep to the lateral fissure (actually about two-thirds of the folded cortical surface lies buried and unexposed to the outer hemisphere surface), and the *limbic lobe* forms the hemisphere's medial border along the interhemispheric fissure.

These lobes are only crude guides to the cerebrum's functional organization. Over the last 150 years pro-

gressively better analysis has parceled the cortical mantle into a mosaic of roughly 50 to 100 areas with more or less distinct structural and functional characteristics. The most famous and enduring cortical *regionalization maps* were generated by Korbinian Brodmann a century ago (Fig. 2.20), although refinements and alternative interpretations abound. Nevertheless, cortical regionalization maps are fundamentally important guides for understanding CNS architecture. Just as one example, virtually the entire thalamus projects topographically on the cortical mantle, which in turn projects topographically on the entire cerebral nuclei (basal ganglia). Information from every sensory modality reaches the cerebral cortex and it in turn sends inputs to virtually the entire motor system.

Most cerebral cortical areas directly modulate activity on the opposite (contralateral) side of the body through descending pathways that cross the midline to reach motor system parts in the contralateral CNS. Furthermore, axon bundles called *commissures* connect cerebral cortical areas of one hemisphere with the same or related areas of the opposite hemisphere—and different areas in the same hemisphere are interconnected through complex *association pathways*. Thus, commissural and association pathways allow comparison and integration of information between cortical areas within and between the cerebral hemispheres.

**FIGURE 2.20** A similar cerebral cortical regionalization plan for mammals was proposed by Korbinian Brodmann in 1909. His cortical parceling was based on regional differences in how neuronal cell bodies tend to distribute in layers, an approach referred to as cytoarchitectonics. This figure illustrates his findings in six species, with different regions, or “areas” as he called them, indicated with different symbols and numbers. He distinguished 47 areas in the human cerebral cortex and showed that generally similar patterns applied to all nine species he analyzed.

Communication between hemispheres is eliminated by commissurotomy, the surgical division of all cerebral commissures (including the hippocampal and anterior commissures). This procedure sometimes is used to treat otherwise intractable epilepsy cases, preventing spread of severe epileptic activity from one hemisphere to the other. Incredibly, commissurotomy patients function very well most of the time, and behavioral studies on such “split brain” patients have yielded remarkable information about cerebral cortical organization (Gazzaniga, 2005). Axon bundles (tracts or pathways) connecting very different structures on the two sides of the CNS usually are called *decussations* to distinguish them from commissures.

### The Nervous System Is Protected by Membranous Coverings

The CNS is completely surrounded by three concentric connective tissue membranes: *pia*, *arachnoid*, and *dura*. The *pia* (“faithful”) is a very thin, vascular membrane. As the name suggests, it adheres closely to the

CNS’s surface, even where there are deep invaginations, as in the cerebral and cerebellar cortex. Then comes the *arachnoid* (“spidery”), which has a tenuous, web-like structure but is histologically similar to *pia*. Finally, the *dura* (“tough”) is a thick, inelastic covering apposed to the skull and vertebral canal’s inner surface. Membranes covering the CNS are continuous with similar coverings of the PNS, where the terminology differs.

In certain CNS regions neural tissue is absent but meninges persist. Here, ependymal cells lining the ventricular system (the monolayer vestige of the embryonic neuroepithelial layer that ends up lining the adult ventricular system) fuse with the *pia* and *arachnoid* layers to form structures known as *choroid plexus*, which contains abundant blood vessels and serves as a component of the blood–brain barrier (the blood–CSF barrier; see Chapter 3). The *choroid plexus* produces CSF in the roof of the lateral, third, and fourth ventricles, and this fluid fills the brain ventricles, and perhaps at least part of the spinal central canal. Under positive hydrostatic pressure, CSF passes out of the brain’s interior through

three foramina (holes) in the fourth ventricle's roof, to fill the subarachnoid space between pia and arachnoid.

## The Brain Is Highly Vascular

The human brain consumes about 20% of the body's oxygen supply at rest, even though it usually weighs only about a kilogram. Thus, the brain must continuously receive a voluminous blood supply, on the order of a liter per minute. Blood reaches the brain through two arterial roots—*vertebral* and *internal carotid arteries*—that anastomose in the circle of Willis, which essentially surrounds the base of the hypothalamus and pituitary gland's stalk. The functional importance of this arterial circle cannot be overemphasized because afterward there is a drastic reduction in anastomoses between brain arteries and arterioles within brain tissue itself. As a result, blockage or rupture of even a small artery or arteriole rapidly deprives the supplied brain region of oxygen, causing a *stroke* or brain attack.

After entering the skull through the foramen magnum with the spinal cord, the paired vertebral arteries fuse into a single *basilar artery*, generating the cerebellar arteries and the posterior cerebral arteries, which supply occipital cerebral regions. The internal carotid arteries divide to form the anterior and middle cerebral arteries; the former supplies each hemisphere's medial surface (especially the limbic lobe), and the latter supplies the rest of the hemisphere (including the speech and somatic sensorimotor areas). By and large, the major arteries course along the cerebral surface and branches dive abruptly into the brain and proliferate into arterioles and capillaries.

A system of large *venous sinuses* collect blood from brain capillaries and return it to the heart, mostly via the paired *internal jugular veins*. The major venous sinuses lie within the dura, whose inelasticity essentially holds the sinuses open. Blood flow through sinuses is slow and under low hydrostatic pressure. Thin-walled venous sinuses surrounded by the tough and immovable dura sets the stage for serious injury when the head is subjected to physical trauma. A well-known example is traumatic injury to the great cerebral vein (of Galen) in the midline that can occur when a boxer is struck in the head. The blow's impact causes the brain to recoil in its CSF cushion, exerting a shearing force against the dura, which remains attached to the skull. This force effectively ruptures the great cerebral vein, leading to serious hemorrhage of venous blood into the subdural space between dura and arachnoid.

## Summary

This chapter reviews common approaches to the problem of understanding the nervous system's fundamental structure and wiring diagram—the basic plan or architecture. One approach examines a series of increasingly complex animals from an evolutionary perspective to gain insight into basic organizing principles. It reveals trends toward centralization, cephalization, bilateral symmetry, and regionalization of the nervous system. It also suggests that basic molecular and cellular mechanisms of neuronal function, including electrical signal propagation and neurotransmitter release, have changed little since the appearance of the simplest nervous systems in hydra, jellyfish, and other cnidarians.

Another approach follows the vertebrate nervous system's development from embryo to adult. At early developmental stages the CNS of all vertebrates has the same basic structure. A polarized, bilaterally symmetrical, regionalized neural plate of ectodermal origin invaginates to form a neural tube whose rostral half presents three swellings (forebrain, midbrain, and then hindbrain), followed by a caudal presumptive spinal cord. These four basic CNS divisions, arranged from rostral to caudal, go on to subdivide repeatedly until all laminated and nuclear neuron groups of the adult CNS are formed. A topographic, "geographic," or regional account of the CNS emerges from this developmental approach.

How the CNS's functional systems or circuitry are arranged into a unified whole is a tantalizing, deep, unsolved problem. The model discussed here equates behavior with motor output, which is driven by a combination of sensory, intrinsic behavioral state, and cognitive inputs—as well as by endogenous neuronal activity within each system. Future behavior is determined partly by sensory feedback related to the original behavior's consequences. As this is written, the relationship between CNS macroregionalization (Figs. 2.14 and 2.15) and functional systems (Fig. 2.16) is not obvious. The correspondence between functional neural systems and gene expression networks is even more obscure, although promising results are beginning to emerge in the embryonic spinal cord and brainstem cranial nerve nuclei.

## Cellular Components of Nervous Tissue

Several types of cellular elements are integrated to constitute normally functioning brain tissue. The neuron is the communicating cell, and many neuronal subtypes are connected to one another via complex circuitries, usually involving multiple synaptic connections. Neuronal physiology is supported and maintained by neuroglial cells, which have highly diverse and incompletely understood functions. These include myelination, secretion of trophic factors, maintenance of the extracellular milieu, and scavenging of molecular and cellular debris from it. Neuroglial cells also participate in the formation and maintenance of the blood–brain barrier, a multicomponent structure that is interposed between the circulatory system and the brain substance and that serves as the molecular gateway to brain tissue.

### NEURONS

The neuron is a highly specialized cell type and is the essential cellular element in the CNS. All neurological processes are dependent on complex cell–cell interactions among single neurons as well as groups of related neurons. Neurons can be categorized according to their size, shape, neurochemical characteristics, location, and connectivity, which are important determinants of that particular functional role of the neuron in the brain. More importantly, neurons form circuits, and these circuits constitute the structural basis for brain function. *Macrocircuits* involve a population of neurons projecting from one brain region to another region, and *microcircuits* reflect the local cell–cell interactions within a brain region. The detailed analysis of

these macro- and microcircuits is an essential step in understanding the neuronal basis of a given cortical function in the healthy and the diseased brain. Thus, these cellular characteristics allow us to appreciate the special structural and biochemical qualities of a neuron in relation to its neighbors and to place it in the context of a specific neuronal subset, circuit, or function.

Broadly speaking, therefore, there are five general categories of neurons: inhibitory neurons that make local contacts (e.g., GABAergic interneurons in the cerebral and cerebellar cortex), inhibitory neurons that make distant contacts (e.g., medium spiny neurons of the basal ganglia or Purkinje cells of the cerebellar cortex), excitatory neurons that make local contacts (e.g., spiny stellate cells of the cerebral cortex), excitatory neurons that make distant contacts (e.g., pyramidal neurons in the cerebral cortex), and neuromodulatory neurons that influence neurotransmission, often at large distances. Within these general classes, the structural variation of neurons is systematic, and careful analyses of the anatomic features of neurons have led to various categorizations and to the development of the concept of cell type. The grouping of neurons into descriptive cell types (such as chandelier, double bouquet, or bipolar cells) allows the analysis of populations of neurons and the linking of specified cellular characteristics with certain functional roles.

### General Features of Neuronal Morphology

Neurons are highly polarized cells, meaning that they develop distinct subcellular domains that subserve different functions. Morphologically, in a typical neuron, three major regions can be defined: (1) the cell

body (*soma* or *perikaryon*), which contains the nucleus and the major cytoplasmic organelles; (2) a variable number of dendrites, which emanate from the perikaryon and ramify over a certain volume of gray matter and which differ in size and shape, depending on the neuronal type; and (3) a single axon, which extends, in most cases, much farther from the cell body than the dendritic arbor (Fig. 3.1). Dendrites may be spiny (as in pyramidal cells) or nonspiny (as in most interneurons), whereas the axon is generally smooth and emits a variable number of branches (collaterals). In vertebrates, many axons are surrounded by an insulating myelin sheath, which facilitates rapid impulse conduction. The axon terminal region, where contacts with other cells are made, displays a wide range of morphological specializations, depending on its target area in the central or peripheral nervous system.

The cell body and dendrites are the two major domains of the cell that receive inputs, and dendrites play a critically important role in providing a massive receptive area on the neuronal surface. In addition, there is a characteristic shape for each dendritic arbor, which can be used to classify neurons into morphological types. Both the structure of the dendritic arbor and the distribution of axonal terminal ramifications confer a high level of subcellular specificity in the localization of particular synaptic contacts on a given neuron. The three-dimensional distribution of dendritic arborization is also important with respect to the type of information transferred to the neuron. A neuron

**FIGURE 3.1** Typical morphology of projection neurons. (Left) A Purkinje cell of the cerebellar cortex and (right) a pyramidal neuron of the neocortex. These neurons are highly polarized. Each has an extensively branched, spiny apical dendrite, shorter basal dendrites, and a single axon emerging from the basal pole of the cell.

with a dendritic tree restricted to a particular cortical layer may receive a very limited pool of afferents, whereas the widely expanded dendritic arborizations of a large pyramidal neuron will receive highly diversified inputs within the different cortical layers in which segments of the dendritic tree are present (Fig. 3.2) (Mountcastle, 1978). The structure of the dendritic tree is maintained by surface interactions between adhesion molecules and, intracellularly, by an array of cytoskeletal components (microtubules, neurofilaments, and associated proteins), which also take part in the movement of organelles within the dendritic cytoplasm.

An important specialization of the dendritic arbor of certain neurons is the presence of large numbers of dendritic spines, which are membranous protrusions. They are abundant in large pyramidal neurons and are much sparser on the dendrites of interneurons (see later).

The perikaryon contains the nucleus and a variety of cytoplasmic organelles. Stacks of rough endoplasmic reticulum are conspicuous in large neurons and, when interposed with arrays of free polyribosomes, are referred to as *Nissl substance*. Another feature of the perikaryal cytoplasm is the presence of a rich cytoskeleton composed primarily of neurofilaments and

**FIGURE 3.2** Schematic representation of four major excitatory inputs to pyramidal neurons. A pyramidal neuron in layer III is shown as an example. Note the preferential distribution of synaptic contacts on spines. Spines are labeled in red. Arrow shows a contact directly on the dendritic shaft.

microtubules, discussed in detail in Chapter 4. These cytoskeletal elements are dispersed in bundles that extend from the soma into the axon and dendrites.

Whereas dendrites and the cell body can be characterized as domains of the neuron that receive afferents, the axon, at the other pole of the neuron, is responsible for transmitting neural information. This information may be primary, in the case of a sensory receptor, or processed information that has already been modified through a series of integrative steps. The morphology of the axon and its course through the nervous system are correlated with the type of information processed by the particular neuron and by its connectivity patterns with other neurons. The axon leaves the cell body from a small swelling called the *axon hillock*. This structure is particularly apparent in large pyramidal neurons; in other cell types, the axon sometimes emerges from one of the main dendrites. At the axon hillock, microtubules are packed into bundles that enter the axon as parallel fascicles. The axon hillock is the part of the neuron where the action potential is generated. The axon is generally unmyelinated in local circuit neurons (such as inhibitory interneurons), but it is myelinated in neurons that furnish connections between different parts of the nervous system. Axons usually have higher numbers of neurofilaments than dendrites, although this distinction can be difficult to make in small elements that contain fewer neurofilaments. In addition, the axon may show extensive, spatially constrained ramified, as in certain local circuit neurons; it may give out a large number of recurrent collaterals, as in neurons connecting different cortical regions; or it may be relatively straight in the case of projections to subcortical centers, as in cortical motor neurons that send their very long axons to the ventral horn of the spinal cord. At the interface of axon terminals with target cells are the synapses, which represent specialized zones of contact consisting of a presynaptic (axonal) element, a narrow synaptic cleft, and a postsynaptic element on a dendrite or perikaryon.

## Synapses and Spines

### *Synapses*

Each synapse is a complex of several components: (1) a *presynaptic element*, (2) a *cleft*, and (3) a *postsynaptic element*. The presynaptic element is a specialized part of the presynaptic neuron's axon, the postsynaptic element is a specialized part of the postsynaptic somatodendritic membrane, and the space between these two closely apposed elements is the cleft. The portion of the axon that participates in the axon is the *bouton*, and it is identified by the presence of synaptic vesicles and a presynaptic thickening at the active

zone (Fig. 3.3). The postsynaptic element is marked by a postsynaptic thickening opposite the presynaptic thickening. When both sides are equally thick, the synapse is referred to as *symmetric*. When the postsynaptic thickening is greater, the synapse is *asymmetric*. Edward George Gray noticed this difference, and divided synapses into two types: *Gray's type 1* synapses are symmetric, and have variably shaped, or pleomorphic, vesicles; *Gray's type 2* synapses are asymmetric, and have clear, round vesicles. The significance of this distinction is that research has shown that in general, Gray's type 1 synapses tend to be inhibitory, whereas Gray's type 2 synapses tend to be excitatory. This correlation greatly enhanced the usefulness of electron microscopy in neuroscience.

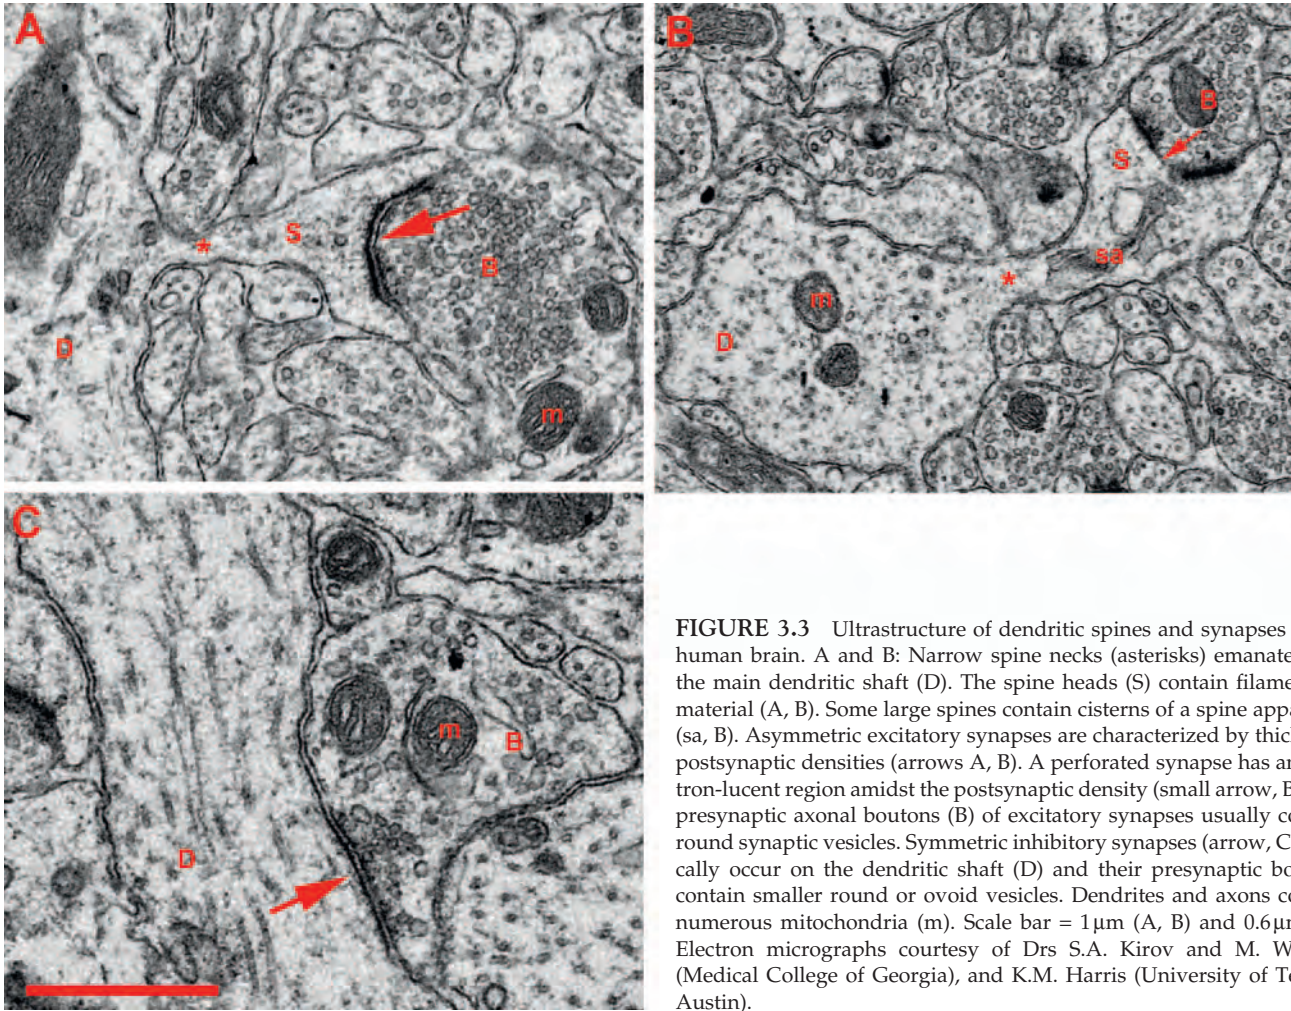

In cross-section on electron micrographs, a synapse looks like two parallel lines separated by a very narrow space (Fig. 3.3). Viewed from the inside of the axon or dendrite, it looks like a patch of variable shape. Some synapses are a simple patch, or *macule*. Macular synapses can grow fairly large, reaching diameters over  $1\mu\text{m}$ . The largest synapses have discontinuities or holes within the macule, and are called *perforated synapses* (Fig. 3.3). In cross-section, a perforated synapse may resemble a simple macular synapse, or several closely spaced smaller macules.

The portion of the presynaptic element that is apposed to the postsynaptic element is the *active zone*. This is the region where the synaptic vesicles are concentrated, and where at any time, a small number of vesicles are docked, and presumably ready for fusion. The active zone is also enriched with voltage gated calcium channels, which are necessary to permit activity-dependent fusion and neurotransmitter release.

The synaptic cleft is truly a space, but its properties are essential. The width of the cleft ( $\sim 20\mu\text{m}$ ) is critical because it defines the volume in which each vesicle releases its contents, and therefore, the peak concentration of neurotransmitter upon release. On the flanks of the synapse, the cleft is spanned by adhesion molecules, which are believed to stabilize the cleft.

The postsynaptic element may be a portion of a soma or a dendrite, or rarely, part of an axon. In the cerebral cortex, most Gray's type 1 synapses are located on somata or dendritic shafts, and most Gray's type 2 synapses are located on dendritic spines, which are specialized protrusions of the dendrite. A similar segregation is seen in cerebellar cortex. In nonspiny neurons, symmetric and asymmetric synapses are often less well separated. Irrespective of location, a postsynaptic thickening marks the postsynaptic element. In Gray's type 2 synapses, the postsynaptic thickening (or postsynaptic density, PSD) is greatly enhanced. Among the molecules that are associated

**FIGURE 3.3** Ultrastructure of dendritic spines and synapses in the human brain. A and B: Narrow spine necks (asterisks) emanate from the main dendritic shaft (D). The spine heads (S) contain filamentous material (A, B). Some large spines contain cisterns of a spine apparatus (sa, B). Asymmetric excitatory synapses are characterized by thickened postsynaptic densities (arrows A, B). A perforated synapse has an electron-lucent region amidst the postsynaptic density (small arrow, B). The presynaptic axonal boutons (B) of excitatory synapses usually contain round synaptic vesicles. Symmetric inhibitory synapses (arrow, C) typically occur on the dendritic shaft (D) and their presynaptic boutons contain smaller round or ovoid vesicles. Dendrites and axons contain numerous mitochondria (m). Scale bar = 1  $\mu\text{m}$  (A, B) and 0.6  $\mu\text{m}$  (C). Electron micrographs courtesy of Drs S.A. Kirov and M. Witcher (Medical College of Georgia), and K.M. Harris (University of Texas – Austin).

with the PSD are neurotransmitter receptors (e.g., NMDA receptors) and molecules with less obvious function, such as PSD-95.

### Spines

Spines are protrusions on the dendritic shafts of some types of neurons and are the sites of synaptic contacts, usually excitatory. Use of the silver impregnation techniques of Golgi or of the methylene blue used by Ehrlich in the late nineteenth century led to the discovery of spiny appendages on dendrites of a variety of neurons. The best known are those on pyramidal neurons and Purkinje cells, although spines occur on neuron types at all levels of the central nervous system. In 1896, Berkley observed that terminal axonal boutons were closely apposed to spines and suggested that spines may be involved in conducting impulses from neuron to neuron. In 1904, Santiago

Ramón y Cajal suggested that spines could collect the electrical charge resulting from neuronal activity. He also noted that spines substantially increase the receptive surface of the dendritic arbor, which may represent an important factor in receiving the contacts made by the axonal terminals of other neurons. It has been calculated that the approximately 20,000 spines of a pyramidal neuron account for more than 40% of its total surface area (Peters *et al.*, 1991).

More recent analyses of spine electrical properties have demonstrated that spines are dynamic structures that can regulate many neurochemical events related to synaptic transmission and modulate synaptic efficacy. Spines are also known to undergo pathologic alterations and have a reduced density in a number of experimental manipulations (such as deprivation of a sensory input) and in many developmental, neurologic, and psychiatric conditions (such as dementing

illnesses, chronic alcoholism, schizophrenia, trisomy 21). Morphologically, spines are characterized by a narrower portion emanating from the dendritic shaft, the neck, and an ovoid bulb or head, although spine morphology may vary from large mushroom-shaped bulbs to small bulges barely discernable on the surface of the dendrite. Spines have an average length of  $\sim 2 \mu\text{m}$ , but there is considerable variability in their dimensions. At the ultrastructural level (Fig. 3.3), spines are characterized by the presence of asymmetric synapses and contain fine and quite indistinct filaments. These filaments most likely consist of actin and  $\alpha$ - and  $\beta$ -tubulins. Microtubules and neurofilaments present in dendritic shafts do not enter spines. Mitochondria and free ribosomes are infrequent, although many spines contain polyribosomes in their neck. Interestingly, most polyribosomes in dendrites are located at the bases of spines, where they are associated with endoplasmic reticulum, indicating that spines possess the machinery necessary for the local synthesis of proteins. Another feature of the spine is the presence of confluent tubular cisterns in the spine head that represent an extension of the dendritic smooth endoplasmic reticulum. Those cisterns are referred to as the *spine apparatus*. The function of the spine apparatus is not fully understood but may be related to the storage of calcium ions during synaptic transmission.

## SPECIFIC EXAMPLES OF DIFFERENT NEURONAL TYPES

### Inhibitory Local Circuit Neurons

#### *Inhibitory Interneurons of the Cerebral Cortex*

A large variety of inhibitory interneuron types is present in the cerebral cortex and in subcortical structures. These neurons contain the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA) and exert strong local inhibitory effects. Their dendritic and axonal arborizations offer important clues as to their role in the regulation of pyramidal cell function. In addition, for several GABAergic interneurons, a subtype of a given morphologic class can be defined further by a particular set of neurochemical characteristics. Interneurons have been extensively characterized in the neocortex and hippocampus of rodents and primates, but they are present throughout the cerebral gray matter and exhibit a rich variety of morphologies, depending on the brain region, as well as on the species studied.

In the neocortex and hippocampus, the targets and morphologies of interneuron axons is most useful to classify them into morphological and functional

groups. For example, *basket cells* have axonal endings surrounding pyramidal cell somata (Somogyi *et al.*, 1983) and provide most of the inhibitory GABAergic synapses to the somas and proximal dendrites of pyramidal cells. These cells are also characterized by certain biochemical features in that the majority of them contain the calcium-binding protein parvalbumin, and cholecystokinin appears to be the most likely neuropeptide in large basket cells.

Chandelier cells have spatially restricted axon terminals that look like vertically oriented "cartridges," each consisting of a series of axonal boutons, or swellings, linked together by thin connecting pieces. These neurons synapse exclusively on the axon initial segment of pyramidal cells (this cell is also known as *axoaxonic cell*), and because the strength of the synaptic input is correlated directly with its proximity to the axon initial segment, there can be no more powerful inhibitory input to a pyramidal cell than that of the chandelier cell (Freund *et al.*, 1983; DeFelipe *et al.*, 1989).

The double bouquet cells are characterized by a vertical bitufted dendritic tree and a tight bundle of vertically oriented varicose axon collaterals (Somogyi and Cowey, 1981). There are several subclasses of double bouquet cells based on the complement of calcium-binding protein and neuropeptide they contain. Their axons contact spines and dendritic shafts of pyramidal cells, as well as dendrites from nonpyramidal neurons.

### Inhibitory Projection Neurons

#### *Medium-sized Spiny Cells*

These neurons are unique to the striatum, a part of the basal ganglia that comprises the caudate nucleus and putamen (see Chapter 31). Medium-sized spiny cells are scattered throughout the caudate nucleus and putamen and are recognized by their relatively large size, compared with other cellular elements of the basal ganglia, and by the fact that they are generally isolated neurons. They differ from all others in the striatum in that they have a highly ramified dendritic arborization radiating in all directions and densely covered with spines. They furnish a major output from the caudate nucleus and putamen and receive a highly diverse input from, among other sources, the cerebral cortex, thalamus, and certain dopaminergic neurons of the substantia nigra. These neurons are neurochemically quite heterogeneous, contain GABA, and may contain several neuropeptides and the calcium-binding protein calbindin. In Huntington disease, a neurodegenerative disorder of the striatum characterized by involuntary movements and progressive dementia, an early and dramatic loss of medium-sized spiny cells occurs.

### *Purkinje Cells*

Purkinje cells are the most salient cellular elements of the cerebellar cortex. They are arranged in a single row throughout the entire cerebellar cortex between the molecular (outer) layer and the granular (inner) layer. They are among the largest neurons and have a round perikaryon, classically described as shaped “like a chianti bottle,” with a highly branched dendritic tree shaped like a candelabrum and extending into the molecular layer where they are contacted by incoming systems of afferent fibers from granule neurons and the brainstem (see Chapter 32). The apical dendrites of Purkinje cells have an enormous number of spines (more than 80,000 per cell). A particular feature of the dendritic tree of the Purkinje cell is that it is distributed in one plane, perpendicular to the longitudinal axes of the cerebellar folds, and each dendritic arbor determines a separate domain of cerebellar cortex (Fig. 3.1). The axons of Purkinje neurons course through the cerebellar white matter and contact deep cerebellar nuclei or vestibular nuclei. These neurons contain the inhibitory neurotransmitter GABA and the calcium-binding protein calbindin. Spinocerebellar ataxia, a severe disorder combining ataxic gait and impairment of fine hand movements, accompanied by dysarthria and tremor, has been documented in some families and is related directly to Purkinje cell degeneration.

### **Excitatory Local Circuit Neurons**

#### *Spiny Stellate Cells*

Spiny stellate cells are small multipolar neurons with local dendritic and axonal arborizations. These neurons resemble pyramidal cells in that they are the only other cortical neurons with large numbers of dendritic spines, but they differ from pyramidal neurons in that they lack an elaborate apical dendrite. The relatively restricted dendritic arbor of these neurons is presumably a manifestation of the fact that they are high-resolution neurons that gather afferents to a very restricted region of the cortex. Dendrites rarely leave the layer in which the cell body resides. The spiny stellate cell also resembles the pyramidal cell in that it provides asymmetric synapses that are presumed to be excitatory, and is thought to use glutamate as its neurotransmitter (Peters and Jones, 1984).

The axons of spiny stellate neurons have primarily intracortical targets and a radial orientation, and appear to play an important role in forming links among layer IV, the major thalamorecipient layer, and layers III, V, and VI, the major projection layers. The spiny stellate neuron appears to function as a high-fidelity relay of thalamic inputs, maintaining strict topographic organization and setting up initial vertical

links of information transfer within a given cortical area (Peters and Jones, 1984).

### **Excitatory Projection Neurons**

#### *Pyramidal Cells*

All cortical output is carried by pyramidal neurons, and the intrinsic activity of the neocortex can be viewed simply as a means of finely tuning their output. A pyramidal cell is a highly polarized neuron, with a major orientation axis perpendicular (or orthogonal) to the pial surface of the cerebral cortex. In cross-section, the cell body is roughly triangular (Fig. 3.1), although a large variety of morphologic types exist with elongate, horizontal, or vertical fusiform, or inverted perikaryal shapes. Pyramidal cells are the major excitatory type of neurons and use glutamate as their neurotransmitter. A pyramidal neuron typically has a large number of dendrites that emanate from the apex and form the base of the cell body. The span of the dendritic tree depends on the laminar localization of the cell body, but it may, as in giant pyramidal neurons, spread over several millimeters. The cell body and dendritic arborization may be restricted to a few layers or, in some cases, may span the entire cortical thickness (Jones, 1984).

In most cases, the axon of a large pyramidal cell extends from the base of the perikaryon and courses toward the subcortical white matter, giving off several collateral branches that are directed to cortical domains generally located within the vicinity of the cell of origin (as explained later). Typically, a pyramidal cell has a large nucleus, and a cytoplasmic rim that contains, particularly in large pyramidal cells, a collection of granular material chiefly composed of *lipofuscin*. Although all pyramidal cells possess these general features, they can also be subdivided into numerous classes based on their morphology, laminar location, and connectivity with cortical and subcortical regions (Fig. 3.4) (Jones, 1975).

#### *Spinal Motor Neurons*

Motor cells of the ventral horns of the spinal cord, also called  $\alpha$  motoneurons, have their cell bodies within the spinal cord and send their axons outside the central nervous system to innervate the muscles. Different types of motor neurons are distinguished by their targets. The  $\alpha$  motoneurons innervate skeletal muscles, but smaller motor neurons (the  $\gamma$  motoneurons, forming about 30% of the motor neurons) innervate the spindle organs of the muscles (see Chapter 28). The  $\alpha$  motor neurons are some of the largest neurons in the entire central nervous system and are characterized by a multipolar perikaryon and a very

**FIGURE 3.4** Morphology and distribution of neocortical pyramidal neurons. Note the variability in cell size and dendritic arborization, as well as the presence of axon collaterals, depending on the laminar localization (I–VI) of the neuron. Also, different types of pyramidal neurons with a precise laminar distribution project to different regions of the brain. Adapted from Jones (1984).

rich cytoplasm that renders them very conspicuous on histological preparations. They have a large number of spiny dendrites that arborize locally within the ventral horn. The  $\alpha$  motoneuron axon leaves the central nervous system through the ventral root of the peripheral nerves. Their distribution in the ventral horn is not random and corresponds to a somatotopic representation of the muscle groups of the limbs and axial musculature (Brodal, 1981). Spinal motor neurons use acetylcholine as their neurotransmitter. Large motor neurons are severely affected in lower motor neuron disease, a neurodegenerative disorder characterized by progressive muscular weakness that affects, at first, one or two limbs but involves more and more of the body musculature, which shows signs of wasting as a result of denervation.

## Neuromodulatory Neurons

### *Dopaminergic Neurons of the Substantia Nigra*

Dopaminergic neurons are large neurons that reside mostly within the pars compacta of the substantia

nigra and in the ventral tegmental area (van Domburg and ten Donkelaar, 1991). A distinctive feature of these cells is the presence of a pigment, *neuromelanin*, in compact granules in the cytoplasm. These neurons are medium-sized to large, fusiform, and frequently elongated. They have several large radiating dendrites. The axon emerges from the cell body or from one of the dendrites and projects to large expanses of cerebral cortex and to the basal ganglia. These neurons contain the catecholamine-synthesizing enzyme *tyrosine hydroxylase*, as well as the monoamine dopamine as their neurotransmitter. Some of them contain both calbindin and calretinin. These neurons are affected severely and selectively in Parkinson disease—a movement disorder different from Huntington disease and characterized by resting tremor and rigidity—and their specific loss is the neuropathologic hallmark of this disorder.

## NEUROGLIA

The term neuroglia, or “nerve glue,” was coined in 1859 by Rudolph Virchow, who conceived of the neuroglia as an inactive “connective tissue” holding neurons together in the central nervous system. The metallic staining techniques developed by Ramón y Cajal and del Rio-Hortega allowed these two great pioneers to distinguish, in addition to the ependyma lining the ventricles and central canal, three types of supporting cells in the CNS: oligodendrocytes, astrocytes, and microglia. In the peripheral nervous system (PNS), the Schwann cell is the major neuroglial component.

### Oligodendrocytes and Schwann Cells Synthesize Myelin

Most brain functions depend on rapid communication between circuits of neurons. As shown in depth later, there is a practical limit to how fast an individual bare axon can conduct an action potential. Organisms developed two solutions for enhancing rapid communication between neurons and their effector organs. In invertebrates, the diameters of axons are enlarged. In vertebrates, the myelin sheath (Fig. 3.5) evolved to permit rapid nerve conduction.

Axon enlargement accelerates action potential propagation in proportion to the square root of axonal diameter. Thus larger axons conduct faster than small ones, but substantial increases in conduction velocity require huge axons. The largest axon in the invertebrate kingdom is the squid giant axon, which is about the thickness of a mechanical pencil lead. This axon

**FIGURE 3.5** An electron micrograph of a transverse section through part of a myelinated axon from the sciatic nerve of a rat. The tightly compacted multilayer myelin sheath (My) surrounds and insulates the axon (Ax). Mit, mitochondria. Scale bar: 75 nm.

conducts the action potential at speeds of 10 to 20 m/s. As the axon mediates an escape reflex, firing must be rapid if the animal is to survive. Bare axons and continuous conduction obviously provide sufficient rates of signal propagation for even very large invertebrates, and many human axons also remain bare. However, in the human brain with 10 billion neurons, axons cannot be as thick as pencil lead, otherwise heads would weigh one hundred pounds or more.

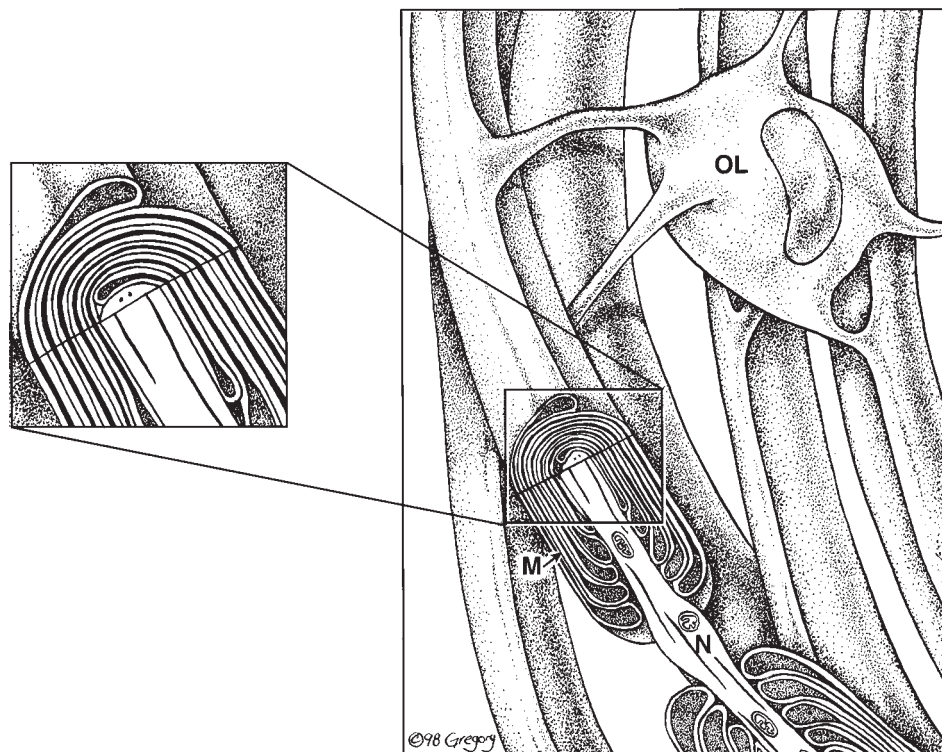

Thus, along the invertebrate evolutionary line, the use of bare axons imposes a natural, insurmountable limit—a constraint of axonal size—to increasing the processing capacity of the nervous system. Vertebrates, however, get around this problem through evolution of the myelin sheath, which allows 10- to 100-fold increases in conduction of the nerve impulse along axons with fairly minute diameters.

In the central nervous system, myelin sheaths (Fig. 3.6) are elaborated by oligodendrocytes. During brain development, these glial cells send out a few cytoplasmic processes that engage adjacent axons and form

myelin around them (Bunge, 1968). Myelin consists of a long sheet of oligodendrocyte plasma membrane, which is spirally wrapped around an axonal segment. At the end of each myelin segment, there is a bare portion of the axon, the node of Ranvier. Myelin segments are thus called *internodes*. Physiologically, myelin has insulating properties such that the action potential can “leap” from node to node and therefore does not have to be regenerated continually along the axonal segment that is covered by the myelin membrane sheath. This leaping of the action potential from node to node allows axons with fairly small diameters to conduct extremely rapidly (Ritchie, 1984), and is called *saltatory conduction*.

Because the brain and spinal cord are encased in the bony skull and vertebrae, CNS evolution has promoted compactness among the supporting cells of the CNS. Each oligodendrocyte cell body is responsible for the construction and maintenance of several myelin sheaths (Fig. 3.6), thus reducing the number of glial cells required. In both PNS and CNS myelin, cytoplasm is removed between each turn of the myelin, leaving only the thinnest layer of plasma membrane. Due to protein composition differences, CNS lamellae are approximately 30% thinner than in PNS myelin. In addition, there is little or no extracellular space or extracellular matrix between the myelinated axons passing through CNS white matter. Brain volume is thus reserved for further expansion of neuronal populations.

Peripheral nerves pass between moving muscles and around major joints, and are routinely exposed to physical trauma. A hard tackle, slipping on an icy sidewalk, or even just occupying the same uncomfortable seating posture for too long, can painfully compress peripheral nerves and potentially damage them. Thus, evolutionary pressures shaping the PNS favor robustness and regeneration rather than conservation of space. Myelin in the PNS is generated by Schwann cells (Fig. 3.7), which are different to oligodendrocytes in several ways. Individual myelinating Schwann cells form a single internode. The biochemical composition of PNS and CNS myelin differs, as discussed later. Unlike oligodendrocytes, Schwann cells secrete copious extracellular matrix components and produce a basal lamina “sleeve” that runs the entire length of myelinated axons. Schwann cell and fibroblast-derived collagens prevent normal wear-and-tear compression damage. Schwann cells also respond vigorously to injury, in common with astrocytes but unlike oligodendrocytes. Schwann cell growth factor secretion, debris removal by Schwann cells after injury, and the axonal guidance function of the basal lamina are responsible for the exceptional regenerative capacity of the PNS compared with the CNS.

**FIGURE 3.6** An oligodendrocyte (OL) in the central nervous system is depicted myelinating several axon segments. A cutaway view of the myelin sheath is shown (M). Note that the internode of myelin terminates in paranodal loops that flank the node of Ranvier (N). (Inset) An enlargement of compact myelin with alternating dark and light electron-dense lines that represent intracellular (major dense lines) and extracellular (intrapariod line) plasma membrane appositions, respectively.

**FIGURE 3.7** An "unrolled" Schwann cell in the PNS is illustrated in relation to the single axon segment that it myelinates. The broad stippled region is compact myelin surrounded by cytoplasmic channels that remain open even after compact myelin has formed, allowing an exchange of materials among the myelin sheath, the Schwann cell cytoplasm, and perhaps the axon as well.

The major integral membrane protein of peripheral nerve myelin is protein zero (P0), a member of a very large family of proteins termed the immunoglobulin gene superfamily. This protein makes up about 80% of the protein complement of PNS myelin. Interactions between the extracellular domains of P0 molecules expressed on one layer of the myelin sheath with those of the apposing layer yield a characteristic regular periodicity that can be seen by thin section electron microscopy (Fig. 3.5). This zone, called the intraperiod line, represents the extracellular apposition of the myelin bilayer as it wraps around itself. On the other side of the bilayer, the cytoplasmic side, the highly charged P0 cytoplasmic domain probably functions to neutralize the negative charges on the polar head groups of the phospholipids that make up the plasma membrane itself, allowing the membranes of the myelin sheath to come into close apposition with one another. In electron microscopy, this cytoplasmic apposition appears darker than the intraperiod line and is termed the major dense line. In peripheral nerves, although other molecules are present in small quantities in compact myelin and may have important functions, compaction (i.e., the close apposition of

membrane surfaces without intervening cytoplasm) is accomplished solely by P0–P0 interactions at both extracellular and intracellular (cytoplasmic) surfaces.

Curiously, P0 is present in the CNS of lower vertebrates such as sharks and bony fish, but in terrestrial vertebrates (reptiles, birds, and mammals), P0 is limited to the PNS. CNS myelin compaction in these higher organisms is subserved by proteolipid protein (PLP) and its alternate splice form, DM-20. These two proteins are generated from the same gene, both span the plasma membrane four times, and differ only in that PLP has a small, positively charged segment exposed on the cytoplasmic surface. Why did PLP/DM-20 replace P0 in CNS myelin? Manipulation of PLP and P0 in CNS myelin established an axonotrophic function for PLP in CNS myelin. Removal of PLP from rodent CNS myelin altered the periodicity of compact myelin and produced a late onset axonal degeneration (Griffiths *et al.*, 1998). Replacing PLP with P0 in rodent CNS myelin stabilized compact myelin but enhanced the axonal degeneration (Yin *et al.*, 2006). These and other observations in primary demyelination and inherited myelin diseases have established axonal degeneration as the major cause of permanent disability in diseases such as multiple sclerosis.

Myelin membranes also contain a number of other proteins such as the myelin basic protein, which is a major CNS myelin component, and PMP-22, a protein that is involved in a form of peripheral nerve disease. A large number of naturally occurring gene mutations can affect the proteins specific to the myelin sheath and cause neurological disease. In animals, these mutations have been named according to the phenotype that is produced: the shiverer mouse, the shaking pup, the rumpshaker mouse, the jumpy mouse, the myelin-deficient rat, the quaking mouse, and so forth. Many of these mutations are well characterized, and have provided valuable insights into the role of individual proteins in myelin formation and axonal survival.

### Astrocytes Play Important Roles in CNS Homeostasis

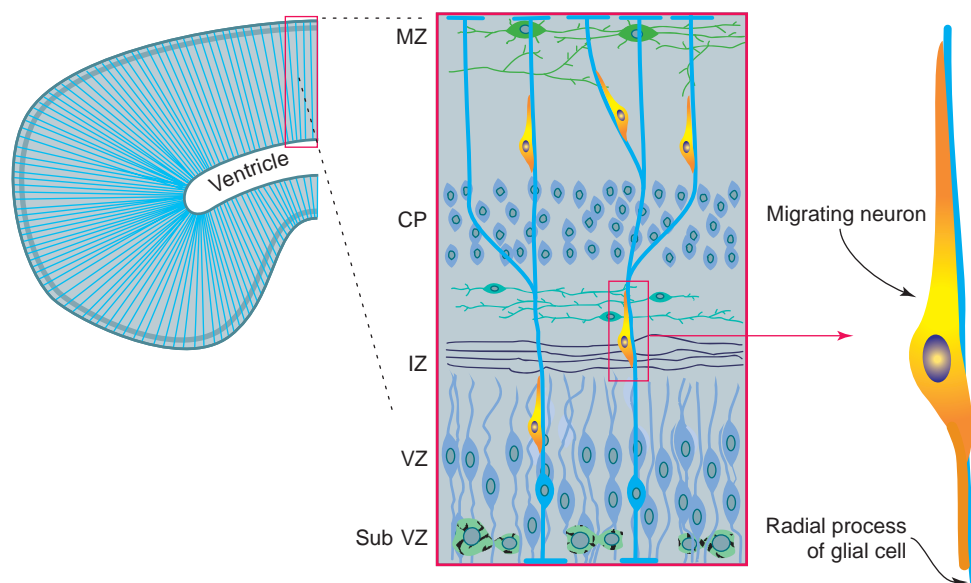

As the name suggests, astrocytes were first described as star-shaped, process-bearing cells distributed throughout the central nervous system. They constitute from 20 to 50% of the volume of most brain areas. Astrocytes appear stellate when stained using reagents that highlight their intermediate filaments, but have complex morphologies when their entire cytoplasm is visualized. The two main forms, protoplasmic and fibrous astrocytes, predominate in gray and white matter, respectively (Fig. 3.8). Embryonically, astrocytes develop from radial glial cells, which transversely

**FIGURE 3.8** The arrangement of astrocytes in human cerebellar cortex. Bergmann glial cells are in red, protoplasmic astrocytes are in green, and fibrous astrocytes are in blue.

compartmentalize the neural tube. Radial glial cells serve as scaffolding for the migration of neurons and play a critical role in defining the cytoarchitecture of the CNS (Fig. 3.9). As the CNS matures, radial glia retract their processes and serve as progenitors of astrocytes. However, some specialized astrocytes of a radial nature are still found in the adult cerebellum and the retina and are known as Bergmann glial cells and Müller cells, respectively.

Astrocytes “fence in” neurons and oligodendrocytes. Astrocytes achieve this isolation of the brain parenchyma by extending long processes projecting to the pia mater and the ependyma to form the glia limitans, by covering the surface of capillaries, and by making a cuff around the nodes of Ranvier. They also ensheath synapses and dendrites and project processes to cell somas (Fig. 3.10). Astrocytes are connected to each other by gap junctions, forming a syncytium that allows ions and small molecules to diffuse across the brain parenchyma. Astrocytes have in common unique cytological and immunological properties that make them easy to identify, including their star shape, the glial end feet on capillaries, and a unique population of large bundles of intermediate filaments. These filaments are composed of an astroglial-specific pro-

**FIGURE 3.9** Radial glia perform support and guidance functions for migrating neurons. In early development, radial glia span the thickness of the expanding brain parenchyma. (Inset) Defined layers of the neural tube from the ventricular to the outer surface: VZ, ventricular zone; IZ, intermediate zone; CP, cortical plate; MZ, marginal zone. The radial process of the glial cell is indicated in blue, and a single attached migrating neuron is depicted at the right.

tein commonly referred to as glial fibrillary acidic protein (GFAP). S-100, a calcium-binding protein, and glutamine synthetase are also astrocyte markers. Ultrastructurally, gap junctions (connexins), desmosomes, glycogen granules, and membrane orthogonal arrays are distinct features used by morphologists to identify astrocytic cellular processes in the complex cytoarchitecture of the nervous system.

For a long time, astrocytes were thought to physically form the blood–brain barrier (considered later in this chapter), which prevents the entry of cells and diffusion of molecules into the CNS. In fact, astrocytes are indeed the blood–brain barrier in lower species. However, in higher species, astrocytes are responsible for inducing and maintaining the tight junctions in endothelial cells that effectively form the barrier. Astrocytes also take part in angiogenesis, which may be important in the development and repair of the CNS. Their role in this important process is still poorly understood.

### Astrocytes Have a Wide Range of Functions

There is strong evidence for the role of radial glia and astrocytes in the migration and guidance of neurons in early development. Astrocytes are a major source of extracellular matrix proteins and adhesion molecules in the CNS; examples are nerve cell–nerve cell adhesion molecule (N-CAM), laminin, fibronectin, cytotactin, and the J-1 family members janusin and tenascin. These

molecules participate not only in the migration of neurons, but also in the formation of neuronal aggregates, so-called nuclei, as well as networks.

Astrocytes produce, *in vivo* and *in vitro*, a very large number of growth factors. These factors act singly or in combination to selectively regulate the morphology, proliferation, differentiation, or survival, or all four, of distinct neuronal subpopulations. Most of the growth factors also act in a specific manner on the development and functions of astrocytes and oligodendrocytes. The production of growth factors and cytokines by astrocytes and their responsiveness to these factors is a major mechanism underlying the developmental function and regenerative capacity of the CNS. During neurotransmission, neurotransmitters and ions are released at high concentration in the synaptic cleft. The rapid removal of these substances is important so that they do not interfere with future synaptic activity. The presence of astrocyte processes around synapses positions them well to regulate neurotransmitter uptake and inactivation (Kettenman and Ransom, 1995). These possibilities are consistent with the presence in astrocytes of transport systems for many neurotransmitters. For instance, glutamate reuptake is performed mostly by astrocytes, which convert glutamate into glutamine and then release it into the extracellular space. Glutamine is taken up by neurons, which use it to generate glutamate and  $\gamma$ -aminobutyric acid, potent excitatory and inhibitory neurotransmitters, respectively (Fig. 3.11). Astrocytes contain ion

**FIGURE 3.10** Astrocytes (in orange) are depicted *in situ* in schematic relationship with other cell types with which they are known to interact. Astrocytes send processes that surround neurons and synapses, blood vessels, and the region of the node of Ranvier and extend to the ependyma, as well as to the pia mater, where they form the glial limitans.

channels for  $K^+$ ,  $Na^+$ ,  $Cl^-$ ,  $HCO_3^-$ , and  $Ca^{2+}$ , as well as displaying a wide range of neurotransmitter receptors.  $K^+$  ions released from neurons during neurotransmission are soaked up by astrocytes and moved away from the area through astrocyte gap junctions. This is known as *spatial buffering*. Astrocytes play a major role in detoxification of the CNS by sequestering metals and a variety of neuroactive substances of endogenous and xenobiotic origin.

In response to stimuli, intracellular calcium waves are generated in astrocytes. Propagation of the  $Ca^{2+}$  wave can be visually observed as it moves across the

**FIGURE 3.11** The glutamate–glutamine cycle is an example of a complex mechanism that involves an active coupling of neurotransmitter metabolism between neurons and astrocytes. The systems of exchange of glutamine, glutamate, GABA, and ammonia between neurons and astrocytes are highly integrated. The postulated detoxification of ammonia and the inactivation of glutamate and GABA by astrocytes are consistent with the exclusive localization of glutamine synthetase in the astroglial compartment.

cell soma and from astrocyte to astrocyte. The generation of  $Ca^{2+}$  waves from cell to cell is thought to be mediated by second messengers, diffusing through gap junctions (see Chapter 11). In the adult brain, gap junctions are present in all astrocytes. Some gap junctions also have been detected between astrocytes and neurons. Thus, they may participate, along with astroglial neurotransmitter receptors, in the coupling of astrocyte and neuron physiology.

In a variety of CNS disorders—neurotoxicity, viral infections, neurodegenerative disorders, HIV, AIDS, dementia, multiple sclerosis, inflammation, and trauma—astrocytes react by becoming hypertrophic and, in a few cases, hyperplastic. A rapid and huge upregulation of GFAP expression and filament formation is associated with astrogliosis. The formation of reactive astrocytes can spread very far from the site of origin. For instance, a localized trauma can recruit astrocytes from as far as the contralateral side, suggesting the existence of soluble factors in the mediation process. Tumor necrosis factor (TNF) and ciliary neurotrophic factors (CNTF) have been identified as key factors in astrogliosis.

## Microglia Are Mediators of Immune Responses in Nervous Tissue

The brain traditionally has been considered an “immunologically privileged site,” mainly because the blood–brain barrier normally restricts the access of immune cells from the blood. However, it is now known that immunological reactions do take place in the central nervous system, particularly during cerebral inflammation. Microglial cells have been termed the tissue macrophages of the CNS, and they function as the resident representatives of the immune system in the brain. A rapidly expanding literature describes microglia as major players in CNS development and in the pathogenesis of CNS disease.

The first description of microglial cells can be traced to Franz Nissl (1899), who used the term “rod cell” to describe a population of glial cells that reacted to brain pathology. He postulated that rod-cell function was similar to that of leukocytes in other organs. Cajal described microglia as part of his “third element” of the CNS—cells that he considered to be of mesodermal origin and distinct from neurons and astrocytes (Ramón y Cajal, 1913).

Del Rio-Hortega (1932) distinguished this third element into microglia and oligodendrocytes. He used silver impregnation methods to visualize the ramified appearance of microglia in the adult brain, and he concluded that ramified microglia could transform into cells that were migratory, ameboid, and phagocytic. Indeed, a hallmark of microglial cells is their ability to become reactive and to respond to pathological challenges in a variety of ways. A fundamental question raised by del Rio-Hortega’s studies was the origin of microglial cells. Some questions about this remain even today.

## Microglia Have Diverse Functions in Developing and Mature Nervous Tissue

On the basis of current knowledge, it appears that most ramified microglial cells are derived from bone marrow-derived monocytes, which enter the brain parenchyma during early stages of brain development. These cells help phagocytose degenerating cells that undergo programmed cell death as part of normal development. They retain the ability to divide and have the immunophenotypic properties of monocytes and macrophages. In addition to their role in remodeling the CNS during early development, microglia secrete cytokines and growth factors that are important in fiber tract development, gliogenesis, and angiogenesis. They are also the major

CNS cells involved in presenting antigens to T lymphocytes. After the early stages of development, ameboid microglia transform into the ramified microglia that persist throughout adulthood (Altman, 1994).

Little is known about microglial function in the healthy adult vertebrate CNS. Microglia constitute a formidable percentage (5–20%) of the total cells in the mouse brain. Microglia are found in all regions of the brain, and there are more in gray than in white matter. The neocortex and hippocampus have more microglia than regions like the brainstem or cerebellum. Species variations also have been noted, as human white matter has three times more microglia than rodent white matter.

Microglia usually have small rod-shaped somas from which numerous processes extend in a rather symmetrical fashion. Processes from different microglia rarely overlap or touch, and specialized contacts between microglia and other cells have not been described in the normal brain. Although each microglial cell occupies its own territory, microglia collectively form a network that covers much of the CNS parenchyma. Because of the numerous processes, microglia present extensive surface membrane to the CNS environment. Regional variation in the number and shape of microglia in the adult brain suggests that local environmental cues can affect microglial distribution and morphology. On the basis of these morphological observations, it is likely that microglia play a role in tissue homeostasis. The nature of this homeostasis remains to be elucidated. It is clear, however, that microglia can respond quickly and dramatically to alterations in the CNS microenvironment.

## Microglia Become Activated in Pathological States

“Reactive” microglia can be distinguished from resting microglia by two criteria: (1) change in morphology and (2) upregulation of monocyte–macrophage molecules (Fig. 3.12). Although the two phenomena generally occur together, reactive responses of microglia can be diverse and restricted to subpopulations of cells within a microenvironment. Microglia not only respond to pathological conditions involving immune activation, but also become activated in neurodegenerative conditions that are not considered immune mediated. This latter response is indicative of the phagocytic role of microglia. Microglia change their morphology and antigen expression in response to almost any form of CNS injury.

**FIGURE 3.12** Activation of microglial cells in a tissue section from human brain. Resting microglia in normal brain (A). Activated microglia in diseased cerebral cortex (B) have thicker processes and larger cell bodies. In regions of frank pathology (C) microglia transform into phagocytic macrophages, which can also develop from circulating monocytes that enter the brain. Arrow in B indicates rod cell. Sections stained with antibody to ferritin. Scale bar = 40  $\mu\text{m}$ .

## CEREBRAL VASCULATURE

Blood vessels form an extremely rich network in the central nervous system, particularly in the cerebral cortex and subcortical gray masses, whereas the white matter is less densely vascularized (Fig. 3.13) (Duvernoy *et al.*, 1981). There are distinct regional patterns of microvessel distribution in the brain. These patterns are particularly clear in certain subcortical structures that constitute discrete vascular territories and in the cerebral cortex, where regional and laminar patterns are striking. For example, layer IV of the primary visual cortex possesses an extremely rich capillary network in comparison with other layers and adjacent regions (Fig. 3.13). Interestingly, most of the inputs from the visual thalamus terminate in this particular layer. Capillary densities are higher in regions containing large numbers of neurons and where synaptic density is high. Progressive occlusion of a large arterial trunk, as seen in stroke, induces an ischemic injury that may eventually lead to necrosis of the brain tissue. The size of the resulting infarction is determined in part by the worsening of the blood circulation through the cerebral microvessels. Occlusion of a large arterial trunk results in rapid swelling of the capillary endothelium and surrounding astrocytes, which may reduce the capillary lumen to about one-third of its normal diameter, pre-

venting red blood cell circulation and oxygen delivery to the tissue. The severity of these changes subsequently determines the time course of neuronal necrosis, as well as the possible recovery of the surrounding tissue and the neurological outcome of the patient. In addition, the presence of multiple microinfarcts caused by occlusive lesions of small cerebral arterioles may lead to a progressively dementing illness, referred to as vascular dementia, affecting elderly humans.

### **The Blood–Brain Barrier Maintains the Intracerebral Milieu**

Capillaries of the central nervous system form a protective barrier that restricts the exchange of solutes between blood and brain. This distinct function of brain capillaries is called the blood–brain barrier (Fig. 3.14) (Bradbury, 1979). Capillaries of the retina have similar properties and are termed the blood–retina barrier. It is thought that the blood–brain and blood–retina barriers function to maintain a constant intracerebral milieu, so that neuronal signaling can occur without interference from substances leaking in from the blood stream. This function is important because of the nature of intercellular communication in the CNS, which includes chemical signals across intercellular spaces. Without a blood–brain barrier, circulating factors in the blood, such as certain hormones,

**FIGURE 3.13** Microvasculature of the human neocortex. (A) The primary visual cortex (area 17). Note the presence of segments of deep penetrating arteries that have a larger diameter than the microvessels and run from the pial surface to the deep cortical layers, as well as the high density of microvessels in the middle layer (layers IVCa and IVCb). (B) The prefrontal cortex (area 9). Cortical layers are indicated by Roman numerals. Microvessels are stained using an antibody against heparan sulfate proteoglycan core protein, a component of the extracellular matrix.

which can also act as neurotransmitters, would interfere with synaptic communication. When the blood–brain barrier is disrupted, edema fluid accumulates in the brain. Increased permeability of the blood–brain barrier plays a central role in many neuropathological

conditions, including multiple sclerosis, AIDS, and childhood lead poisoning, and may also play a role in Alzheimer’s disease. The cerebral capillary wall is composed of an endothelial cell surrounded by a very thin (about 30nm) basement membrane or basal

**FIGURE 3.14** Human cerebral capillary obtained at biopsy. Blood–brain barrier (BBB) capillaries are characterized by the paucity of transcytotic vesicles in endothelial cells (E), a high mitochondrial content (large arrow), and the formation of tight junctions (small arrows) between endothelial cells that restrict the transport of solutes through the interendothelial space. The capillary endothelium is encased within a basement membrane (arrowheads), which also houses pericytes (P). Outside the basement membrane are astrocyte foot processes (asterisk), which may be responsible for the induction of BBB characteristics on the endothelial cells. L, lumen of the capillary. Scale bar =  $1\mu\text{m}$ . From Claudio *et al.* (1995).

lamina. End feet of perivascular astrocytes are apposed against this continuous basal lamina. Around the capillary lies a virtual perivascular space occupied by another cell type, the pericyte, which surrounds the capillary walls. The endothelial cell forms a thin monolayer around the capillary lumen, and a single endothelial cell can completely surround the lumen of the capillary (Fig. 3.14).

A fundamental difference between brain endothelial cells and those of the systemic circulation is the presence in brain of interendothelial tight junctions, also known as zonula occludens. In the systemic circulation, the interendothelial space serves as a diffusion pathway that offers little resistance to most blood solutes entering the surrounding tissues. In contrast, blood–brain barrier tight junctions effectively restrict

the intercellular route of solute transfer. The blood–brain barrier interendothelial junctions are not static seals; rather they are a series of active gates that can allow certain small molecules to penetrate. One such molecule is the lithium ion, used in the control of manic depression.

Another characteristic of endothelial cells of the brain is their low transcytotic activity. Brain endothelium, therefore, is by this index not very permeable. It is of interest that certain regions of the brain, such as the area postrema and periventricular organs, lack a blood–brain barrier. In these regions, the perivascular space is in direct contact with the nervous tissue, and endothelial cells are fenestrated and show many pinocytotic vesicles. In these brain regions, neurons are known to secrete hormones and other factors that require rapid and uninhibited access to the systemic circulation.

Because of the high metabolic requirements of the brain, blood–brain barrier endothelial cells must have transport mechanisms for the specific nutrients needed for proper brain function. One such mechanism is glucose transporter isoform 1 (GLUT-1), which is expressed asymmetrically on the surface of blood–brain barrier endothelial cells. In Alzheimer's disease, the expression of GLUT-1 on brain endothelial cells is reduced. This reduction may be due to a lower metabolic requirement of the brain after extensive neuronal loss. Other specific transport mechanisms on the cerebral endothelium include the large neutral amino acid carrier-mediated system that transports, among other amino acids, L-3,4-dihydroxyphenylalanine (L-dopa), used as a therapeutic agent in Parkinson disease. Also on the surface of blood–brain barrier endothelial cells are transferrin receptors that allow the transport of iron into specific areas of the brain. The amount of iron that is transported into the various areas of the brain appears to depend on the concentration of transferrin receptors on the surface of endothelial cells of that region. Thus, the transport of specific nutrients into the brain is regulated during physiological and pathological conditions by blood–brain barrier transport proteins distributed according to the regional and metabolic requirements of brain tissue.

In general, disruption of the blood–brain barrier causes perivascular or vasogenic edema, which is the accumulation of fluids from the blood around the blood vessels of the brain. This is one of the main features of multiple sclerosis. In multiple sclerosis, inflammatory cells, primarily T cells and macrophages, invade the brain by migrating through the blood–brain barrier and attack cerebral elements as if these elements were foreign antigens. It has been observed by many investigators that the degree of edema accu-

mulation causes the neurological symptoms experienced by people suffering from multiple sclerosis.

Studying the regulation of blood–brain barrier permeability is important for several reasons. Therapeutic treatments for neurological disease need to be able to cross the barrier. Attempts to design drug delivery systems that take therapeutic drugs directly into the brain have been made by using chemically engineered carrier molecules that take advantage of receptors such as that for transferrin, which normally transports iron into the brain. Development of an *in vitro* test system of the blood–brain barrier is of importance in the creation of new neurotropic drugs that are targeted to the brain.

# Subcellular Organization of the Nervous System: Organelles and Their Functions

Cells have many features in common, but each cell type also possesses a functional architecture related to its unique physiology. In fact, cells may become so specialized in fulfilling a particular function that virtually all cellular components may be devoted to it. For example, the machinery inside mammalian erythrocytes is completely dedicated to the delivery of oxygen to the tissues and the removal of carbon dioxide. Toward this end, this cell has evolved a specialized plasma membrane, an underlying cytoskeletal matrix that molds the cell into a biconcave disk, and a cytoplasm rich in hemoglobin. Modification of the cell machinery extends even to the discarding of structures such as the nucleus and the protein synthetic apparatus, which are not needed after the red blood cell matures. In many respects, the terminally differentiated, highly specialized cells of the nervous system exhibit comparable commitment—the extensive development of subcellular components reflects the roles that each plays.

The neuron serves as the cellular correlate of information processing and, in aggregate, all neurons act together to integrate responses of the entire organism to the external world. It is therefore not surprising that the specializations found in neurons are more diverse and complex than those found in any other cell type. Single neurons commonly interact in specific ways with hundreds of other cells—other neurons, astrocytes, oligodendrocytes, immune cells, muscle, and glandular cells. This chapter defines the major functional domains of the neuron, describes the subcellular elements that compose the building blocks of these domains, and examines the processes that create and maintain neuronal functional architecture.

## AXONS AND DENDRITES: UNIQUE STRUCTURAL COMPONENTS OF NEURONS

Neural cells are remarkably complex (Peters *et al.*, 1991). As discussed in Chapter 3, the perikaryon, or cell body, contains the nucleus and the protein synthetic machinery. In neurons, nuclei are large and contain a preponderance of euchromatin. Because protein synthesis must be kept at a high level just to maintain the neuronal extensions, transcription levels in neurons are generally high. In turn, the variety of different polypeptides associated with cellular domains in a neuron requires that many different genes be transcribed constantly.

As mRNAs are synthesized, they move from the nucleus into a protein-synthesizing region termed the “translational cytoplasm,” comprising cytoplasmic (“free”) and membrane-associated polysomes, the intermediate compartment of the smooth endoplasmic reticulum, and the Golgi complex. Neurons have relatively large amounts of translational cytoplasm to accommodate high levels of protein synthesis. This protein synthetic machinery is arranged in discrete intracellular “granules,” termed Nissl substance after the histologist who first discovered these structures in the nineteenth century. The Nissl substance is actually a combination of stacks of rough endoplasmic reticulum (RER), interposed with rosettes of free polysomes. This arrangement is unique to neurons, and its functional significance remains unknown. Most, but not all proteins used by the neuron are synthesized in the perikaryon. During or after synthesis and processing, proteins are packaged into membrane-limited

organelles, incorporated into cytoskeletal elements, or remain as soluble constituents of the cytoplasm. After packaging, membrane proteins are transported to their sites of function.

In general, neurons have two discrete functional domains, the axonal and somatodendritic compartments, each of which encompasses a number of microdomains (Fig. 4.1). The axon classically is defined as the cellular process by which a neuron makes contact with a target cell to transmit information. It provides a conduit for transmitting the action potential to a synapse, and acts as a specialized subdomain for transmission of a signal from neuron to target cell (neuron, muscle, etc.), usually by release of neurotransmitters. Consequently, most axons end in a presynaptic terminal, although a single axon may have hundreds or thousands of presynaptic specializations known as “en passant” synapses along its length. Characteristics of presynaptic terminals are presented in greater detail later.

The axon is the first neuronal process to differentiate during development. A typical neuron has only a single axon that proceeds some distance from the cell body before branching extensively. Usually the longest process of a neuron, axons come in many sizes. In a human adult, axons range in length from a few micrometers for small interneurons to a meter or more for large motor neurons, and they may be even longer in large animals (such as giraffes, elephants, and whales). In mammals and other vertebrates, the longest axons generally extend approximately half the body length.

Axonal diameters also are quite variable, ranging from 0.1 to 20  $\mu\text{m}$  for large myelinated fibers in vertebrates. Invertebrate axons grow to even larger diameters, with the giant axons of some squid species achieving diameters in the millimeter range. Invertebrate axons reach such large diameters because they lack the myelinating glia that speed conduction of the action potential. As a result, axonal caliber must be large to sustain the high rate of conduction needed for the reflexes that permit escape from predators and capture of prey. Although axonal caliber is closely regulated in both myelinated and nonmyelinated fibers, this parameter is critical for those organisms that are unable to produce myelin.

The region of the neuronal cell body where the axon originates has several specialized features. This domain, called the axon hillock, is distinguished most readily by a deficiency of Nissl substance. Therefore, protein synthesis cannot take place to any appreciable degree in this region. Cytoplasm in the vicinity of the axon hillock may have a few polysomes but is dominated by the cytoskeletal and membranous organelles

that are being delivered to the axon. Microtubules and neurofilaments begin to align roughly parallel to each other, helping to organize membrane-limited organelles destined for the axon. The hillock is a region where materials either are committed to the axon (cytoskeletal elements, synaptic vesicle precursors, mitochondria, etc.) or are excluded from the axon (RER and free polysomes, dendritic microtubule-associated proteins). The molecular basis for this sorting is not understood. Cytoplasm in the axon hillock does not appear to contain a physical “sizing” barrier (like a filter) because large organelles such as mitochondria enter the axon readily, whereas only a small number of essentially excluded structures such as polysomes are occasionally seen only in the initial segment of the axon and not in the axon proper. An exception to this general rule is during development when local protein synthesis does take place at the axon terminus or growth cone. In the mature neuron, the physiological significance of this barrier must be considerable because axonal structures are found to accumulate in this region in many neuropathologies, including those due to degenerative diseases (such as amyotrophic lateral sclerosis) and to exposure to neurotoxic compounds (such as acrylamide).

The initial segment of the axon is the region of the axon adjacent to the axon hillock. Microtubules generally form characteristic fascicles, or bundles, in the initial segment of the axon. These fascicles are not seen elsewhere. The initial segment and, to some extent, the axon hillock also have a distinctive specialized plasma membrane. Initially, the plasmalemma was thought to have a thick electrondense coating actually attached to the inner surface of the membrane, but this dense undercoating is in reality separated by 5–10 nm from the plasma membrane inner surface and has a complex ultrastructure. Neither the composition nor the function of this undercoating is known. Curiously, the undercoating is present in the same regions of the initial segment as the distinctive fasciculation of microtubules, although the relationship is not understood.

**FIGURE 4.1** Basic elements of neuronal subcellular organization. The neuron consists of a soma, or cell body, in which the nucleus, multiple cytoplasm-filled processes termed dendrites, and the (usually single) axon are placed. The neuron is highly extended in space; one with a cell body of the size shown here might maintain an axon several miles in length! The unique shape of each neuron is the result of a cooperative interplay between plasma membrane components and cytoskeletal elements. Most large neurons in vertebrates are myelinated by oligodendrocytes in the CNS and by Schwann cells in the PNS. The compact wraps of myelin encasing the axon distal to the initial segment permit rapid conduction of the action potential by a process termed “saltatory conduction” (see Chapter 3).

### Large PNS Neuron with Myelin Sheath

The plasma membrane is specialized in the initial segment and axon hillock in that it contains voltage-sensitive ion channels in large numbers, and most action potentials originate in this domain. The molecular composition of the axon initial segment is very similar to that of the node of Ranvier; however, evidence is growing that the mechanisms that govern the assembly of these components in the two locations are distinct.

Ultimately, axonal structure is geared toward the efficient conduction of action potentials at a rate appropriate to the function of that neuron. This can be seen from both the ultrastructure and the composition of axons. Axons are roughly cylindrical in cross-section with little or no taper. As discussed later, this diameter is maintained by regulation of the cytoskeleton. Even at branch points, daughter axons are comparable in diameter to the parent axon. This constant caliber helps ensure a consistent rate of conduction. Similarly, the organization of membrane components is regulated to this end. Voltage-gated ion channels are distributed to maximize conduction. Sodium channels are distributed more or less uniformly in small nonmyelinated axons, but are concentrated at high density in the regularly spaced unmyelinated gaps, known as nodes of Ranvier. An axon so organized will conduct an action potential or train of spikes long distances with high fidelity at a defined speed. These characteristics are essential for maintaining the precise timing and coordination seen in neuronal circuits.

Nodes of Ranvier in myelinated fibers are flanked by paranodal axoglial junctions comprised of the axolemmal proteins Caspr/Paranodin and Contactin and the glial isoform of neurofascin, Nfasc155. There has been considerable debate about the role of axoglial junctions in assembling the node of Ranvier, but, at least in the PNS, the nodal isoform of Neurofascin, Nfasc186, seems to be the crucial molecule that allows NrCAM, beta-IV spectrin, ankyrin-G and sodium channels to form a nodal complex (Sherman and Brophy, 2005).

Most vertebrate neurons have multiple dendrites arising from their perikarya. Unlike axons, dendrites branch continuously and taper extensively with a reduction in caliber in daughter processes at each branching. In addition, the surface of dendrites is covered with small protrusions, or spines, which are postsynaptic specializations. Although the surface area of a dendritic arbor may be quite extensive, dendrites in general remain in the relative vicinity of the perikaryon. A dendritic arbor may be contacted by the axons of many different and distant neurons or innervated by a single axon making multiple synaptic contacts.

The base of a dendrite is continuous with the cytoplasm of the cell body. In contrast to the axon, Nissl substance extends into dendrites, and certain proteins are synthesized predominantly in dendrites. There is evidence for the selective placement of some mRNAs in dendrites as well (Steward, 1995). For example, whereas RER and polysomes extend well into the dendrites, the mRNAs that are transported and translated in dendrites are a subset of the total neuronal mRNA, deficient in some mRNA species (such as neurofilament mRNAs) and enriched in mRNAs with dendritic functions (such as microtubule-associated protein, MAP2, mRNAs). Also, certain proteins appear to be targeted, postsynthesis, to the dendritic compartment as well.

The shapes and complexity of dendritic arborizations may be remarkably plastic. Dendrites appear relatively late in development and initially have only limited numbers of branches and spines. As development and maturation of the nervous system proceed, the size and number of branches increase. The number of spines increases dramatically, and their distribution may change. This remodeling of synaptic connectivity may continue into adulthood, and environmental effects can alter this pattern significantly. Eventually, in the aging brain, there is a reduction in complexity and size of dendritic arbors, with fewer spines and thinner dendritic shafts. These changes correlate with changes in neuronal function during development and aging.

As defined by classical physiology, axons are structural correlates for neuronal output, and dendrites constitute the domain for receiving information. A neuron without an axon or one without dendrites therefore might seem paradoxical, but such neurons do exist. Certain amacrine and horizontal cells in the vertebrate retina have no identifiable axons, although they do have dendritic processes that are morphologically distinct from axons. Such processes may have both pre- and postsynaptic specializations or may have gap junctions that act as direct electrical connections between two cells. Similarly, the pseudounipolar sensory neurons of dorsal root ganglia (DRG) have no dendrites. In their mature form, these DRG sensory neurons give rise to a single axon that extends a few hundred micrometers before branching. One long branch extends to the periphery, where it may form a sensory nerve ending in muscle spindles or skin. Large DRG peripheral branches are myelinated and have the morphological characteristics of an axon, but they contain neither pre- nor postsynaptic specializations. The other branch extends into the central nervous system, where it forms synaptic contacts. In DRG neurons, the action potential is generated at distal

sensory nerve endings and then is transmitted along the peripheral branch to the central branch and the appropriate central nervous system (CNS) targets, bypassing the cell body. The functional and morphological hallmarks of axons and dendrites are listed in Table 4.1.

**Summary**

Neurons are polarized cells that are specialized for membrane and protein synthesis, as well as for conduction of the nerve impulse. In general, neurons have a cell body, a dendritic arborization that usually is located near the cell body, and an extended axon that may branch considerably before terminating to form synapses with other neurons.

**PROTEIN SYNTHESIS IN NERVOUS TISSUE**

Both neurons and glial cells have strikingly extended morphologies. Protein and lipid components are synthesized and assembled into the membranes of these cell extensions through pathways of membrane biogenesis that have been elucidated primarily in other cell types. However, some adaptations of these general mechanisms have been necessary, due to the specific requirements of cells in the nervous system. Neurons, for example, have devised mechanisms for ensuring that the specific components of the axonal and dendritic plasma membranes are selectively delivered (targeted) to each plasma membrane subdomain.

**TABLE 4.1** Functional and Morphological Hallmarks of Axons and Dendrites<sup>a</sup>

Axons	Dendrites
With rare exceptions, each neuron has a single axon.	Most neurons have multiple dendrites arising from their cell bodies.
Axons appear first during neuronal differentiation.	Dendrites begin to differentiate only after the axon has formed.
Axon initial segments are distinguished by a specialized plasma membrane containing a high density of ion channels and distinctive cytoskeletal organization.	Dendrites are continuous with the perikaryal cytoplasm, and the transition point cannot be distinguished readily.
Axons typically are cylindrical in form with a round or elliptical cross-section.	Dendrites usually have a significant taper and small spinous processes that give them an irregular cross-section.
Large axons are myelinated in vertebrates, and the thickness of the myelin sheath is proportional to the axonal caliber.	Dendrites are not myelinated, although a few wraps of myelin may occur rarely.
Axon caliber is a function of neurofilament and microtubule numbers with neurofilaments predominating in large axons.	The dendritic cytoskeleton may appear less organized, and microtubules dominate even in large dendrites.
Microtubules in axons have a uniform polarity with plus ends distal from the cell body.	Microtubules in proximal dendrites have mixed polarity, with both plus and minus ends oriented distal to the cell body.
Axonal microtubules are enriched in tau protein with a characteristic phosphorylation pattern.	Dendritic microtubules may contain some tau protein, but MAP2 is not present in axonal compartments and is highly enriched in dendrites.
Ribosomes are excluded from mature axons, although a few may be detectable in initial segments.	Both rough endoplasmic reticulum and cytoplasmic polysomes are present in dendrites, with specific mRNAs being enriched in dendrites.
Axonal branches tend to be distal from the cell body.	Dendrites begin to branch extensively near the perikaryon and form extensive arbors in the vicinity of the perikaryon.
Axonal branches form obtuse angles and have diameters similar to the parent stem.	Dendritic branches form acute angles and are smaller than the parent stem.
Most axons have presynaptic specializations that may be <i>en passant</i> or at the ends of axonal branches.	Dendrites are rich in postsynaptic specializations, particularly on the spines that project from the dendritic shaft.
Action potentials usually are generated at the axon hillock and conducted away from the cell body.	Dendrites may generate action potentials, but more commonly they modulate the electrical state of perikaryon and initial segment.
Traditionally, axons are specialized for conduction and synaptic transmission, i.e., neuronal output.	Dendritic architecture is most suitable for integrating synaptic responses from a variety of inputs, i.e., neuronal input.

<sup>a</sup>Neurons typically have two classes of cytoplasmic extensions that may be distinguished using electrophysiological, morphological, and biochemical criteria. Although some neuronal processes may lack one or more of these features, enough parameters can generally be defined to allow unambiguous identification.

The distribution to specific loci of organelles, receptors, and ion channels is critical to normal neuronal function. In turn, these loci must be “matched” appropriately to the local microenvironment and specific cell–cell interactions. Similarly, in myelinating glial cells during the narrow developmental window when the myelin sheath is being formed, these cells synthesize sheets of insulating plasma membrane at an unbelievably high rate. To understand how the plasma membrane of neurons and glia might be modeled to fit individual functional requirements, it is necessary to review the progress that has been made so far in our understanding of how membrane components and organelles are generated in eukaryotic cells.

There are two major categories of membrane proteins: integral and peripheral. Integral membrane proteins, which include the receptors for neurotransmitters (e.g., the acetylcholine receptor subunits) and polypeptide growth factors (e.g., the dimeric insulin receptor), have segments that either are embedded in the lipid bilayer or are bound covalently to molecules that insert into the membrane, such as those proteins linked to glycosyl phosphatidylinositol at their C termini (e.g., Thy-1). A protein with a single membrane-embedded segment and an N terminus exposed at the extracellular surface is said to be of type I, whereas type II proteins retain their N termini on the cytoplasmic side of the plasma membrane. Peripheral membrane proteins are localized on the cytoplasmic surface of the membrane and do not traverse any membrane during their biogenesis. They interact with membranes either by means of their associations with membrane lipids or the cytoplasmic tails of integral proteins, or by means of their affinity for other peripheral proteins (e.g., platelet-derived growth factor receptor-Grb2-Sos-Ras complex). In some cases, they may bind electrostatically to the polar head groups of the lipid bilayer (e.g., myelin basic protein).

### Integral Membrane and Secretory Polypeptides Are Synthesized *de Novo* in the Rough Endoplasmic Reticulum

The subcellular destinations of integral and peripheral membrane proteins are determined by their sites of synthesis. In the secretory pathway, integral membrane proteins and secretory proteins are synthesized in the rough endoplasmic reticulum, whereas the mRNAs encoding peripheral proteins are translated on cytoplasmic “free” polysomes, which are not membrane associated but which may interact with cytoskeletal structures.

The pathway by which secretory proteins are synthesized and exported was first postulated through the

elegant ultrastructural studies on the pancreas by George Palade and colleagues (Palade, 1975). Pancreatic acinar cells were an excellent choice for this work because they are extremely active in secretion, as revealed by the abundance of their RER network, a property they share with neurons. Nissl deduced, in the nineteenth century, that pancreatic cells and neurons would be found to have common secretory properties because of similarities in the distribution of the Nissl substance (Fig. 4.2).

**FIGURE 4.2** The secretory pathway. Transport and sorting of proteins in the secretory pathway occur as they pass through the Golgi before reaching the plasma membrane. Sorting occurs in the *cis*-Golgi network (CGN), also known as the intermediate compartment, and in the *trans*-Golgi network (TGN). Proteins exit from the Golgi at the TGN. The default pathway is the direct route to the plasma membrane. Proteins bound for regulated secretion or transport to endosomes are diverted from the default path by means of specific signals. In endocytosis, one population of vesicles is surrounded by a clathrin cage and is destined for late endosomes.

Pulse–chase radioautography has revealed that in eukaryotic cells newly synthesized secretory proteins move from the RER to the Golgi apparatus, where the proteins are packaged into secretory granules and transported to the plasma membrane across which they are released by exocytosis. Pulse–chase studies in neurons reveal a similar sequence of events for proteins transported into the axon. Unraveling of the detailed molecular mechanisms of the pathway began with the successful reconstitution of secretory protein biosynthesis *in vitro* and the direct demonstration that, very early during synthesis, secretory proteins are translocated into the lumen of RER vesicles, prepared by cell fractionation, termed microsomes. A key observation here was that the fate of the protein was sealed as a result of encapsulation in the lumen of the RER at the site of synthesis. This cotranslational insertion model provided a logical framework for understanding the synthesis of integral membrane proteins with a transmembrane orientation.

The process by which integral membrane proteins are synthesized closely follows the secretory pathway, except that integral proteins are of course not released from the cell, but instead remain bound to cellular membranes. Synthesis of integral proteins begins with synthesis of the nascent chain on a polysome that is not yet bound to the RER membrane (Fig. 4.3). Emergence of the N terminus of the nascent protein from the protein synthesizing machinery allows a ribonucleoprotein, a signal recognition particle (SRP), to bind to an emerging hydrophobic signal sequence and prevent further translation (Walter and Johnson, 1994). Translation arrest is relieved when SRP docks with its cognate receptor in the RER and dissociates from the signal sequence in a process that requires GTP. Synthesis of transmembrane proteins on RER is an extremely energy-efficient process. The passage of a fully formed and folded protein through a membrane is thermodynamically formidably expensive; it is infinitely “cheaper” for cells to thread amino acids, in tandem, through a membrane during initial protein synthesis. Protein synthesis then resumes, and the emerging polypeptide chain is translocated into the RER membrane through a conceptualized “aqueous pore” termed the “translocon.”

A few polypeptides deviate from the common pathway for secretion. For example, certain peptide growth factors, such as basic fibroblast growth factor and ciliary neurotrophic factor, are synthesized without signal peptide sequences but are potent biological modulators of cell survival and differentiation. These growth factors appear to be released under certain conditions, although the mechanisms for such release are still controversial. One possibility is that release of

**FIGURE 4.3** Translocation of proteins across the rough endoplasmic reticulum (RER). Integral membrane and secretory protein synthesis begins with partial synthesis on a free polysome not yet bound to the RER. The N-terminus of the nascent protein emerges and allows a ribonucleoprotein, signal recognition particle (SRP), to bind to the hydrophobic signal sequence and prevent further translation. Translation arrest is relieved once the SRP docks with its receptor at the RER and dissociates from the signal sequence in a GTP-dependent process. Once protein synthesis resumes, translocation occurs through an aqueous pore termed the translocon, which includes the translocating chain associating membrane protein (TRAM). The signal sequence is removed by a signal peptidase in the RER lumen.

these factors may be associated primarily with cellular injury.

Two cotranslational modifications commonly are associated with the emergence of the polypeptide on the luminal face of the RER. First, an N-terminal hydrophobic signal sequence that is used for insertion into the RER usually is removed by a signal peptidase. Second, oligosaccharides rich in mannose sugars are transferred from a lipid carrier, dolichol phosphate, to the side chains of asparagine residues (Kornfeld and Kornfeld, 1985). The asparagines must be in the sequence N X T (or S), and they are linked to mannose sugars by two molecules of *N*-acetylglucosamine. The significance of glycosylation is not well understood, and furthermore, it is not a universal feature of integral membrane proteins: some proteins, such as

**FIGURE 4.4** (A) General mechanisms of vesicle targeting and docking in the ER and Golgi. Assembly of coat proteins (COPs) around budding vesicles is driven by ADP-ribosylation factors (ARFs) in a GTP-dependent fashion. Dissociation of the coat is triggered by hydrolysis of GTP bound to ARF, which is stimulated by a GTPase-activating protein (GAP) in the Golgi membrane. The cycle of coat assembly and disassembly can continue when replacement of GDP on ARF by GTP is catalyzed by a guanine nucleotide exchange factor (GEF). Fusion of vesicles with target membrane in the Golgi is regulated by a series of proteins, including NSF, soluble NSF attachment proteins (SNAPs), and SNAP receptors (SNAREs), which together assist vesicle docking with target membrane. SNAREs on vesicles (v-SNAREs) are believed to associate with corresponding t-SNAREs on target membrane. (B) Mechanisms of vesicle targeting and docking in the synaptic terminal. The synaptic counterpart of v-SNARE is synaptobrevin (also known as VAMP), and syntaxin corresponds to t-SNARE. SNAP-25 is an accessory protein that binds to syntaxin. Synaptotagmin is believed to be the Ca<sup>2+</sup> sensitive regulatory protein in the complex that binds to syntaxin. Neurexins appear to have a role in conferring Ca<sup>2+</sup> sensitivity to these interactions.

ticularly important and diverse category of plasma membrane proteins in neurons and myelinating glial cells), however, many variations on this basic theme have been found. Simply stated:

1. Signal sequences for membrane insertions need not be only N-terminal; those that lie within a polypeptide sequence are not cleaved.
2. A second type of signal, a “halt” or “stop” transfer signal, functions to arrest translocation through the membrane bilayer. The halt transfer signal is also hydrophobic and usually is flanked by positive charges. This arrangement effectively stabilizes a polypeptide segment in the RER membrane bilayer.
3. The sequential display in tandem of insertion and halt transfer signals in a polypeptide as it is being synthesized ultimately determines its disposition with respect to the phospholipid bilayer, and thus its final topology in its target membrane. By synthesizing transmembrane polypeptides in this way, virtually any topology may be generated.

the proteolipid proteins of CNS myelin, neither lose their signal sequence nor become glycosylated.

In general, however, for the vast majority of polypeptides destined for release from the cell (secretory polypeptides), an N-terminal “signal sequence” first mediates the passage of the protein into the RER and is cleaved immediately from the polypeptide by a signal peptidase residing on the luminal side of the RER. For proteins destined to remain as permanent residents of cellular membranes (and these form a par-

### Newly Synthesized Polypeptides Exit from the RER and Are Moved Through the Golgi Apparatus

When the newly synthesized protein has established its correct transmembrane orientation in the RER, it is incorporated into vesicles and must pass through the Golgi complex before reaching the plasma membrane (Fig. 4.2). For membrane proteins, the Golgi serves two major functions: (1) it sorts and targets proteins and, (2) it performs further posttranslational modifications,

particularly on the oligosaccharide chains that were added in the RER. Sorting takes place in the *cis*-Golgi network (CGN), and in the *trans*-Golgi network (TGN), whereas sculpting of oligosaccharides is primarily the responsibility of the *cis*-, *medial*-, and *trans*-Golgi stacks. The TGN is a tubulovesicular network wherein proteins are targeted to the plasma membrane or to organelles.

The CGN serves an important sorting function for proteins entering the Golgi from the RER. Because most proteins that move from the RER through the secretory pathway do so by default, any resident endoplasmic reticulum proteins must be restrained from exiting or returned promptly to the RER from the CGN should they escape. Although no retention signal has been demonstrated for the endoplasmic reticulum, two retrieval signals have been identified: a Lys-Asp-Glu-Leu or KDEL sequence in type I proteins and the Arg-Arg or RR motif in the first five amino acids of proteins with a type II orientation in the membrane. The KDEL tetrapeptide binds to a receptor called Erd 2 in the CGN, and the receptor-ligand complex is returned to the RER. There may also be a receptor for the N arginine dipeptide; alternatively, this sequence may interact with other components of the retrograde transport machinery, such as microtubules.

Movement of proteins between Golgi stacks proceeds by means of vesicular budding and fusion (Rothman and Wieland, 1996). The essential mechanisms for budding and fusion have been shown to require coat proteins (COPs) in a manner that is analogous to the role of clathrin in endocytosis. Currently, two main types of COP complex, COPI and COPII, have been distinguished. Although both have been shown to coat vesicles that bud from the endoplasmic reticulum, they may have different roles in membrane trafficking. Coat proteins provide the external framework into which a region of a flattened Golgi cisternae can bud and vesiculate. A complex of these COPs forms the coatamer (coat protomer) together with a p200 protein, AP-1 adaptins, and a family of GTP-binding proteins called ADP-ribosylation factors (ARFs). Immunolocalization of one of the coatamer proteins,  $\beta$ -COP, predominantly to the CGN and *cis*-Golgi indicates that these proteins may also take part in vesicle transport into the Golgi (Fig. 4.4). The function of ARF is to drive the assembly of the coatamer and therefore vesicle budding in a GTP-dependent fashion. Dissociation of the coat is triggered when hydrolysis of the GTP bound to ARF is stimulated by a GTPase-activating protein (GAP) in the Golgi membrane. The cycle of coat assembly and disassembly can continue when the replacement of GDP on ARF by GTP is catalyzed by a guanine nucleotide exchange factor (GEF).

Fusion of vesicles with their target membrane in the Golgi apparatus is believed to be regulated by a series of proteins, *N*-ethylmaleimide-sensitive factor (NSF), soluble NSF attachment proteins (SNAPs), and SNAP receptors (SNAREs), which together assist the vesicle in docking with its target membrane. The emerging view is that complementary SNAREs on membranes destined to fuse (e.g., synaptic vesicles and the presynaptic membrane) are fundamentally responsible for driving membrane fusion. In addition, Rabs, a family of membrane-bound GTPases, act in concert with their own GAPs, GEFs, and a cytosolic protein that dissociates Rab-GDP from membranes after fusion called guanine-nucleotide dissociation inhibitor. Rabs are believed to regulate the action of SNAREs, the proteins directly engaged in membrane-membrane contact prior to fusion. The tight control necessary for this process and the importance of ensuring that vesicle fusion takes place only at the appropriate target membrane may explain why eukaryotic cells contain so many Rabs, some of which are known to take part specifically in the internalization of endocytic vesicles at the plasma membrane (Fig. 4.2).

Exocytosis of the neurotransmitter at the synapse must occur in an even more finely regulated manner than endocytosis. The proteins first identified in vesicular fusion events in the secretory pathway (namely NSF, SNAPs, and SNAREs or closely related homologues) appear to play a part in the fusion of synaptic vesicles with the active zones of the presynaptic neuronal membrane (Fig. 4.4) (Jahn and Scheller, 2006).

Originally a distinction was made between so-called v-SNAREs and t-SNAREs reflecting their different locations in the donor and acceptor compartments. An example of specificity is the fact that the synaptic counterpart of vSNARE is synaptobrevin (also known as vesicle-associated membrane protein (VAMP)), and syntaxin corresponds to t-SNARE. VAMP does not facilitate fusion with endocytotic vesicle compartments. SNAP-25 is an accessory protein that binds to syntaxin. In the constitutive pathway, such as between the RER and Golgi apparatus, assembly of the complex at the target membrane promotes fusion. However, at the presynaptic membrane,  $\text{Ca}^{2+}$  influx is required to stimulate membrane fusion. Synaptotagmin is believed to be the  $\text{Ca}^{2+}$ -sensitive regulatory protein in the complex that binds syntaxin. Neurexins appear to have a role in regulation as well, because, in addition to interacting with synaptotagmin, they are the targets of black widow spider venom ( $\alpha$ -latrotoxin, which deregulates the  $\text{Ca}^{2+}$ -dependent exocytosis of the neurotransmitter. However, a superficially disturbing lack of specificity in the ability of other membrane-bound SNAREs to complex indicates that much remains to

be learned about the regulation of SRAE-mediated membrane fusion.

When comparing secretion in slow-releasing cells, such as the pancreatic ( $\beta$ )-cell, and neurotransmitter release at the neuromuscular junction, two differences stand out. First, the speed of neurotransmitter release is much greater both in release from a single vesicle and in total release in response to a specific signal. Releasing the contents of a single synaptic vesicle at a mouse neuromuscular junction takes from 1 to 2 ms, and the response to an action potential involving the release of many synaptic vesicles is over in approximately 5 ms. In contrast, releasing the insulin in a single secretory granule by a pancreatic ( $\beta$ )-cell takes from 1 to 5 s, and the full release response may take from 1 to 5 min. A 103- to 105-fold difference in rate is an extraordinary range, making neurotransmitter release one of the fastest biological events routinely encountered, but this speed is critical for a properly functioning nervous system.

A second major difference between slow secretion and fast secretion is seen in the recycling of vesicles. In the pancreas, secretory vesicles carrying insulin are used only once, and so new secretory vesicles must be assembled *de novo* and released from the TGN to meet future requirements. In the neuron, the problem is that the synapse may be at a distance of 1 m or more from the protein synthetic machinery of the perikaryon, and so newly assembled vesicles even traveling at rapid axonal transport rates (see later) may take more than a day to arrive. Now, the number of synaptic vesicles released in 15 min of constant stimulation at a single frog neuromuscular junction has been calculated to be on the order of 105 vesicles, but a single terminal may have only a few hundred vesicles at any one time. These measurements would make no sense if synaptic vesicles had to be replaced constantly through new synthesis in the perikaryon, as is the case with insulin-carrying vesicles. The reason that these numbers are possible is that synaptic vesicles are taken up locally by endocytosis, refilled with neurotransmitter, and reutilized at a rate fast enough to keep up with normal physiological stimulation levels. This takes place within the presynaptic terminal, and evidence shows that these recycled synaptic vesicles are used preferentially. Such recycling does not require protein synthesis because the classical neurotransmitters are small molecules, such as acetylcholine, or amino acids, such as glutamate, that can be synthesized or obtained locally.

Significantly, neurons have fast and slow secretory pathways operating in parallel in the presynaptic terminal (Sudhof, 2004). Synapses that release classical neurotransmitters (acetylcholine, glutamate, etc.)

with these fast kinetics also contain dense core granules containing neuropeptides (calcitonin gene-related peptide, substance P, etc.) that are comparable to the secretory granules of the pancreatic ( $\beta$ )-cell. These are used only once because neuropeptides are produced from large polypeptide precursors that must be made by protein synthesis in the cell body. The release of neuropeptides is relatively slow; as is the case in endocrine release, neuropeptides serve primarily as modulators of synaptic function. The small clear synaptic vesicles containing the classic neurotransmitters can in fact be depleted pharmacologically from the presynaptic terminal, whereas the dense core granules remain. These observations indicate that even though fast and slow secretory mechanisms have many similarities and may even have common components, in neurons they can operate independent of one another.

### Proteins Exit the Golgi Complex at the *trans*-Golgi Network

Most of the N-linked oligosaccharide chains acquired at the RER are remodeled in the Golgi cisternae, and while the proteins are in transit, another type of glycosyl linkage to serine or threonine residues through N-acetylgalactosamine can also be made. Modification of existing sugar chains by a series of glycosidases and the addition of further sugars by glycosyl transferases occur from the *cis* to the *trans* stacks. Some of these enzymes have been localized to particular cisternae. For example, the enzymes ( $\beta$ )-1,4-galactosyltransferase and ( $\alpha$ )-2,6-sialyltransferase are concentrated in the *trans*-Golgi. How they are retained there is a matter of some debate. One idea is that these proteins are anchored by oligomerization. Another view is that the progressively rising concentration of cholesterol in membranes more distal to the ER in the secretory pathway increases membrane thickness, which in turn anchors certain proteins and causes an arrest in their flow along the default route.

The default or constitutive pathway seems to be the direct route to the plasma membrane taken by vesicles that bud from the TGN (Fig. 4.2). This is how, in general, integral plasma membrane proteins reach the cell surface. Proteins bound for regulated secretion or for transport to endosomes and from there to lysosomes are diverted from the default path by means of specific signals. It has been assumed that the sorting of proteins for their eventual destination takes place at the TGN itself. However, recent analyses of the three-dimensional structure of the TGN have provoked a revision of this view. These studies have shown that the TGN is tubular, with two major types of vesicles that bud from distinct populations of tubules. The

implication is that sorting may already have occurred in the *trans*-Golgi prior to the protein's arrival at the TGN. One population of vesicles consists of those surrounded by the familiar clathrin cage, which are destined for late endosomes. The other population appears to be coated in a lace-like structure, which may prove to be made from the elusive coat protein required for vesicular transport to the plasma membrane. The  $\beta$ -COP protein and related coatomer proteins active in more proximal regions of the secretory pathway are absent from the TGN.

### Endocytosis and Membrane Cycling Occurs in the *trans*-Golgi Network

Two types of membrane invagination occur at the surface of mammalian cells and are clearly distinguishable by electron microscopy. The first type is a caveola, which has a thread-like structure on its surface made of the protein caveolin. Caveolae mediate the uptake of small molecules and may also have a role in concentrating proteins linked to the plasma membrane by the glycosylphosphatidylinositol anchor. Demonstration of the targeting of protein tyrosine kinases to caveolae by the tripeptide signal MGC (Met-Gly-Cys) also suggests that caveolae may function in signal transduction cascades.

The other type of endocytic vesicle at the cell surface is that coated with the distinctive meshwork of clathrin triskelions. The triskelion comprises three copies of a clathrin heavy chain and three copies of a clathrin light chain (Maxfield and McGraw, 2004). The ease with which these triskelions can assemble into a cage structure demonstrates how they promote the budding of a vesicle from a membrane invagination. Clathrin binds selectively to regions of the cytoplasmic surface of membranes that are selected by adaptins. The AP-2 complex, which is primarily active at the plasma membrane, consists of 100-kDa  $\alpha$  and  $\beta$  subunits and two subunits of 50 and 17kDa each. AP-1 complexes localize to the TGN and have  $\gamma$  and subunits of 100kDa together with smaller polypeptides of 46 and 19kDa. Adaptins bind to the cytoplasmic tails of membrane proteins, thus recruiting clathrin for budding at these sites.

A further component of the endocytic complex at the plasma membrane is the GTPase dynamin, which seems to be required for the normal budding of coated vesicles during endocytosis. Dynamins are a family of 100-kDa GTPases found in both neuronal and non-neuronal cells that may interact with the AP-2 component of a clathrin-coated pit (Murthy and De Camilli, 2003). Oligomers of dynamin form a ring at the neck of a budding clathrin-coated vesicle, and GTP hydroly-

ysis appears to be necessary for the coated vesicle to pinch off from the plasma membrane. The existence of a specific neuronal form of dynamin (dynamin I) may be a manifestation of the unusually rapid rate of synaptic vesicle recycling.

The primary function of clathrin-coated vesicles at the plasma membrane is to deliver membrane proteins together with any ligands bound to them to the early endosomal apparatus. Regulation of membrane cycling in the endosomal compartment is likely to include the Rab family of small GTP-binding proteins. Indeed, each stage of the endocytic pathway may have its own Rab protein to ensure efficient targeting of the vesicle to the appropriate membrane. Rab6 is believed to have a role in transport from the TGN to endosomes, whereas Rab9 may regulate vesicular flow in the reverse direction. In neurons, Rab5a has a role in regulating the fusion of endocytic vesicles and early endosomes and appears to function in endocytosis from both somatodendritic domains and the axon. The association of the protein with synaptic vesicles in nerve terminals, attached presumably by means of its isoprenoid tail, also suggests that early endosomal compartments may have a role in the packaging and recycling of synaptic vesicles.

### How Are Peripheral Membrane Proteins Targeted to Their Appropriate Destinations?

Peripheral membrane proteins are synthesized in the same type of free polysome in which the bulk of the cytosolic proteins are made. However, the cell must ensure that these membrane proteins are sent to the plasma membrane rather than allowed to attach in a haphazard way to other intracellular organelles. The fact that a complex machinery has evolved to ensure the correct delivery of integral membrane proteins suggests that some equivalent targeting mechanism must exist for proteins that attach to the cytoplasmic surface of the plasma membrane. Such proteins are translated on "free" polysomes, but these polysomes are associated with cytoskeletal structures and are not distributed uniformly throughout the cell body. In a number of cases, mRNAs that encode soluble cytosolic proteins are concentrated in discrete regions of the cell, resulting in a local accumulation of the translated protein close to the site of action. For some peripheral membrane proteins, this is the plasma membrane.

Evidence that this mechanism might operate in peripheral membrane protein synthesis came from studies showing biochemically and by *in situ* hybridization that mRNAs encoding the myelin basic proteins are concentrated in the myelinating processes that extend from the cell body of oligodendrocytes

(Colman *et al.*, 1982). As in oligodendrocytes, Schwann cells also transport MBP mRNA by microtubule-based transport, which also appears to require specialized cytoplasmic channels called Cajal bands (Court *et al.*, 2004).

Myelin basic protein may be a special case because of its very strong positive charge and consequent propensity for binding promiscuously to the negatively charged polar head groups of membrane lipids. Nevertheless, the fact that actin mRNAs are localized to the leading edge of cultured myocytes and mRNA for the microtubule-associated protein MAP2b is concentrated in the dendrites of neurons suggest that targeting by local synthesis is more common than originally thought. This mechanism is probably less important for peripheral membrane proteins that associate with the cytoplasmic surface of the plasma membrane by means of strong specific associations with proteins already located at the membrane because such proteins would act as specific receptors. Because only selected cytoplasmic mRNAs are localized to the periphery, the process is specific. However, no mRNAs are localized exclusively to the periphery, and a significant fraction typically is localized proximal to the nucleus in a region rich with the translational and protein-processing machinery of the cell (the Nissl substance or translational cytoplasm).

### Summary

Membrane biogenesis and protein synthesis in neurons and glial cells are accomplished by the same mechanisms that have been worked out in great detail in other cell types. Integral membrane proteins are synthesized in the rough endoplasmic reticulum, and peripheral membrane proteins are products of cytoplasmic-free ribosomes that are found in the cell sap. For transmembrane proteins and secretory polypeptides, synthesis in the RER is followed by transport to the Golgi apparatus, where membranes and proteins are sorted and targeted for delivery to precise intracellular locations. It is likely that the neuron and glial cell have evolved additional highly specialized mechanisms for membrane and protein sorting and targeting because these cells are so greatly extended in space, although these additional mechanisms have yet to be fully described. The basic features of the process of secretion, which includes neurotransmitter delivery to presynaptic terminals, are beginning to be understood as well. The key features of this process are apparently common to all cells, including yeast, although the neuron has developed certain specializations and modifications of the secretory pathway that reflect its unique properties as an excitable cell.

## CYTOSKELETONS OF NEURONS AND GLIAL CELLS

The cytoskeleton of eukaryotic cells is an aggregate structure formed by three classes of cytoplasmic structural proteins: microtubules (tubulins), microfilaments (actins), and intermediate filaments. Each of these elements exists concurrently and independently in overlapping cellular domains. Most cell types contain one or more examples of each class of cytoskeletal structure, but there are exceptions. For example, mature mammalian erythrocytes contain no microtubules or intermediate filaments, but they do have highly specialized actin cytoskeletons. Among cells of the nervous system, the oligodendrocyte is unusual in that it contains no cytoplasmic intermediate filaments. Typically, each cell type in the nervous system has a unique complement of cytoskeletal proteins that are important for the differentiated function of that cell type.

Although the three classes of cytoskeletal elements interact with each other and with other cellular structures, all three are dynamic structures rather than passive structural elements. Their aggregate properties form the basis of cell morphologies and plasticity in the nervous tissue. In many cases, the cytoskeleton is biochemically specialized for a particular cell type, function, and developmental stage. Each type of cytoskeletal element has unique functions essential for a functional nervous system.

### Microtubules Are an Important Determinant of Cell Architecture

Microtubules are near ubiquitous cytoskeletal components in eukaryotes (Hyams and Lloyd, 1994). They play key roles in intracellular transport, are a primary determinant of cell morphology, form the structural correlate of the mitotic spindle, and are the functional core of cilia. Microtubules are very abundant in the nervous system, and tubulin subunits of microtubules may constitute more than 10% of total brain protein. As a result, many fundamental properties of microtubules were defined with microtubule protein from brain extracts. However, neuronal microtubules have biochemical specializations to meet the unique demands imposed by neuronal size and shape.

Intracellular transport and generation of cell morphologies are the most important roles played by microtubules in the nervous system. In part, this comes from their ability to organize cytoplasmic polarity. Microtubules *in vitro* are dynamic, polar structures with plus and minus ends that correspond to the fast- and slow-growing ends, respectively. In contrast, both

stable and labile microtubules can be identified *in vivo*, where they help define both microscopic and macroscopic aspects of intracellular organization in cells. Microtubule organization, stability, and composition are all highly regulated in the nervous system.

By electron microscopy, microtubules appear as hollow tubes 25 nm in diameter and can be hundreds of micrometers in length in axons. Microtubule walls typically comprise 13 protofilaments formed by a linear arrangement of globular subunits. Globular subunits in microtubule walls are heterodimers of  $\alpha$ - and  $\beta$ -tubulin, with a variety of microtubule-associated proteins (MAPs) binding to microtubule surfaces.

Neuronal microtubules are remarkable for their genetic and biochemical diversity. Multiple genes exist for both  $\alpha$ - and  $\beta$ -tubulins. These genes are expressed differentially according to cell type and developmental stage. Some genetic isotypes are expressed ubiquitously, whereas others are expressed only at specific times in development, in specific cell types, or both. Most tubulin genes are expressed in nervous tissue, and some are enriched or specific to neurons. Specific tubulin isotypes prepared in a pure form, vary in assembly kinetics and ability to bind ligands. However, when more than one isotype is expressed in a single cell, such as a neuron, they coassemble into microtubules with mixed composition.

The most common posttranslational modifications of tubulins are tyrosination–detyrosination, acetylation–deacetylation, and phosphorylation. The first two are intimately linked to assembled microtubules, but little is known about physiological functions for any tubulin modification. Most  $\alpha$ -tubulin isotypes are synthesized with a Glu-Tyr dipeptide at the C terminus (Tyr-tubulin), but the tyrosine is removed by tubulin carboxypeptidase after incorporation into a microtubule, leaving a terminal glutamate (Glu-tubulin). Microtubules assembled for a longer time are enriched in Glu-tubulin, but when Glu-tubulin enriched microtubules are disassembled, liberated  $\alpha$ -tubulins are rapidly retyrosinated by tubulin tyrosine ligase. The tyrosination state of  $\alpha$ -tubulin does not affect assembly–disassembly kinetics *in vitro*, but detyrosination may affect interactions of microtubules with other cellular structures. Concurrent with detyrosination,  $\alpha$ -tubulins can be subject to a specific acetylation. Tubulin acetylation was first described in flagellar tubulins, but this modification is widespread in neurons and many other cell types. Acetylase acts preferentially on  $\alpha$ -tubulin in assembled microtubules, so long-lived or stable microtubules tend to be acetylated, but the distribution of microtubules rich in acetylated tubulin may not be identical to that of Glu-tubulin. Acetylated  $\alpha$ -tubulin is rapidly deacetylated upon microtubule

disassembly, but acetylation does not alter microtubule stability *in vitro*.

Tubulin phosphorylation involves  $\beta$ -tubulin and may be restricted to an isotype expressed preferentially in neurons and neuron-like cells. Various kinases can phosphorylate tubulin *in vitro*, but the endogenous kinase is unknown. Effects of phosphorylation on assembly are unknown, but phosphorylation is upregulated during neurite outgrowth. As with  $\alpha$ -tubulin modifications, the physiological role of phosphorylation on neuronal  $\beta$ -tubulin has yet to be determined. Other posttranslational modifications have been reported, but their significance and distribution in the nervous system are not well documented.

The biochemical diversity of microtubules is increased through association of different MAPs with different populations of microtubules (Table 4.2). The significance of microtubule diversity is incompletely understood, but may include functional differences as well as variations in assembly and stability. In particular, MAP composition may define specific neuronal domains. For example, MAP-2 is restricted to dendritic regions of the neuron, whereas tau proteins are modified differentially in axons. Similarly, oligodendrocyte progenitors transiently express a novel MAP-2 isoform with an additional microtubule-binding repeat; that is, 4-repeat MAP-2c or MAP-2d. This MAP is in cell bodies but not in processes, suggesting that MAP-2d might have a role distinct from its capacity to bundle microtubules (Vouyiouklis and Brophy, 1995).

MAPs in nervous tissue fall into two heterogeneous groups: tau proteins and high molecular weight MAPs. Tau proteins have been of intense interest because posttranslationally modified tau proteins are the primary constituents of neurofibrillary tangles in the brains of Alzheimer patients. Tau proteins are primarily neuronal MAPs, although tau may be found outside neurons as well. Tau binds to microtubules during assembly–disassembly cycles with a constant stoichiometry and promotes microtubule assembly and stabilization. Tau exists in a number of molecular weight isoforms expressed differentially in different regions of the nervous system and developmental stage. For example, tau proteins in the adult CNS are typically 60–75 kDa, whereas PNS axons contain a higher molecular mass tau of 100 kDa. Different isoforms of tau protein are generated from a single mRNA by alternative splicing, and additional heterogeneity is produced by phosphorylation.

High molecular weight MAPs are a diverse group of largely unrelated proteins found in various tissues, some of which are brain specific. All have molecular masses greater than 1300 kDa and form side arms protruding from microtubule surfaces. Many MAPs may

TABLE 4.2 Major Microtubule Proteins and Microtubule Motors in Mammalian Brain

Location and Function	
Tubulins	
$\alpha$ - and $\beta$ -tubulins	Neurons, glia, and nonneuronal cells except mature mammalian erythrocytes. Multigene family with some genes expressed preferentially in brain, whereas others are ubiquitous. Primary structural polypeptides of microtubules.
$\gamma$ -Tubulin	Present near microtubule-organizing center in all microtubule-containing cells. Needed for nucleation of microtubules.
Microtubule-Associated Proteins (MAPs)	
MAP-1a/1b	Widely expressed in neurons and glia, including both axons and dendrites; developmentally regulated phosphoproteins.
MAP-2a/2b MAP-2c	Dendrite-specific MAPs. The smaller MAP-2c is regulated developmentally, becoming restricted to spines in adults, whereas 2a and 2b are major phosphoproteins in adult brain.
LMW tau	Tau proteins are enriched in axons with a distinctive phosphorylation pattern. A single tau gene is alternatively spliced to give multiple isoforms.
HMW tau	
Microtubule Severing Proteins	
Katanin	Enriched at the microtubule organizing center and thought to be important in the release of microtubules for transport into axons and dendrites.
Motor Proteins	
Kinesins (kinesin-1s, kinesin-2s, kinesin-3s, and others)	Kinesin-1s are plus-end directed motors associated with membrane-bound organelles and moving them in fast axonal transport. The other members of the kinesin family are a diverse set of motor proteins with a kinesin-related motor domain and varied tails. Many are regulated developmentally and some are mitotic motors, restricted to dividing cells.
Axonemal dynein	A set of minus-end-directed microtubule motors associated with cilia and flagella, such as ependymal cells.
Cytoplasmic dynein	Cytoplasmic forms may be involved in the axonal transport of either organelles or cytoskeletal elements.

participate in microtubule assembly and cytoskeletal organization. Traditionally, high molecular weight MAPs comprise five polypeptides: MAPs 1a, 1b, 1c, 2a, and 2b. MAP-2 proteins are closely related and located primarily in dendrites. In contrast, the polypeptides known as MAP-1 are unique polypeptides with little sequence homology. MAPs 1a and 1b are expressed widely and regulated developmentally. MAPs 1a, 1b, and 2 are all thought to play important roles in stabilizing and organizing the microtubule cytoskeleton.

In most cell types, cytoplasmic microtubules are dynamic, although stable microtubule segments are found in all cells. In nonneuronal cells, such as astrocytes and other glia, microtubules typically are anchored in centrosomal regions that serve as microtubule-organizing centers. As a result, their cytoplasmic microtubules are oriented with plus ends at the cell periphery. The biochemistry of microtubule-organizing centers is not fully understood, but they contain a novel tubulin subunit,  $\gamma$ -tubulin, which functions as a microtubule nucleating protein. In contrast, dendritic and axonal microtubules of neurons are not continuous with a microtubule-organizing center, so alternate mechanisms must exist for their stabilization and organization. The situation is complicated further

because dendritic and axonal microtubules differ in both composition and organization. Both axonal and dendritic microtubules are nucleated at the microtubule-organizing center but are subsequently released for delivery to the appropriate compartment. The release of microtubules from the microtubule-organizing center appears to involve the microtubule severing protein, katanin (Baas, 2002). Surprisingly, axonal and dendritic compartments are not equivalent. First, dendritic and axonal MAPs differ in both identity and phosphorylation state. Second, microtubule orientation in axons has the plus end distal similar to other cell types, but microtubules in dendrites may exhibit both polarities. Finally, dendritic microtubules are less likely to be aligned with one another and are less regular in their spacing. As a result, dendritic diameters taper, whereas axons have a constant diameter as one proceeds away from the cell body.

Stabilization of axonal and dendritic microtubules is essential because of the volume of cytoplasm and the distance from sites of protein synthesis for tubulin. A common side effect of one class of antineoplastic drugs, the vinca alkaloids, underscores the importance of microtubule stability in axons. Vincristine and other vinca alkaloids act by destabilizing spindle micro-

tubules, but dosage must be monitored carefully to prevent development of peripheral neuropathies due to loss of axonal microtubules. Microtubules play critical roles in both dendritic and axonal function, so mechanisms to ensure their proper extent and organization exist.

Axonal microtubules contain a particularly stable subset of microtubule segments resistant to depolymerization by antimetabolic drugs, cold, and calcium. Stable microtubule segments are biochemically distinct and may constitute more than half of the axonal tubulin. Stable domains in microtubules may serve to regulate the axonal cytoskeleton by nucleating and organizing microtubules as well as stabilizing them. The biochemical basis of microtubule stability is not well understood but may include posttranslational modification of tubulins, presence of stabilizing proteins, or both. Relatively little is known about regulation of dendritic microtubules, but local synthesis of MAP-2 in dendrites may play a role.

### Microfilaments and the Actin-Based Cytoskeleton Are Involved in Intracellular Transport and Cell Movement

The actin cytoskeleton is universal in eukaryotes, although microfilaments are most familiar as thin filaments in skeletal muscle. Microfilaments (Table 4.3) play critical roles in contractility for both muscle

and nonmuscle cells. Actin and its contractile partner myosin are particularly abundant in nervous tissue relative to other nonmuscle tissues. In fact, one of the earliest descriptions of nonmuscle actin and myosin was in brain. In neurons, microfilaments are most abundant in presynaptic terminals, dendritic spines, growth cones, and subplasmalemmal cortex. Although concentrated in these regions, microfilaments are present throughout the cytoplasm of neurons and glia as short filaments (4–6 nm in diameter and 400–800 nm long).

Multiple actin genes exist in both vertebrates and invertebrates. Four  $\alpha$ -actin human genes have been cloned, each expressed specifically in a different muscle cell type (skeletal, cardiac, vascular smooth, and enteric smooth muscle). In addition, two nonmuscle actin genes ( $\beta$ - and  $\gamma$ -actin) are present in humans.  $\beta$ -actin and  $\gamma$ -actin genes are expressed ubiquitously and are abundant in nervous tissue. The functional significance of different genetic isoforms is not clear because actins are highly conserved. Across the range of known actin sequences, amino acids are identical at approximately two of three positions. Even the positions of introns within different actin genes are highly conserved across species and genes. Despite the high degree of conservation, differences in distribution of specific isoforms within a single neuron are seen. For example,  $\beta$ -actin may be enriched in growth cones. The prominent actin bundles seen in some nonneuronal cells in culture are not characteristic of neurons and most neuronal microfilaments are less than 1  $\mu$ m in length.

Many microfilament-associated proteins are found in nervous tissue (myosin, tropomyosin, spectrin,  $\alpha$ -actinin, etc.), but less is known about their distribution and normal function in neurons and glia. Myosins and myosin-associated proteins are considered in the section on molecular motors, but multiple categories of actin-binding proteins exist (Table 4.3). Monomer actin-binding proteins such as profilin and thymosins are abundant in the developing brain and are thought to help regulate assembly of microfilaments by sequestering actin monomers, which may be mobilized rapidly in response to appropriate signals. For example, phosphatidylinositol 4,5-bisphosphate causes the actin–profilin complex to dissociate, freeing monomer for explosive microfilament assembly. This may play a role in growth cone motility, where actin assembly is critical for filopodial extension.

Several proteins have been identified that cap microfilaments, serving to anchor them to other structures or regulate microfilament length. The ezrin–radixin–moesin gene family encodes barbed-end capping proteins that are concentrated at sites where the microfilaments meet the plasma membrane, suggesting a role in anchoring microfilaments or linking them to

extracellular components through membrane proteins. They are prominent components of nodal and paranodal structures in nodes of Ranvier. A mutation in a member of this family expressed in Schwann cells, merlin or schwannomin, is responsible for the human disease neurofibromatosis type 2. Development of numerous tumors with a Schwann cell lineage in neurofibromatosis type 2 suggests that this microfilament-binding protein acts as a tumor suppressor.

Whereas some membrane proteins interact directly with microfilaments in the membrane cytoskeleton, others interact with the actin cytoskeleton through intermediaries. Proteins such as spectrin (fodrin),  $\alpha$ -actinin, and dystrophins cross-link, or bundle, microfilaments, giving rise to higher order complexes. Spectrin is enriched in the cortical membrane cytoskeleton and is thought to have a role in localization of integral membrane proteins such as ion channels and receptors. Dystrophin is the best known member of a family of proteins that appear to be essential for clustering of receptors in muscle and nervous tissue. A mutation in dystrophin is responsible for Duchenne muscular dystrophy. Positioning of integral membrane proteins on the cell surface is an essential function of the actin-rich membrane cytoskeleton, acting in concert with a class of proteins that contain the protein-binding module, the PDZ domain.

Members of the gelsolin family have multiple activities. They not only cap the barbed end of a microfilament, but also sever microfilaments and can nucleate microfilament assembly. Severing-capping proteins may be critical for reorganizing the actin cytoskeleton. The  $\text{Ca}^{2+}$  dependence of gelsolin severing activity may provide a mechanism for altering the membrane cytoskeleton in response to  $\text{Ca}^{2+}$  transients. Other second messengers, such as phosphatidylinositol 4,5-bisphosphate, may also regulate gelsolin function, suggesting interplay between different classes of actin-binding proteins such as gelsolin and profilin. Oligodendrocytes are the only nonneural cells in the CNS that express significant amounts of the actin-binding and microfilament-severing protein gelsolin.

Proteins with other functions may interact directly with actin or actin microfilaments. For example, some membrane proteins, such as epidermal growth factor receptor, bind actin microfilaments directly, which may be important in anchoring these components at a particular location on the cell surface. Other cytoskeletal structures also interact with microfilaments. Both MAP-2 and tau microtubule-associated proteins can interact with microfilaments *in vitro* and may mediate interactions between microtubules and microfilaments. Finally, the synaptic vesicle-associated phosphoprotein, synapsin I, has a phosphorylation-sensitive inter-

action with microfilaments that may be important for targeting and storage of synaptic vesicles in the pre-synaptic terminal (Murthy and De Camilli, 2003). Many of these interactions were defined by *in vitro*-binding studies, and their physiological significance is not always established. The presence of actin as a major component of both pre- and postsynaptic specializations, as well as in growth cones, gives the actin cytoskeleton special significance in the nervous system (Murthy and De Camilli, 2003). The enrichment of the microfilament cytoskeleton at the plasma membrane makes them the cytoskeletal components most responsive to changes in the local external environment of the neuron. Microfilaments also play a critical role in positioning receptors and ion channels at specific locations on neuronal surfaces. Although we emphasize enrichment of the microfilament cytoskeleton at the plasma membrane, microfilaments are also abundant in the deep cytoplasm. The microfilaments are best regarded as a uniquely plastic component of the neuronal cytoskeleton that plays a critical role in local trafficking of cytoskeletal and membrane components.

### Intermediate Filaments Are Prominent Constituents of Nervous Tissue

Intermediate filaments appear as solid, ropelike fibrils from 8 to 12 nm in diameter that may be many micrometers long (Lee and Cleveland, 1996). Intermediate filament proteins constitute a superfamily of five classes with expression patterns specific to cell type and developmental stage (Table 4.4). Type I and type II intermediate filament proteins are keratins, hallmarks of epithelial cells. Keratins are not associated with nervous tissue and will not be considered further. In contrast, all nucleated cells contain type V intermediate filament proteins, nuclear lamins. Lamins are the most evolutionarily divergent of intermediate filament genes, with regard to both intron/exon distribution and polypeptide domain structure. Cytoplasmic intermediate filaments in the nervous system are all either type III or type IV.

Type III intermediate filaments are a diverse family that includes vimentin (characteristic of fibroblasts and embryonic cells including embryonic neurons) and glial fibrillary acidic protein (GFAP, a marker for astrocytes and Schwann cells). Type III intermediate filament subunits are typically 45 to 60 kDa with a conserved rod domain and relatively small gene-specific amino- and carboxy-terminal sequences. As a result, type III intermediate filament subunits form smooth filaments without side arms. Type III polypeptides can form homopolymers or coassemble with other type III intermediate filament subunits.

**TABLE 4.4** Intermediate Filament Proteins of the Nervous System

Class and Name	Cell Type
Types I and II	
Acidic and basic keratins	Epithelial and endothelial cells
Type III	
Glial fibrillary acidic protein	Astrocytes and nonmyelinating Schwann cells
Vimentin	Neuroblasts, glioblasts, fibroblasts, etc.
Desmin	Smooth muscle
Peripherin	A subset of peripheral and central neurons
Type IV	
NF triplet (NFH, NFM, NFL)	Most neurons, expressed at highest level in large myelinated fibers
$\alpha$ -Internexin	Developing neurons, parallel fibers of cerebellum
Nestin	Early neuroectodermal cells The most divergent member of this class; some have classified it as a sixth type
Type V	
Nuclear lamins	Nuclear membranes

Type III intermediate filament proteins in the nervous system typically are restricted to glia or embryonic neurons. Vimentin is abundant in a many cells during early development, including both glioblasts and neuroblasts. Some Schwann cells and astrocytes also contain vimentin. Curiously, mature oligodendrocytes do not have intermediate filaments; an exception to the general rule that metazoan cells contain all three classes of cytoskeletal structures. Oligodendrocyte precursors, however, do express vimentin and may express GFAP transiently.

Peripherin is one type III intermediate filament protein unique to neurons. Peripherin has a characteristic expression during development and regeneration in specific neuronal populations and may be coexpressed with type IV neurofilament proteins. It can coassemble with type IV neurofilament subunits both *in vitro* and *in vivo*, where it can substitute for the low molecular weight neurofilament subunit (NFL). However, whether coassembly is generally the case is not known. Unlike type IV intermediate filaments, intermediate filaments made from type III subunits tend to disassemble more readily under physiological conditions. Thus, the presence of type III intermediate filament subunit proteins may produce more dynamic structures, which could be important during development or regeneration.

Neuronal intermediate filaments typically have side arms that limit packing density, whereas glial intermediate filaments lack side arms and may be very tightly packed. Neuronal intermediate filaments have an unusual degree of metabolic stability, which makes them well suited to the role of stabilizing and maintaining neuronal morphology. Due to this stability, the existence of neurofilaments was recognized long before much was known about their biochemistry or function. Neurofilaments were seen in early electron micrographs, and many traditional histological procedures to visualize neurons were based on a specific reaction of silver and other metals with neurofilaments.

Most neuronal intermediate filament have three distinct subunits present in varying stoichiometries, all type IV polypeptides. Apparent molecular mass for neurofilament subunits vary widely across species, but mammalian forms are typically a triplet ranging from 180 to 200 kDa for the high molecular weight subunit (NFH), from 130 to 170 kDa for the medium subunit (NFM), and from 60 to 70 kDa for NFL. Neurofilament triplet proteins are each encoded by a separate type IV intermediate filament gene, which have a characteristic domain structure that can be recognized in both primary sequence and gene structure. Type IV genes typically are expressed only in neurons, although Schwann cells in damaged peripheral nerves may also transiently express NFM and NFL. Neurofilament polypeptides initially were identified from axonal transport studies. Neurofilament subunits are highly phosphorylated in axons, particularly NFM and NFH. In humans and some other species, NFH has more than 50 repeats of a consensus phosphorylation site at its carboxy terminus, and levels of NFH phosphorylation indicate that most are phosphorylated *in vivo*. This high level of phosphorylation in neurofilament tail domains is a distinctive characteristic of neurofilaments.

A second motif characteristic of neurofilaments is the presence of a glutamate-rich region in the tail adjacent to the core rod domain. This glutamate region has particular significance for neuroscientists because it appears to be the basis for reaction of the classic neurofibrillary silver stains for neurons. These stains were introduced in the late nineteenth century and used extensively by histologists and neuroanatomists from Ramon y Cajal's time to the present. The molecular basis of neurofibrillary stains was unknown until 1968, when F. O. Schmitt showed that neurofibrils were formed by neurofilaments. Remarkably, the ability of neurofilament subunits to react with silver histological stains is retained even after separation in gel electrophoresis for neurofilaments from organisms as diverse as human, squid, and the marine fanworm,

*Myxicola*. Conservation of this glutamate-rich domain suggests both an important functional role and early divergence of neurofilaments from the other intermediate filament families.

Neurofilaments and neurofilament triplet proteins play a critical role in determining axonal caliber. As noted earlier, neurofilaments have characteristic side arms, unique among intermediate filaments. Although all three subunits contribute to the neurofilament central core, side arms are formed only by carboxy-terminal regions of NFM and NFH. Phosphorylation of NFH and NFM side arms alters charge density on the neurofilament surface, repelling adjacent similarly charged neurofilaments. Although cross bridges between neurofilaments often are noted, direct studies of interactions between neurofilaments provide little evidence of stable crosslinks between neurofilaments or between neurofilaments and other cytoskeletal structures. The high density of surface charge due to phosphorylation of neurofilaments makes it difficult to imagine a stable interaction between neurofilaments and other structures of like charge. However, dynamic interactions between neurofilaments and cellular structures or proteins may be critical for neurofilament function and metabolism.

Altered expression levels of neurofilament subunits or mutations in neurofilament genes are associated with some neuropathologies. Disruption of neurofilament organization is a hallmark of pathology for many degenerative diseases of the nervous system, particularly those affecting large myelinated axons such as those of spinal motor neurons, such as amyotrophic lateral sclerosis. Overexpression of normal NFH or expression of some mutant NFL genes in transgenic mouse models leads to the accumulation of neurofilaments in the cell body and proximal axon of spinal motor neurons, similar to those seen in amyotrophic lateral sclerosis and related motor neuron diseases. Similarly, an early indicator of neuropathies due to neurotoxins such as acrylamide and hexanedione is accumulation of neurofilaments in either proximal or distal regions of axons. However, the question of whether neurofilament defects are a primary event in pathogenesis or reflect an underlying metabolic pathology remains unclear.

Another type IV intermediate filament gene expressed only in neurons is  $\alpha$ -internexin. Unlike the triplet,  $\alpha$ -internexin is expressed preferentially early in development and disappears from most neurons during maturation. Intermediate filament with  $\alpha$ -internexin do persist in some adult neurons, such as the branched axons of granule cells in the cerebellar cortex. Although  $\alpha$ -internexin can coassemble with neurofilament triplet subunits, it also forms homopol-

ymERIC filaments. The primary sequence of  $\alpha$ -internexin has features in common with NFL and NFM that are thought to confer assembly properties distinct from other type IV intermediate filaments.

The final intermediate protein expressed in the nervous system is nestin, which is seen transiently during early development. Nestin is expressed in neurons, Schwann cells and oligodendrocyte progenitors, which appear late in the development of the embryonic nervous system. Remarkably, nestin is expressed almost exclusively in ectodermal cells after commitment to the neuroglial lineage, but prior to terminal differentiation. At 1250 kDa, nestin is the largest intermediate filament subunit and the most divergent in sequence. Several distinctive features lead some to classify nestin as a sixth type of intermediate filament, whereas others group it with type IV genes. Relatively little is known about assembly properties of nestin *in vivo* or physiological functions of nestin filaments in neuroectodermal cells.

### How Do the Various Cytoskeletal Systems Interact?

Each class of cytoskeletal structures may be found without the others in some cellular domains, but all three classes—microtubules, microfilaments, and intermediate filaments—coexist in many domains and inevitably interact. These interactions are typically dynamic, rather than through stable cross-links to one another. As mentioned earlier, microtubules and neurofilaments have highly phosphorylated side arms projecting from their surfaces. The high density of negative surface charge tends to repel structures with a like charge and rigidify microtubules and neurofilaments, affecting axon diameter.

The growth cone is a unique neuronal domain with distinctive cytoskeletal organization, such as longer microfilaments in filopodia and neurofilaments are excluded from growth cones, typically extending no further than the growth cone neck. In contrast, microtubules and microfilaments play complementary roles in growth cones. Microfilaments are critical in sprouting but less critical for elongation. In contrast, disrupting microtubules in distal neurites inhibits neurite elongation, but does not affect sprouting.

### Summary

The intracellular framework giving shape to neurons and glia is the cytoskeleton, a complicated set of structures and their associated proteins. These organelles are also responsible for intracellular movement of materials and, during development, for cell migration and plasma membrane extension within nervous tissue.

## MOLECULAR MOTORS IN THE NERVOUS SYSTEM

Until 1985, our knowledge of molecular motors in vertebrate cells of any type was restricted to myosins and flagellar dyneins. Myosins were identified in nervous tissue, but functions were uncertain. The preponderance of evidence indicated that fast axonal transport was microtubule based, so there was considerable interest in cytoplasmic dyneins, but initial studies failed to find a functional cytoplasmic dynein. However, a better understanding of molecular motors in the nervous system has now emerged, largely through studies on axonal transport (Brady and Sperry, 1995; Hirokawa and Takemura, 2005).

Myosins and dyneins can be distinguished pharmacologically by their differential susceptibility to inhibitors of ATPase activity, but the spectrum of inhibitors active against fast axonal transport fails to match properties of either myosin or dynein. The most striking difference between inhibitor effects on axonal transport and on myosin or dynein motors was seen with a nonhydrolyzable analog of ATP. Adenylylimidodiphosphate (AMP-PNP) is a weak competitive inhibitor of both myosin and dynein, requiring a 10- to 100-fold excess of analog. In contrast, both anterograde and retrograde axonal transport stop within minutes of AMP-PNP perfusion into isolated axoplasm, even in the presence of stoichiometric concentrations of ATP. Organelles moving in both directions freeze in place and remain attached to microtubules. AMP-PNP weakens interactions of myosin with microfilaments and of dynein with microtubules, but stabilizes binding of membrane-bound organelles to microtubules. Thus, effects of AMP-PNP indicated that axonal transport of membrane-bound organelles involved another type of motor, distinct from both myosins and dyneins.

The effects of AMP-PNP both demonstrated the existence of a new type of motor protein and provided a basis for identifying its constituent polypeptides. Binding of this ATPase to microtubules should be increased by AMP-PNP and decreased by ATP. Polypeptides meeting this criterion soon were identified and the new mechanochemical ATPase was named kinesin, based initially on an ability to move microtubules across glass coverslips as plus-end directed motor. Studies soon established that kinesin was a microtubule-activated ATPase with minimal basal activity. This combination of ATPase activity and motility *in vitro* confirmed it as the first member of a new class of microtubule-based motor, the kinesins (Brady and Sperry, 1995; Hirokawa and Takemura, 2005).

Kinesins are now known to comprise over 40 different genes in at least 14 subfamilies all with a highly conserved motor domain that includes ATP- and microtubule-binding domains, (Miki *et al.*, 2005). Multiple members of the kinesin superfamily are expressed in both adult and developing brains. Many kinesin family members are associated with mitosis, although some of these are also in postmitotic neurons. Members of kinesin families 1–6 are implicated in various neuronal functions ranging from transport of membrane-bound organelles to translocation of microtubules in dendrites, and others may also have functions in the nervous system. This proliferation of motor proteins dramatically has altered the questions being asked about motor function in the brain. Most kinesins move toward the plus end of microtubules, but some move toward the minus end increasing the number of potential functions that kinesin family members might serve, including a role in transport of cytoskeletal structures. Studies continue to identify new functions for members of the kinesin superfamily expressed in neurons or glial cells.

Kinesin-1, the founding member of the kinesin superfamily, remains the most abundant class of kinesin expressed in brain and other tissues, leading to an extensive characterization of its biochemical, pharmacological, immunochemical, and molecular properties. Electron microscopic and biophysical analyses reveal kinesin as a long, rod-shaped protein, approximately 80 nm in length. Kinesin-1 is a heterotetramer with two heavy chains (115–130 kDa) and two light chains (62–70 kDa). Localization of antibodies specific for kinesin subunits by high resolution electron microscopy of brain kinesin indicates that two heavy chains arranged in parallel, forming the heads and much of the shaft, whereas light chains are localized to the fan-shaped tail region (Fig. 4.5).

ATP-binding and microtubule-binding domains of kinesin are in the heavy chain head regions. Axonal microtubules are oriented with plus ends distal from the cell body, so anterograde transport would require a motor that moves organelles toward the plus end direction. Three different genes for kinesin-1 heavy chain are expressed in neurons, one of which is neuron-specific, along with two light chain genes. Kinesin-1 appears associated with a variety of membrane-bound organelles, including synaptic vesicles or their precursors, mitochondria, and endosomes. Mechanisms for associating specific kinesin-1 isoforms with specific neuronal cargoes are incompletely understood. In the case of kinesin, the interaction is thought to involve both kinesin light chains and the carboxy termini of the heavy chains. Remarkably, mutations in the neuron-specific isoform of kinesin-1 can lead to a form

**FIGURE 4.5** Examples of microtubule motor proteins in the mammalian nervous system. The first microtubule motor identified in nervous tissue was a kinesin 1, but showed 3 kinesin 1 genes including a neuron-specific form (kinesin 1A). Motor domains are well conserved by tail domains and appear to be specialized for interaction with various targets, such as different membrane-bound organelles. After the sequence of the kinesin heavy chain was established, the presence of additional genes that contained sequences homologous to the motor domain of kinesin was soon recognized. The molecular organization of these various motor proteins is diverse, including monomers (Kinesin 3A), trimers (Kinesin 2), and tetramers (ubiquitous and neuron-specific kinesins). Cytoplasmic dynein may interact with membrane-bound organelles and cytoskeletal structures. Genetic methods have established that there may be > 40 kinesin-related genes and 16 dynein heavy chains genes in a single organism.

of hereditary spastic paraplegia, an adult onset neurodegenerative disease of motor neurons.

An indirect result of the discovery of kinesin was the long sought cytoplasmic form of dynein, previously identified as a high molecular weight MAP in brain called MAP-1c. Both cytoplasmic dynein and kinesin-1 can be isolated from brain by incubation of

microtubules with nucleotide-free soluble extracts. Both are bound to microtubules under these conditions and released by ATP. MAP-1c dynein moved microtubules *in vitro* with a polarity opposite that seen with kinesin and was identified as a two-headed cytoplasmic dynein using both structural and biochemical criteria. Dynein heavy chains are also a gene

family with 14 flagellar dyneins and two cytoplasmic dyneins (Pfister *et al.*, 2006). Some, but not all, functions of cytoplasmic dynein also involve another complex of polypeptides known as dynactin (Schroer, 2004).

Cytoplasmic dyneins are a 40-nm-long complex of molecular mass  $1.6 \times 10^6$  Da, that include two heavy chains as well as multiple intermediate and light chains (Fig. 4.5). Nonneuronal cells show immunoreactivity for dynein on mitotic spindles and a punctate pattern of immunoreactivity present in interphase cells is thought to be dynein bound to membrane-bounded organelles. Dyneins are widely thought to be the motor for retrograde fast axonal transport, but are also implicated as motors for slow axonal transport (Baas and Buster, 2004). As with kinesin-1, partial loss of cytoplasmic dynein function leads to degeneration of motor neurons, reflecting the importance of dyneins in neuronal function (Levy and Holzbaaur, 2006).

Myosins from muscle were the first molecular motors identified, but research in nonmuscle myosins has increased the number of myosins expressed in humans to some 40 different genes grouped in 18 different subfamilies (Berg *et al.*, 2001). As with kinesins, all myosins share considerable homology in their motor domains but diverge widely in other domains. Many nonmuscle myosins are expressed in neurons and glia (Brown and Bridgman, 2004). Myosins play critical roles in neuronal growth and development, as well as in specialized cells such as sensory hair cells of the cochlea and vestibular organs (Gillespie and Cyr, 2004).

The most familiar myosins are myosin II (Fig. 4.6), forming the thick filaments of smooth and skeletal muscle, but also present in nonmuscle cells. Myosin II heavy chains form a dimer that may interact with other myosin II dimers to form bipolar filaments. In tissue culture, many cells contain bundled actin microfilament stress fibers with a characteristic sarcomeric distribution of myosin II, but stress fibers are not apparent in neurons and glia *in situ*. However, bipolar thick filaments assembled from myosin II dimers can be isolated from nervous tissues. Although brain myosin II was one of the first nonmuscle myosins to be described, relatively little is known about myosin II function in neurons. Many cellular contractile events in non-neuronal cells, such as the contractile ring in mitosis, involve myosin II.

Myosin I proteins have a single, smaller heavy chain that does not form filaments but possesses a homologous actin-activated ATPase domain and has been purified from neural and neuroendocrine tissues (Fig. 4.6). Some myosin I motors have the ability to interact directly with membrane surfaces, which may generate

**FIGURE 4.6** Examples of myosin motor proteins found in mammalian brain. Myosin heavy chains contain the motor domain, whereas light chains regulate motor function. Myosin II was the first molecular motor characterized biochemically from skeletal muscle and brain. Genetic approaches have now defined more than 15 classes of myosin, many of which are found in brain. Myosin II is a classic two-headed myosin forming thick filaments in nonmuscle cells. Myosin I motors have single motor domains, but may interact with actin microfilaments or membranes. Myosin V has multiple binding sites for calmodulin that act as light chains. Mutations in other classes of myosin have been linked to deafness. Myosins I, II, and V have been detected in growth cones as well as in mature neurons.

movements of plasma membrane components or intracellular organelles. Mammals have at least three myosin 1 genes and multiple forms are in brain. For example, myosin Ic is in cochlear and vestibular hair cell stereocilia and plays a key role in mechanotransduction (Gillespie and Cyr, 2004).

The mouse mutation *dilute*, which affects coat color, results from mutations in a myosin V gene, which is distinct from both myosins I and II (Fig. 4.6). Coat color changes in *dilute* mouse are due to ineffective pigment delivery to developing hairs by dendritic pigment cells, but *dilute* mutants also have complex neurological deficits, including seizures in early adulthood that may lead to death. The specific cellular localization and function of myosin V motors in neurons remain unclear. Genes for myosin VI and VIIA are implicated in some forms of congenital deafness, but are expressed in both brain and other tissues. Myosin VI is the gene responsible for Snell's Walzer deafness, and myosin

VIIA is associated with Usher syndrome type 1B, a human disease involving both deafness and blindness. Both of these myosins are expressed in cochlear and vestibular hair cells, but exhibit a different localization from each other and from myosin Ic.

The diversity of brain myosins and their distinctive localization suggests that the various myosins may have narrowly defined functions. However, relatively little is known about specific neuronal functions for most myosins despite intensive study of myosins in the nervous system. Myosins likely play roles in growth cone motility, synaptic plasticity, and even neurotransmitter release. The axonal transport of myosin II-like proteins was described, but relatively little progress has been made in defining functions of myosin II in the mature nervous system. Even less is known about myosin I in the nervous system beyond their role in hair cell function. There are few instances in our knowledge of neuronal function in which we fully understand the role played by specific molecular motors, but members of all three classes are abundant in nervous tissue. Proliferation of different motor molecules and isoforms suggests that some physiological activities may require multiple classes of motor molecules.

### Summary

The concept is now firmly in place that neurons and glial cells, like other cells, contain multiple molecular motors responsible for moving discrete populations of molecules, particles, and organelles through intracellular compartments. The complex morphologies and diverse functional interactions of neurons mean that motor proteins and their regulation play a critical role in the nervous system.

## BUILDING AND MAINTAINING NERVOUS SYSTEM CELLS

The functional architecture of neurons comprises many specializations in cytoskeletal and membranous components. Each of these specializations is dynamic, constantly changing, and being renewed at a rate determined by the local environment and cellular metabolism. Axonal transport processes represent a key to understanding neuronal dynamics and provide a basis for exploring neuronal development, regeneration, and neuropathology. Recent advances provide insight into the molecular mechanisms underlying axonal transport and its role in both normal neuronal function and pathology.

### Slow Axonal Transport Moves Soluble Proteins and Cytoskeletal Structures

Slow axonal transport has two major components, both representing movement of cytoplasmic constituents (Fig. 4.7). Cytoplasmic elements in axonal transport move at rates comparable to the rate of neurite elongation. Slow component a (SCa) is movement of cytoskeletal elements, primarily neurofilaments and microtubules, SCa rates typically range from 0.1 to 1 mm/day and newly synthesized cytoskeletal proteins may take more than 1000 days to reach the end of a meter-long axon. Slow component b (SCb) is a complex and heterogeneous rate component, including hundreds of distinct polypeptides from cytoskeletal proteins such as actin (and sometimes tubulin) to soluble enzymes of intermediary metabolism (i.e., glycolytic enzymes). SCb moves at 2 to 4 mm/day and is the rate-limiting component for nerve growth or regeneration.

The coordinated movement of neurofilament and microtubule proteins provided strong evidence for the “structural hypothesis.” For example, in pulse-labeling experiments labeled neurofilament proteins move as a bell-shaped wave with little or no trailing of neurofilament protein (Baas and Buster, 2004). Neurofilament stability under physiological conditions indicates that soluble neurofilament subunit pools are negligible, so coherent transport of neurofilament triplet proteins implied a transport complex—neurofilaments. Similarly, coordinate transport of tubulin and MAPs made sense only if microtubules move, because MAPs do not interact with unpolymerized tubulin. The simplest explanation is that neurofilaments and microtubules move as discrete cytological structures, but this idea was controversial for many years.

Development of fluorescently tagged neurofilament or microtubule subunits and methods for visualizing these structures in living cells resolved this issue by documenting movements of individual microtubules and neurofilaments neurites of cultured neurons (Brown, 2003). Direct observations of individual microtubule or neurofilament segments indicated that they move down axons as assembled polymers. Video images of fluorescently tagged microtubules or neurofilaments reveal discontinuous movements, with long pauses punctuated by brief, rapid translocations at 1 to 2  $\mu\text{m}/\text{sec}$ . Due to long pauses, average rates are two to three orders of magnitude slower than instantaneous velocities (Baas and Buster, 2004; Brown, 2003). Remarkably, dynein plays a major role in slow axonal transport of microtubules and neurofilaments (He *et al.*, 2005).

**FIGURE 4.7** Slow axonal transport represents the delivery of cytoskeletal and cytoplasmic constituents to the periphery. Cytoplasmic proteins are synthesized on free polysomes and organized for transport as cytoskeletal elements or macromolecular complexes (1). Microtubules are formed by nucleation at the microtubule-organizing center near the centriolar complex (2) and then released for migration into axons or dendrites. Slow transport appears to be unidirectional with no net retrograde component. Studies suggest that cytoplasmic dynein may move microtubules with their plus ends leading (3). Neurofilaments may move on their own or may hitchhike on microtubules (4). Once cytoplasmic structures reach their destinations, they are degraded by local proteases (5) at a rate that allows either growth (in the case of growth cones) or maintenance of steady-state levels. The different composition and organization of cytoplasmic elements in dendrites suggest that different pathways may be involved in delivery of cytoskeletal and cytoplasmic materials to dendrites (6). In addition, some mRNAs are transported into dendrites, but not into axons.

Studies on transport of neurofilament proteins indicated that little or no degradation occurs until neurofilaments reach nerve terminals, where they are degraded rapidly. Comparable results were obtained with microtubule proteins. Differential metabolism appears to be a key to targeting of cytoplasmic and cytoskeletal proteins. Proteins with slow degradative rates accumulate, reaching higher steady-state levels. Altering degradation rates changes that steady-state

concentration, so enrichment of actin in presynaptic terminals is due to slower turnover of actin than neurofilaments and tubulin. As a result, inhibiting calpain causes neurofilament accumulation in terminals. Differential turnover may involve specific proteases or posttranslational modifications that affect susceptibility to degradation. Regardless, cytoplasmic proteins are degraded in the distal axon and do not return in retrograde axonal transport.

## Fast Axonal Transport Is the Rapid Movement of Membrane Vesicles and Their Contents Over Long Distances within a Neuron

Early biochemical and morphological studies established that material moving in fast axonal transport was associated with membrane-bound organelles (Fig. 4.8) (Brady, 1995). Mitochondria, membrane-associated receptors, synaptic vesicle proteins, neurotransmitters, and neuropeptides all move in fast anterograde transport. Many cargoes moving down axons in anterograde transport return by retrograde transport (Kristensson, 1987). In addition, exogenous materials taken up in distal regions of axons may be moved back to the cell body by retrograde transport (Fig. 4.8). Exogenous materials in retrograde transport include neurotrophins, such as nerve growth factor, and viral particles invading the nervous system.

Electron microscopic analysis of materials accumulated at a ligation or crush demonstrated that organelles moving in the anterograde direction were morphologically distinct from those moving in the retrograde direction (Tsukita and Ishikawa, 1980). Consistent with ultrastructural differences, radiolabel and immunocytochemical studies indicate quantitative and qualitative differences between anterograde and retrograde moving material. These differences indicate that processing or repackaging events must occur for turnaround in axonal transport. Both proteases and kinases may play a role in turnaround processing for retrograde transport.

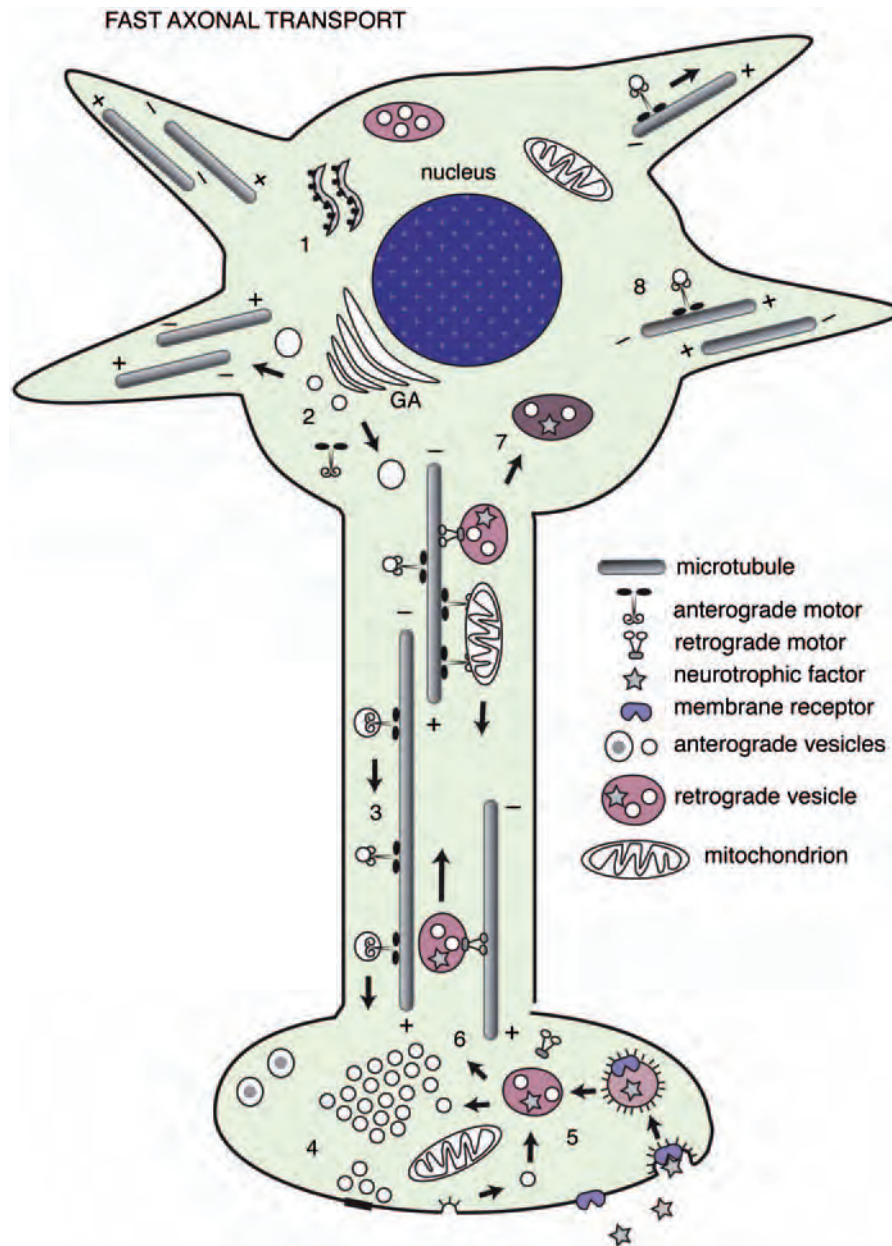

Biochemical and morphological approaches resulted in a detailed description of materials moved in fast axonal transport but were not suitable for identifying molecular motors for axonal transport. Methods that permitted direct observation of organelle movements and precise control of experimental conditions were required. Development of video-enhanced contrast (VEC) microscopy allowed characterization of bidirectional movement of membrane-bounded organelles in giant axons from the squid *Loligo pealeii* (Brady, 1995). Years before, studies showed that axoplasm could be extruded from the giant axon as an intact cylinder. VEC microscopic analysis of axoplasm revealed that fast axonal transport continued unabated in isolated axoplasm for hours despite lacking a plasma membrane or other permeability barriers. Combining VEC microscopy with isolated axoplasm, complemented by biochemical and pharmacological approaches, permitted rigorous dissection of mechanisms for fast axonal transport and led to the discovery of kinesin molecular motors (Brady and Sperry, 1995) as well as allowing characterization of regulatory mechanisms associated with fast axonal transport.

## How Is Axonal Transport Regulated?

The diversity of polypeptides in each axonal transport rate component and the coherent movement of proteins with very different molecular weights is a conundrum: How can so many different polypeptides move down the axon as a group? Rate components of axonal transport move as discrete waves, each with a characteristic rate and a distinctive composition (Figs. 4.7 and 4.8). The structural hypothesis was formulated in response to such observations. The hypothesis is deceptively simple: Axonal transport represents movement of discrete cytological structures. Proteins in axonal transport do not move as individual polypeptides. Instead, they move as part of a cytological structure or in association with a cytological structure. The only assumption made is that a limited number of elements can interact directly with transport motors so transported material must be packaged appropriately to be moved. Different rate components result from packaging of transported material into distinct cytological structures. In other words, membrane-associated proteins move as membrane-bounded organelles (vesicles, etc.), whereas tubulins move as microtubules.

Kinesin-1 isoforms appear to be the major (but not sole) motors for fast anterograde movement of membrane-bounded organelles such as vesicles and mitochondria. Similarly, cytoplasmic dynein appears to be the motor for fast retrograde transport of membrane-bounded structures. However, cytoplasmic dynein is also involved in the anterograde transport of microtubules in slow axonal transport. Regulation of motor proteins is needed to assure that appropriate levels of axonal and synaptic components are delivered where needed in the neuron.

Because synthesis of proteins occurs at some distance from many functional domains of a neuron, transport to distal regions of a neuron is necessary, but not sufficient, for proper function. Specific materials must also be delivered to proper sites of utilization and not left in inappropriate locations. For example, synaptophysin has no known function in axons or cell body, so it must be delivered to a presynaptic terminal along with other components necessary for regulated neurotransmitter release. The traditional picture places the presynaptic terminal at the axon end. Such images imply that synaptic vesicles need only move along axonal microtubules until reaching their ends in the presynaptic terminal. However, many CNS synapses are not at axon ends. Many terminals may be located sequentially along a single axon, making en passant contacts with multiple target cells. Targeting of synaptic vesicles then becomes a more complex problem and

**FIGURE 4.8** Fast axonal transport represents transport of membrane-associated materials, having both anterograde and retrograde components. For anterograde transport, most polypeptides are synthesized on membrane-bound polysomes, also known as rough endoplasmic reticulum (1), and then transferred to the Golgi for processing and packaging into specific classes of membrane-bound organelles (2). Proteins following this pathway include both integral membrane proteins and secretory polypeptides in the vesicle lumen. Cytoplasmic peripheral membrane proteins such as kinesins are synthesized on free polysomes. Once vesicles are assembled and appropriate motors associate with them, they move down the axon at a rate of 100–400mm per day (3). Different membrane structures are delivered to different compartments and may be regulated independently. For example, dense core vesicles and synaptic vesicles are both targeted for presynaptic terminals (4), but release of vesicle contents involves distinct pathways. After vesicles merge with the plasma membrane, their protein constituents are taken up in coated vesicles via the receptor-mediated endocytic pathway and delivered to a sorting compartment (5). After proper sorting into appropriate compartments, membrane proteins either are committed to retrograde axonal transport or recycled (6). Retrograde moving organelles are morphologically and biochemically distinct from anterograde vesicles. These larger vesicles have an average velocity about half that of anterograde transport. The retrograde pathway is an important mechanism for delivery of neurotrophic factors to the cell body. Material delivered by retrograde transport typically fuses with cell body compartments to form mature lysosomes (7), where constituents are recycled or degraded. However, neurotrophic factors and neurotrophic viruses act at the level of the cell body and escape this pathway. Vesicle transport also occurs into dendrites (8); less is known about this process.

targeting ion channels to nodes of Ranvier or other appropriate sites on the neuronal surface is equally challenging.

Although specific details of targeting are not well understood, a simple model for targeting of synaptic

vesicle precursors or ion channels serves to illustrate how such targeting may occur (Fig. 4.9). A local change in the balance between kinase and phosphatase activity in a subdomain like a node of Ranvier or presynaptic terminal can lead to phosphorylation of the motor

**FIGURE 4.9** Axonal dynamics in a myelinated axon from the peripheral nervous system (PNS). Axons are in a constant flux with many concurrent dynamic processes. This diagram illustrates a few of the many dynamic events occurring at a node of Ranvier in a myelinated axon from the PNS. Axonal transport moves cytoskeletal structures, cytoplasmic proteins, and membrane-bound organelles from the cell body toward the periphery (from right to left). At the same time, other vesicles return to the cell body by retrograde transport (retrograde vesicle). Membrane-bound organelles are moved along microtubules by motor proteins such as the kinesins and cytoplasmic dyneins. Each class of organelles must be directed to the correct functional domain of the neuron. Synaptic vesicles must be delivered to a presynaptic terminal to maintain synaptic transmission. In contrast, organelles containing sodium channels must be targeted specifically to nodes of Ranvier for saltatory conduction to occur. Cytoskeletal transport is illustrated by microtubules (rods in the upper half of the axon) and neurofilaments (bundle of rope-like rods in the lower half of the axon) representing the cytoskeleton. They move in the anterograde direction as discrete elements and are degraded in the distal regions. Microtubules and neurofilaments interact with each other transiently during transport, but their distribution in axonal cross-sections suggests that they are not stably cross-linked. In axonal segments without compact myelin, such as the node of Ranvier or following focal demyelination, a net dephosphorylation of neurofilament side arms allows the neurofilaments to pack more densely. Myelination is thought to alter the balance between kinase (K indicates an active kinase; k is an inactive kinase) and phosphatase (P indicates an active phosphatase; p is an inactive phosphatase) activity in the axon. Most kinases and phosphatases have multiple substrates, suggesting a mechanism for targeting vesicle proteins to specific axonal domains. Local changes in the phosphorylation of axonal proteins may alter the binding properties of proteins. The action of synapsin I in squid axoplasm suggests that dephosphorylated synapsin cross-links synaptic vesicles to microfilaments. When a synaptic vesicle encounters the dephosphorylated synapsin and actin-rich matrix of a presynaptic terminal, the vesicle is trapped at the terminal by inhibition of further axonal transport, effectively targeting the synaptic vesicle to a presynaptic terminal. Similarly, a sodium channel-binding protein may be present at nodes of Ranvier in a high-affinity state (i.e., dephosphorylated). Transport vesicles for nodal sodium channels (Na channel vesicle) would be captured upon encountering this domain, effectively targeting sodium channels to the nodal membrane. Interactions between cells could in this manner establish the functional architecture of the neuron.

protein on a vesicle carrying a cargo targeted to that domain. Thus, phosphorylation of kinesin-1 carrying Na channels at the node of Ranvier would allow delivery of Na channels to the nodal membrane. Evidence for such a mechanism exists for delivery of membrane proteins to growth cones (Morfini *et al.*, 2002) and other domains. A number of kinases have been identified that can regulate kinesin and/or dynein function. Significantly, many of these kinases are misregulated in neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's disease, raising the possibility that axonal transport is disrupted in these diseases.

Although such models are speculative, they satisfy criteria that any mechanism for targeting to specific neuronal subdomains must address. Specifically, mechanisms must act locally because distances to cell body can be great and the number of targets is large. There must be some means to connect a targeting signal to the external microenvironment, such as a glial or muscle cell. Finally, there must be a way of distinguishing subdomains. Thus, synaptic vesicles will not be delivered to nodes of Ranvier and voltage-gated sodium channels for nodes are not targeted to presynaptic terminals. Careful segregation of different organelles and proteins to different domain of a neuron suggests that highly efficient targeting mechanisms do exist.

## Summary

A well-studied feature of the neuron is the phenomenon of axonal transport, which moves in both anterograde and retrograde directions. Axonal transport is responsible for delivery of both membrane-associated and cytoplasmic materials from the cell body to distant parts of the neuron, membrane retrieval and circulation, and uptake of materials from presynaptic terminals and dendrites as well as their delivery to the cell soma. Precise molecular mechanisms by which anterograde and retrograde transport are targeted within an individual dendrite or axon are still being defined.

Neurons and glial cells have unusually large cell volumes enclosed within extensive plasma membrane surfaces. Nature has evolved a number of "universal" mechanisms in other systems and adapted them for the special needs of nervous tissue cells. The synthesis and packaging of components, and in particular proteins, destined for cytoplasmic organelles and cell surface subdomains engage general and evolutionarily conserved molecular mechanisms and pathways that are employed in single-cell yeasts as well as in cells in complex nervous tissue.

Once synthesized and sorted, most intracellular organelles (vesicles destined for axonal or dendritic domains, mitochondria, cytoskeletal components) must be distributed, and targeted, to precise intracellular locations. Because they are so extended in space and exhibit exceptionally complex functional architecture, neurons and glial cells have adapted and developed to a high degree mechanisms that operate to distribute components within all cells. In neurons, movement of materials within the axon has been the central focus of most studies. The motors, cargoes, and regulation of axonal transport is now understood in some measure at the molecular level.

# Electrotonic Properties of Axons and Dendrites

The functional operations of neurons are the neural basis of behavior. In order to understand those operations, we need to understand how the different parts of the neuron interact. In this chapter we begin by considering how electrical current spreads.

Neurons characteristically have elaborate dendritic trees arising from their cell bodies and single axons with their own terminal branching patterns (see Chapters 3 and 4). With this structural apparatus, neurons carry out five basic functions (Fig. 5.1):

1. Generate intrinsic activity (at any given site in the neuron through voltage-dependent membrane properties and internal second-messenger mechanisms).
2. Receive synaptic inputs (mostly in dendrites, to some extent in cell bodies, and in some cases in axon hillocks, initial axon segments, and axon terminals).
3. Integrate signals by combining synaptic responses with intrinsic membrane activity (in dendrites, cell bodies, axon hillocks, and initial axon segments).
4. Encode output patterns in graded potentials or action potentials (at any given site in the neuron).
5. Distribute synaptic outputs (from axon terminals and, in some cases, from cell bodies and dendrites).

In addition to synaptic inputs and outputs, neurons may receive and send nonsynaptic signals in the form of electric fields, volume conduction through the extracellular environment of neurotransmitters and gases, and release of hormones into the bloodstream.

## TOWARD A THEORY OF NEURONAL INFORMATION PROCESSING

A fundamental goal of neuroscience is to develop quantitative descriptions of these functional operations and their coordination within the neuron that enable the neuron to function as an integrated information processing system. This is the necessary basis for testing experiment-driven hypotheses that can lead to realistic empirical computational models of neurons, neural systems, and networks and their roles in information processing and behavior.

Toward these ends, the first task is to understand how activity spreads. To do this for a single process, such as the axon, is difficult enough; for the branching dendrites it becomes extremely challenging; and for the interactions between the two even more so. It is no exaggeration to say that the task of understanding how intrinsic activity, synaptic potentials, and active potentials spread through and are integrated within the complex geometry of dendritic trees to produce the input-output operations of the neuron is one of the main frontiers of molecular and cellular neuroscience.

This chapter begins with the passive properties of the membrane underlying the spread of most types of neuronal activity. Chapter 12 then considers the active membrane properties that contribute to more complex types of information processing, particularly the types that take place in dendrites. Together, the two chapters provide an integrated theoretical framework for understanding the neuron as a complex information processing system. Both draw on other chapters for the specific properties—membrane receptors (Chapter 9), internal

FIGURE 5.1 Nerve cells have four main regions and five main functions. Electrotonic potential spread is fundamental for coordinating the regions and their functions.

receptors (Chapter 10), synaptically gated membrane channels (Chapter 9), intrinsic voltage-gated channels (Chapter 6), and second-messenger systems (Chapter 10)—that mediate the operations of the neuron.

### BASIC TOOLS: CABLE THEORY AND COMPARTMENTAL MODELS

Slow spread of neuronal activity is by ionic or chemical diffusion or active transport. Our main interest in this chapter is in rapid spread by electric current. What are the factors that determine this spread? The most basic are *electrotonic properties*.

Our understanding of electrotonic properties arose in the nineteenth century from a merging of the study

of current spread in nerve cells and muscle with the development of cable theory for long distance transmission of electric current through cables on the ocean floor. The electrotonic properties of neurons therefore often are referred to as *cable properties*. Electrotonic theory was first applied mathematically to the nervous system in the late nineteenth century for spread of electric current through nerve fibers. By the 1930s and 1940s, it was applied to simple invertebrate (crab and squid) axons—the first steps toward the development of the Hodgkin–Huxley equations (Chapter 6) for the action potential in the axon.

Mathematically it is impractical to apply cable theory to complex branching dendrites, but in the 1960s, Wilfrid Rall showed how this problem could be solved by the development of computational compartmental models (Rall, 1964, 1967, 1977; Rall and Shepherd, 1968). These models have provided the basis for a theory of dendritic function (Segev *et al.*, 1995). Combined with mathematical models for the generation of synaptic potentials and action potentials, they provide the basis for a complete theoretical description of neuronal activity.

A variety of software packages now makes it possible for even a beginning student to explore functional properties and construct realistic neuron models. These tools are all freely accessible on the Web (see NEURON; GENESIS; ModelDB; Ziv *et al.*, 1994). We therefore present modern electrotonic theory within the context of constructing these compartmental models. Exploration of these models will aid the student greatly in understanding the complexities that are present in even the simplest types of passive spread of current in axons and dendrites.

### SPREAD OF STEADY-STATE SIGNALS

#### Modern Electrotonic Theory Depends on Simplifying Assumptions

The successful application of cable theory to nerve cells requires that it be based as closely as possible on the structural and functional properties of neuronal processes. The problem confronting the neuroscientist is that processes are complicated. As discussed in Chapters 3 and 4, a segment of axon or dendrite contains a variety of molecular species and organelles, is bounded by a plasma membrane with its own complex structure and irregular outline, and is surrounded by myriad of neighboring processes (see Fig. 5.2A).

Describing the spread of electric current through such a segment therefore requires some carefully

**FIGURE 5.2** Steps in construction of a compartmental model of the passive electrical properties of a nerve cell process. (A) Identification of a segment of the process and its organelles. (B) Abstraction of an equivalent electrical circuit based on the membrane capacitance ( $c_m$ ), membrane resistance ( $r_m$ ), resting membrane potential ( $E_r$ ), and internal resistance ( $r_i$ ). (C) Abstraction of the circuit for steady-state electrotonus, in which  $c_m$  and  $E_r$  can be ignored. (D) The space clamp used in voltage-clamp analysis reduces the equivalent circuit even further to only the membrane resistance ( $r_m$ ), usually depicted as membrane conductances ( $g$ ) for different ions. In a compartmental modeling program, the equivalent circuit parameters are scaled to the size of each segment.

chosen simplifying assumptions, which allow the construction of an *equivalent circuit* of the electrical properties of such a segment. These are summarized in Box 5.1. Understanding them is essential for describing electrotonic spread under the different conditions that the nervous system presents.

### Electrotonic Spread Depends on the Characteristic Length

We begin by using the assumptions in Box 5.1 to represent a segment of a process by electrical resistances: an internal resistance  $r_i$  connected to the  $r_i$  of the neighboring segments and through the membrane resistance  $r_m$  to ground (see Fig. 5.2B). Let us first consider the spread of electrotonic potential under steady-state conditions (Fig. 5.2C). In standard cable theory, this is described by

$$V = \frac{r_m}{r_i} \cdot \frac{d^2V}{dx^2}. \quad (5.1)$$

This equation states that if there is a steady-state current input at point  $x = 0$ , the electrotonic potential ( $V$ ) spreading along the cable is proportional to the second derivative of the potential ( $d^2V$ ) with respect to

distance and the ratio of the membrane resistance ( $r_m$ ) to the internal resistance ( $r_i$ ) over that distance. The steady-state solution of this equation for a cable of infinite extension for positive values of  $x$  gives

$$V = V_0 e^{-x/\lambda}, \quad (5.2)$$

where  $\lambda$  is defined as the square root of  $r_m/r_i$  (in centimeters) and  $V_0$  is the value of  $V$  at  $x = 0$ .

Inspection of this equation shows that when  $x = \lambda$ , the ratio of  $V$  to  $V_0$  is  $e^{-1} = 1/e = 0.37$ . Thus,  $\lambda$  is a critical parameter defining the length over which the electrotonic potential spreading along an infinite cable decays (is attenuated) to a value of 0.37 of the value at the site of the input. It is referred to as the *characteristic length* (space constant, length constant) of the cable. The higher the value of the specific membrane resistance ( $R_m$ ), the higher the value of  $r_m$  for that segment, the larger the value for  $\lambda$ , and the greater the spread of electrotonic potential through that segment (Fig. 5.3). Specific membrane resistance ( $R_m$ ) is thus an important variable in determining the spread of activity in a neuron.

Most of the passive electrotonic current may be carried by  $K^+$  “leak” channels, which are open at “rest” and are largely responsible for holding the cell at its resting potential. However, as mentioned earlier, many cells or regions within a cell are seldom at “rest” but are constantly active, in which case electrotonic current is carried by a variety of open channels. Thus, the effective  $R_m$  can vary from values of less than  $1000 \Omega \text{cm}^2$  to more than  $100,000 \Omega \text{cm}^2$  in different neurons and in different parts of a neuron. Note that  $\lambda$  varies with the square root of  $R_m$ , so a 100-fold difference in  $R_m$  translates into only a 10-fold difference in  $\lambda$ .

Conversely, the higher the value of the specific internal resistance ( $R_i$ ), the higher the value of  $r_i$  for that segment, the smaller the value of  $\lambda$ , and the less the spread of electrotonic potential through that segment (see Fig. 5.3). Traditionally, the value of  $R_i$  has been believed to be in the range of approximately  $50\text{--}100 \Omega \text{cm}$  based on muscle cells and the squid axon. In mammalian neurons, estimates now tend toward a value of  $200 \Omega \text{cm}$ . This limited range may suggest that  $R_i$  is less important than  $R_m$  in controlling passive current spread in a neuron. The square-root relation further reduces the sensitivity of  $\lambda$  to  $R_i$ . However, as noted in assumption 7 in Box 5.1, the membranous and filamentous organelles in the cytoplasm may alter the effective  $R_i$ . The presence of these organelles in very thin processes, such as distal dendritic branches, spine stems, and axon preterminals, may thus have potentially significant effects on the spread of electrotonic current through them. Furthermore, the relative

## BOX 5.1

## BASIC ASSUMPTIONS UNDERLYING CABLE THEORY

1. **Segments are cylinders.** A segment is assumed to be a cylinder with constant radius.

This is the simplest assumption; however, compartmental simulations can readily incorporate different geometrical shapes with differing radii if needed (Fig. 5.2B).

2. **The electrotonic potential is due to a change in the membrane potential.** At any instant of time, the “resting” membrane potential ( $E_r$ ) at any point on the neuron can be changed by several means: injection of current into the cell, extracellular currents that cross the membrane, and changes in membrane conductance (caused by a driving force different from that responsible for the membrane potential). Electric current then begins to spread between that point and the rest of the neuron, in accord with

$$V = V_m - E_r$$

where  $V$  is the electrotonic potential and  $V_m$  is the changed membrane potential.

Modern neurobiologists recognize that the membrane potential is rarely at rest. In practice, “resting” potential means the membrane potential at any given instant of time other than during an action potential or rapid synaptic potential.

3. **Electrotonic current is ohmic.** Passive electrotonic current flow is usually assumed to be ohmic, i.e., in accord with the simple linear equation

$$E = IR,$$

where  $E$  is the potential,  $I$  is the current, and  $R$  is the resistance.

This relation is largely inferred from macroscopic measurements of the conductance of solutions having the composition of the intracellular medium, but rarely is measured directly for a given nerve process. Also largely untested is the likelihood that at the smallest dimensions (0.1  $\mu\text{m}$  diameter or less), the processes and their internal organelles may acquire submicroscopic electrochemical properties that deviate significantly from macroscopic fluid conductance values; compartmental models permit the incorporation of estimates of these properties.

4. **In the steady state, membrane capacitance is ignored.** The simplest case of electrotonic spread occurs from the point on the membrane of a steady-state change (e.g., due to injected current, a change in synaptic conductance, or a change in voltage-gated conductance) so that time-varying properties (transient charging or discharg-

ing of the membrane) due to the membrane capacitance can be ignored (Fig. 5.2C).

5. **The resting membrane potential can usually be ignored.** In the simplest case, we consider the spread of electrotonic potential ( $V$ ) relative to a uniform resting potential ( $E_r$ ) so that the value of the resting potential can be ignored. Where the resting membrane potential may vary spatially,  $V$  must be defined for each segment as

$$V = E_m - V_r.$$

6. **Electrotonic current divides between internal and membrane resistances.** In the steady state, at any point on a process, current divides into two local resistance paths: further within the process through an internal (axial) resistance ( $r_i$ ) or across the membrane through a membrane resistance ( $r_m$ ) (see Fig. 5.2C).

7. **Axial current is inversely proportional to diameter.** Within the volume of the process, current is assumed to be distributed equally (in other words, the resistance across the process, in the  $Y$  and  $Z$  axes, is essentially zero). Because resistances in parallel sum to decrease the overall resistance, axial current ( $I$ ) is inversely proportional to the cross-sectional area ( $I \propto \frac{1}{A} \propto \frac{1}{m^2}$ ); thus, a thicker process has a lower overall axial resistance than a thinner process. Because the axial resistance ( $r_i$ ) is assumed to be uniform throughout the process, the total cross-sectional axial resistance of a segment is represented by a single resistance,

$$r_i = R_i/A,$$

where  $r_i$  is the internal resistance per unit length of  $r_i$  cylinder (in ohms per centimeter of axial length),  $R_i$  is the specific internal resistance (in ohms centimeter, or ohm cm), and  $A (= \pi r^2)$  is the cross-sectional area.

The internal structure of a process may contain membranous or filamentous organelles that can raise the effective internal resistance or provide high-conductance submicroscopic pathways that can lower it. In voltage-clamp experiments, the space clamp eliminates current through  $r_i$ , so that the only current remaining is through  $r_m$ , thereby permitting isolation and analysis of different ionic membrane conductances, as in the original experiments of Hodgkin and Huxley (Fig. 5.2D; see also Chapter 6).

8. **Membrane current is inversely proportional to membrane surface area.** For a unit length of cylinder, the

### BOX 5.1 (cont'd)

membrane current ( $i_m$ ) and the membrane resistance ( $r_m$ ) are assumed to be uniform over the entire surface. Thus, by the same rule of the summing of parallel resistances, the membrane current is inversely proportional to the membrane area of the segment so that a thicker process has a lower overall membrane resistance. Thus,

$$r_m = R_m/c$$

where  $r_m$  is the membrane resistance for unit length of cylinder (in ohm cm of axial length),  $R_m$  is the specific membrane resistance (in ohm cm), and  $c (= 2\pi r)$  is the circumference. For a segment, the entire membrane resistance is regarded as concentrated at one point; that is, there is no axial current flow within a segment but only between segments (Fig. 5.2C).

Membrane current passes through ion channels in the membrane. The density and types of these channels vary in different processes and indeed may vary locally in different segments and branches. These differences are incorporated readily into compartmental representations of the processes.

**9. The external medium along the process is assumed to have zero resistivity.** In contrast with the internal axial resistivity ( $r_i$ ), which is relatively high because of the small dimensions of most nerve processes, the external medium has a relatively low resistivity for current because of its relatively large volume. For this reason, the resistivity of the paths either along a process or to ground generally is regarded as negligible, and the potential outside the membrane is assumed to be everywhere equivalent to ground (see Fig. 5.2C). This greatly simplifies the equations that describe the spread of electrotonic potentials inside and along the membrane.

Compartmental models can simulate any arbitrary distribution of properties, including significant values for

extracellular resistance where relevant. Particular cases in which external resistivity may be large, such as the special membrane caps around synapses on the cell body or axon hillock of a neuron, can be addressed by suitable representation in the simulations. However, for most simulations, the assumption of negligible external resistance is a useful simplifying first approximation.

**10. Driving forces on membrane conductances are assumed to be constant.** It usually is assumed that ion concentrations across the membrane are constant during activity.

Changes in ion concentrations with activity may occur, particularly in constricted extracellular or intracellular compartments; these changes may cause deviations from the assumptions of constant driving forces for the membrane currents, as well as the assumption of uniform  $E_r$ . For example, accumulations of extracellular  $K^+$  may change local  $E$ , and intracellular accumulations of ions within the tiny volumes of spine heads may change the driving force on synaptic currents. These special properties are easily included in most compartmental models.

**11. Cables have different boundary conditions.** In classical electrotonic theory, a cable such as one used for long-distance telecommunication is very long and can be considered of infinite length (one customarily assumes a semi-infinite cable with  $V = 0$  at  $x = 0$  and only positive values of length  $x$ ). This assumption carries over to the application of cable theory to long axons, but most dendrites are relatively short. This imposes boundary conditions on the solutions of the cable equations, which have very important effects on electrotonic spread.

In highly branched dendritic trees, boundary conditions are difficult to deal with analytically but are readily represented in compartmental models.

*Gordon M. Shepherd*

significance of  $R_i$  and  $R_m$  depends greatly on the length of a given process, as will be seen shortly.

### Electrotonic Spread Depends on the Diameter of a Process

The space constant ( $\lambda$ ) depends not only on the internal and membrane resistance, but also on the diameter of a process (Fig. 5.4). Thus, from the relations between  $r_m$  and  $R_m$ , and  $r_i$  and  $R_i$ , discussed in the preceding section,

$$\lambda = \sqrt{\frac{r_m}{r_i}} = \sqrt{\frac{R_m}{R_i} \cdot \frac{d}{4}}. \quad (5.3)$$

Neuronal processes vary widely in diameter. In the mammalian nervous system, the thinnest processes are the distal branches of dendrites, the necks of some dendritic spines, and the cilia of some sensory cells; these processes may have diameters of only  $0.1 \mu\text{m}$  or less (the thinnest processes in the nervous system are approximately  $0.02 \mu\text{m}$ ). In contrast, the thickest processes in the mammal are the largest myelinated axons

**FIGURE 5.3** Dependence of the space constant governing the spread of electrotonic potential through a nerve cell process on the square root of the ratio between the specific membrane resistance ( $R_m$ ) and the specific internal resistance ( $R_i$ ). (A) Potential profiles for processes with three different values of  $\lambda$ . (B) Dotted lines represent the location of  $1/e$  on each of the three processes.

and the largest dendritic trunks, which may have diameters as large as 20 to 25  $\mu\text{m}$ . This means that the range of diameters is approximately three orders of magnitude (1000-fold). Note, again, that the relation to  $\lambda$  is the square root; thus, over a 10-fold difference in diameter, the difference in  $\lambda$  is only about three-fold (Fig. 5.4).

### Electrotonic Properties Must Be Assessed in Relation to the Lengths of Neuronal Processes

Application of classical cable theory to neuronal processes assumes that the processes are infinitely long (assumption 11 in Box 5.1). However, because neuronal processes have finite lengths, the length of a given process must be compared with  $\lambda$  to assess the extent to which  $\lambda$  accurately describes the actual electrotonic spread in that process. One of the largest processes in any nervous system, the squid giant axon, has

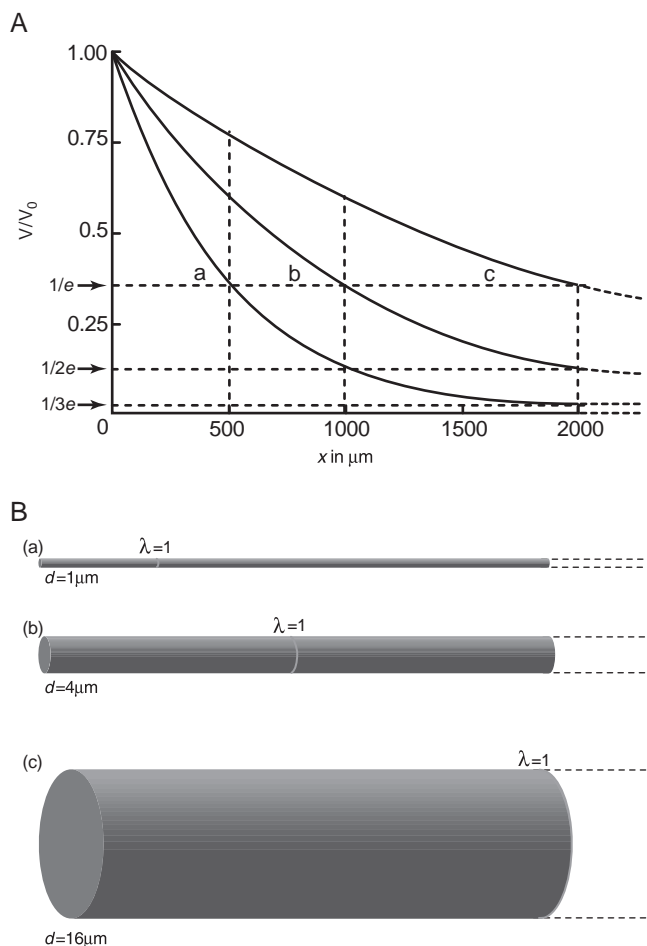

a diameter of approximately 1 mm.  $R_m$  for this axon has been estimated as  $600 \Omega \text{cm}^2$  (a very low value compared to most values of  $R_m$  in mammals), and  $R_i$  as approximately  $80 \Omega \text{cm}$ , the value of Ringer solution (note that the very large diameter is counterbalanced by the very low  $R_m$ ). Putting these values into Eq. (5.3) gives a  $\lambda$  of approximately 5.5 mm. The real length of the giant axon is several centimeters; to relate real length to characteristic length, we define *electrotonic length* ( $L$ ) as

$$L = x/\lambda \quad (5.4)$$

Thus, if  $x = 30 \text{ mm}$ , then  $L = 30 \text{ mm}/4.5 \text{ mm} = 7$ . The electrotonic potential decays to a small percentage of the original value by only three characteristic lengths (see Fig. 5.4), so for this case the assumption of an infinite length is justified. In contrast to axons, dendritic branches have lengths that are usually much shorter than three characteristic lengths. In dendrites, therefore, the branching patterns come to dominate the extent of potential spread. We discuss the methods for dealing with these branching patterns later in this chapter.

A reason often given for why the nervous system needs action potentials is that they overcome the severe attenuation of passively spreading potentials that occurs over the considerable lengths required for transmission of signals by axons. This applies to the long axons of projection neurons, but not necessarily to shorter axons and their collaterals. Recent studies in fact have revealed that excitatory synaptic potentials in the soma may spread through the axon to reach terminal boutons onto nearby cells; the variable amount of synaptic depolarization thus acts as an analog signal to modify the digital signaling carried by the axonal action potentials. This mechanism has been shown in the mossy fiber terminals of dentate granule cells onto CA3 pyramidal cells in the hippocampus (Alle and Geiger, 2006), and in the axon terminals of layer 5 pyramidal neurons onto neighboring cells in the cerebral cortex (Shu *et al.*, 2006). The combined analog and digital signaling is computationally more powerful than digital signaling alone.

A reverse situation is seen in the retina, where a particular type of horizontal cell has elaborate branches of both its dendrites and its terminal axon, interconnected by a long thin axon. Physiological studies have shown that each branching system processes different properties of the visual signal, but they do not interact, because the axon has passive properties that give it a short length constant. This enables one cell to provide two distinct input-output processing systems (Nelson

**FIGURE 5.4** Dependence of the space constant on the square root of the diameter of the process. (A) Potential profiles for processes with three different diameters but fixed values of  $R_i$  and  $R_m$ . (B) The three axon profiles in A. Note that to double  $\lambda$ , the diameter must be quadrupled.

*et al.*, 1975). Never underestimate the ingenuity of the nervous system!

## Summary

Passive spread of electrical potential along the cell membrane underlies all types of electrical signaling in the neuron. It is thus the foundation for understanding the interactive substrate whereby the neuron can generate, receive, integrate, encode, and send signals.

Electrotonic spread shares properties with electrical transmission through electrical cables; the mathematical study of cable transmission has put these properties on a quantitative basis. The theoretical basis for

extension of cable theory to complex dendritic trees has been developed in parallel with compartmental modeling methods for simulating dendritic signal processing.

Cable theory depends on a number of reasonable simplifying assumptions about the geometry of neuronal processes and current flow within them. Steady-state electrotonus in dendrites depends on passive resistance of the membrane and of the internal cytoplasm and on the diameter and length of a nerve process.

## SPREAD OF TRANSIENT SIGNALS

### Electrotonic Spread of Transient Signals Depends on Membrane Capacitance

Until now, we have considered only the passive spread of steady-state inputs. However, the essence of many neural signals is that they change rapidly. In mammals, fast action potentials characteristically last from 1 to 5 ms, and fast synaptic potentials last from 5 to 30 ms. How do the electrotonic properties affect spread of these rapid signals?

Rapid signal spread depends not only on all the factors discussed thus far, but also on the membrane capacitance ( $c_m$ ), which is due to the lipid moiety of the plasma membrane. Classically, the value of the specific membrane capacitance ( $C_m$ ) has been considered to be  $1 \mu\text{F cm}^{-2}$ . However, a value of  $0.6\text{--}0.75 \mu\text{F cm}^{-2}$  is now preferred for the lipid moiety itself, with the remainder being due to gating charges on membrane proteins (Jack *et al.*, 1975).

The simplest case demonstrating the effect of membrane capacitance on transient signals is that of a single segment or a cell body with no processes. This is a very unrealistic assumption, equivalent to the single node of neural network models, but a simple starting point. In the equivalent electrical circuit for a neural process, the membrane capacitance is placed in parallel with ohmic components of the membrane conductance and the driving potentials for ion flows through those conductances (see Fig. 5.2B). Again neglecting the resting membrane potential, we take as an example the injection of a current step into a soma; in this case, the time course of the current spread to ground is described by the sum of the capacitive and resistive current (plus the input current,  $I_{\text{pulse}}$ ):

$$C \frac{dV_m}{dt} + \frac{V_m}{R} = I_{\text{pulse}}. \quad (5.5)$$

Rearranging,

$$RC \frac{dV_m}{dt} + V_m = I_{\text{pulse}} \cdot R \quad (5.6)$$

where  $RC = \tau$  ( $\tau$  is the time constant of the membrane).

The solution of this equation for the response to a step change in current ( $I$ ) is

$$V_m(T) = I_{\text{pulse}} R(1 - e^{-T}). \quad (5.7)$$

where  $T = t/\tau$ .

When the pulse is terminated, the decay of the initial potential ( $V_0$ ) to rest is given by

$$V_m(T) = V_0 e^{-T}. \quad (5.8)$$

These “on” and “off” transients are shown in Figure 5.5. The significance of tau is shown in the diagram; it is the time required for the voltage change across the membrane to reach  $1/e = 0.37$  of its final value. This time constant of the membrane defines the transient voltage response of a segment of membrane to a current step in terms of the electrotonic properties of the segment. It is analogous to the way that the length constant defines the spread of voltage change over distance.

### A Two-Compartment Model Defines the Basic Properties of Signal Spread

These spatial and temporal cable properties can be combined in a two-compartment model (Shepherd, 1994) that can be applied to the generation and spread of any arbitrary transient signal (Fig. 5.6).

In the simplest case, current is injected into one of the compartments, as in an electrophysiological experiment. Positive charge injected into compartment A attempts to flow outward across the membrane, partially opposing the negative charge on the inside of the lipid membrane (the charge responsible for the negative resting potential), thereby depolarizing the membrane capacitance ( $C_m$ ) at that site. At the same time,

FIGURE 5.5 The equivalent circuit of a single isolated compartment responds to an injected current step by charging and discharging along a time course determined by the time constant,  $\tau$ . In actuality, because nerve cell segments are parts of longer processes (axonal or dendritic) or larger branching trees, the actual time courses of charging or discharging are modified.  $V$  steady-state voltage;  $I_m$ , injected current applied to membrane;  $I_c$ , current through the capacitance;  $I_i$ , current through the ionic leak conductance; m, membrane time constant. From Jack *et al.* (1975).

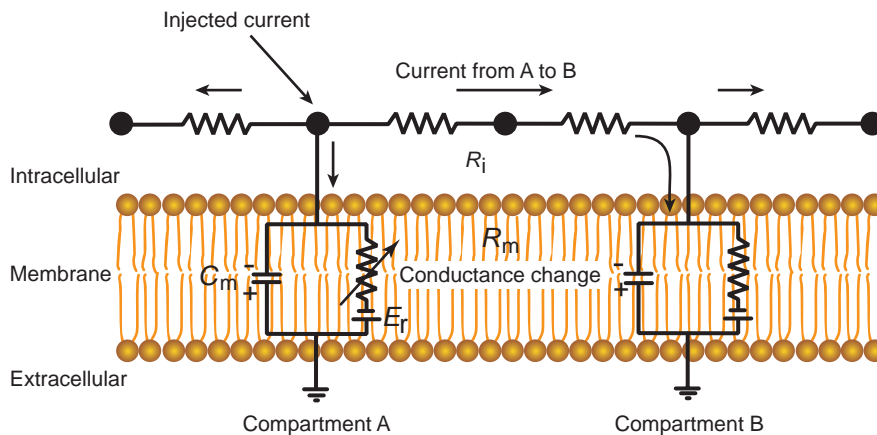

FIGURE 5.6 The equivalent circuit of two neighboring compartments or segments (A and B) of an axon or dendrite shows the pathways for current spread in response to an input (injected current or increase in membrane conductance) at segment A. See text for full explanation.

the charge begins to flow as current across the membrane through the resistance of the ionic membrane channels ( $R_m$ ) that are open at that site. The proportion of charge divided between  $C_m$  and  $R_m$  determines the rate of charge of the membrane; that is, the membrane time constant,  $\tau$ . However, charge also starts to flow through the internal resistance ( $R_i$ ) into compartment B, where the current again divides between capacitance and resistance. The charging (and discharging) transient in compartment A departs from the time constant of a single isolated compartment, being faster because of the impedance load (e.g., current sink) of the rest of the cable (represented by compartment B). Thus, the time constant of the system no longer describes the charging transient in the system because of the conductance load of one compartment on another. The system is entirely passive; the response to a second current pulse sums linearly with that of the first.

This case is a useful starting point because an experimenter often injects electrical currents in a cell to analyze nerve function. However, a neuron normally generates current spread by means of localized conductance changes across the membrane. In Figure 5.6, consider such a change in the ionic conductance for  $\text{Na}^+$ , as in the initiation of an action potential or an excitatory postsynaptic potential, producing an inward positive current in compartment A. The charge transferred to the interior surface of the membrane attempts to follow the same paths followed by the injected current just described by opposing the negativity inside the membrane capacitance, crossing the membrane through the open membrane channels to ground, and spreading through the internal resistance to the next compartment, where the charge flows are similar.

Thus, the two cases start with different means of transferring positive charge within the cell, but from that point the current paths and the associated spread of the electrotonic potential are similar. The electrotonic current that spreads between the two segments is referred to as the *local current*. The charging transient in compartment A is faster than the time constant of the resting membrane; this difference is due both to the conductance load of compartment B (as in the injected current case) and to the fact that the imposed conductance increase in compartment A reduces the time constant of compartment A (by reducing effective  $R_m$ ). This illustrates a critical point first emphasized by Wilfrid Rall (1964): changes in membrane conductance alter the system so that it is no longer a linear system, even though it is a passive system. Thus, passive electrotonic spread is not so simple as most people think! Nonlinear summation of

synaptic responses is discussed further later in this chapter.

## Summary

In addition to the properties underlying steady-state electrotonus, passive spread of *transient* potentials depends on the membrane capacitance. Initiation of electrotonic spread by intracellular injection of a transient electrical current pulse produces an electrotonic potential that spreads by passive local currents from point to point. It is more attenuated in amplitude than the steady-state case as it spreads along an axon or dendrite due to the low-pass filtering action of the membrane capacitance. Simultaneous current pulses at that site or other sites produce potentials that add linearly because the passive properties are invariant. However, transient conductance changes, as in synaptic responses, generate electrotonic potentials that do not sum linearly because of the nonlinear interactions of the conductances.

## ELECTROTONIC PROPERTIES UNDERLYING PROPAGATION IN AXONS

### Impulses Propagate in Unmyelinated Axons by Means of Local Electrotonic Currents

We next apply our knowledge of electrotonic current properties to propagation of an action potential in an unmyelinated axon, that is, one that is not surrounded by myelin or other membranes that restrict the spread of extracellular current. Details on the ionic mechanisms of the nerve impulse can be found in Chapter 6. The local current spreading through the internal resistance to the neighboring compartment enables the action potential to propagate along the membrane of the axon. The rate of propagation is determined by both the passive cable properties and the kinetics of the action potential mechanism.

Each of the cable properties is relevant in specific ways. For brief signals such as the action potential,  $C_m$  is critical in controlling the rate of change of the membrane potential. For long processes such as axons,  $R_i$  increasingly opposes electrotonic current flow as the value of  $r_i$  increases beyond the characteristic length  $\lambda$ , whereas the effect of  $r_m$  decreases, due to the increased membrane area for parallel current paths (see earlier). This effect is greater in thinner axons, which have shorter characteristic lengths. Finally,  $R_m$  is a parame-

ter that can vary widely. Thus, each of these parameters must be assessed in order to understand the exquisite effects of passive variables on the rates of impulse propagation in axons.

A high value of  $R_m$ , for example, forces current further along the membrane, increasing the characteristic length and consequently the spread of electrotonic potential, as we have seen; however, at the same time, it increases the membrane time constant, thus slowing the response of a neighboring compartment to a rapid change. Increasing the diameter of the axon lowers the effective internal resistance of a compartment, thereby also increasing the characteristic length, but without a concomitant effect on the time constant. Thus, changing the diameter is a direct way of affecting the rate of impulse propagation through changes in passive electrotonic properties. The conduction rate of any given axon depends on the particular combination of these properties (Rushton, 1951; Ritchie, 1995). For example, in the squid giant axon, the very large diameter (as large as 1 mm) promotes rapid impulse propagation; the very low value of  $R_m$  (600 gV cm) lowers the time constant (promoting rapid current spread) but also decreases the length constant (limiting the spatial extent of current spread).

The effects of these passive properties on impulse velocity also depend on other factors. For example, on the basis of the cable equations, we can show that the conduction velocity should be related to the square root of the diameter (Rushton, 1951). However, the density of  $\text{Na}^+$  channels in fibers of different diameters is not constant; thus, the binding of saxitoxin molecules, for example, to  $\text{Na}^+$  channels varies greatly with diameter, from almost  $300\text{m}^{-2}$  in the squid axon to only  $35\mu\text{m}^{-2}$  in the garfish olfactory nerve (Ritchie, 1995). Thus, both active and passive properties must be assessed in order to understand a particular functional property.

### Myelinated Axons Have Membrane Wrappings and Booster Sites for Faster Conduction

The evolution of larger brains to control larger bodies and more complex behavior required communication over longer distances within the brain and body. This requirement placed a premium on the ability of axons to conduct impulses as rapidly as possible. As noted in the preceding section, a direct way of increasing the rate of conduction is by increasing the diameter, but larger diameters mean fewer axons within a given space, and complex behavior must be mediated by many axons. Another way of increasing the rate of conduction is to make the kinetics of the impulse mechanism faster; that is, to make the rate of

increase in  $\text{Na}^+$  conductance with increasing membrane depolarization faster. The Hodgkin–Huxley equations (Chapter 6) for the action potential in mammalian nerves in fact have this faster rate.

As we have seen, the rapid spread of local currents is promoted by an increase in  $R_m$  but is opposed by an associated increase in the time constant. What is needed is an increase in  $R_m$  with a concomitant decrease in  $C_m$ . This is brought about by putting more resistances in series with the membrane resistance (because resistances in series add) while putting more capacitances in series with the membrane capacitance (capacitances in series add as the reciprocals, much like resistances in parallel, as noted earlier). The way the nervous system does this is through a special satellite cell called a Schwann cell, a type of glial cell. As described in Chapters 3 and 4, Schwann cells wrap many layers of their plasma membranes around an axon. The membranes contain special constituents and together are called myelin. Myelinated nerves contain the fastest conducting axons in the nervous system. A general empirical finding known as the Hursh factor (Hursh, 1939) states that the rate of propagation of an impulse along a myelinated axon in meters per second is six times the diameter of the axon in micrometers. Thus, the largest axons in the mammalian nervous system are approximately 20 m in diameter, and their conduction rate is approximately  $120\text{ms}^{-1}$ , whereas the thin myelinated axons of about  $1\mu\text{m}$  in diameter have conduction rates of approximately  $5$  to  $10\text{ms}^{-1}$ .

As discussed in Chapter 4, myelinated axons are not myelinated along their entire length; at regular intervals (approximately 1 mm in peripheral nerves), the myelin covering is interrupted by a node of Ranvier. The node has a complex structure. The density of voltage sensitive  $\text{Na}^+$  channels at the node is high ( $10,000\mu\text{m}^{-2}$ ), whereas it is very low ( $20\mu\text{m}^{-2}$ ) in the internodal membrane. This difference in density means that the impulse actively is generated only at the node; the impulse jumps, so to speak, from node to node, and the process therefore is called *saltatory conduction*. A myelinated axon therefore resembles a passive cable with active booster stations.

In rapidly conducting axons the impulse may extend over considerable lengths; for example, in a  $20\text{-}\mu\text{m}$ -diameter axon conducting at  $120\text{ms}^{-1}$ , at any instant of time an impulse of 1-ms duration extends over a 120-mm length of axon, which includes more than 100 nodes of Ranvier. It is therefore more appropriate to conceive that the impulse is generated simultaneously by many nodes, with their summed local currents spreading to the next adjacent nodes to activate them.

The specific membrane resistance ( $R_m$ ) at the node is estimated to be only  $50 \Omega \text{cm}^2$ , due to a large number of open ionic channels at rest. This value of  $R_m$  reduces the time constant of the nodal membrane to approximately 50 ms, which enables the nodal membrane to charge and discharge quickly, aiding rapid impulse generation greatly. For axons of equal cross-sectional area, myelination is estimated to increase the impulse conduction rate 100-fold.

In all axons, a critical relation exists between the amount of local current spreading down an adjacent axon and the threshold for opening  $\text{Na}^+$  channels in the membrane of the adjacent axon so that propagation of the impulse can continue. This introduces the notion of a *safety factor*—the amount by which the electrotonic potential exceeds the threshold for activating the impulse. The safety factor must protect against a wide range of operating conditions, including adaptation (during high frequency firing), fatigue, injury, infection, degeneration, and aging.

Normally, an excess of local current ensures an adequate margin of safety against these factors. In the squid axon, the safety factor ranges from 4 to 5. In myelinated axons, an exquisite matching between internodal electrotonic properties and nodal active properties ensures that the electrotonic potential reaching a node has an adequate amplitude and the node has sufficient  $\text{Na}^+$  channels to generate an action potential that will spread to the next node. The safety factors for myelinated axons range from 5 to 10. Thus, the interaction of passive and active properties underlies the safety factors for impulse propagation in axons. Similar considerations apply to the orthodromic spread of signals in dendritic branches and the back-propaga-

tion of action potentials from the axon hillock into the soma and dendrites.

Theoretically, the conduction velocity, space constant, and impulse wavelength of myelinated fibers scale linearly with fiber diameter (Rushton, 1951; Ritchie, 1995), as indeed is indicated in the aforementioned Hursh factor. This difference between myelinated and unmyelinated fibers in their dependence on diameter thus is related to the scaling of the internodal length. At approximately  $1 \mu\text{m}$  in diameter, the Hursh factor breaks down; at less than  $1 \mu\text{m}$  in diameter, there is an advantage, all other factors being equal, for an axon to be unmyelinated. However, myelinated axons are found down to a diameter of only  $0.2 \mu\text{m}$ , which has been correlated with shorter internodal distances (Waxman and Bennett, 1972). Thus, conduction velocity in myelinated nerve depends on a complex interplay between passive and active properties.

### Summary: Passive Spread and Active Propagation

Impulses propagate continuously through unmyelinated fibers because the local currents spread directly to neighboring sites on the membrane. The rate of propagation is determined directly by the electrotonic properties of the fiber. In myelinated axons, the impulse propagates discontinuously from node to node. The electrotonic properties of both the nodal and internodal regions determine not only the rate of impulse propagation, but also the safety factor for impulse transmission.

Here and in Chapter 12, it will contribute to clarity to distinguish between passive spread and active propagation (see Box 5.2).

#### BOX 5.2

### ELECTROTONIC POTENTIALS SPREAD, ACTION POTENTIALS PROPAGATE

It is important to distinguish between passive and active spread of potentials, which is helped by using different terms. Based on common dictionary definitions, “spreading” has a more general meaning of distributing something (in this case a current or potential) over an area or along an object. It applies specifically to passive electrotonic “spread” and to the local circuit currents that spread before an action potential, and can also be used in a general way to refer to spread of the action potential

itself. “Conduction” also has a general meaning in the electrical sense. In contrast, “propagating” refers specifically to the action potential, because it carries the dictionary meaning of spreading by sequential active processes of reproducing oneself, which is what an action potential does along an axon or dendrite.

These distinctions of meaning as applied to nervous conduction date from the work of Wilfrid Rall in the 1960s, and continue to be useful.

## ELECTROTONIC SPREAD IN DENDRITES

Dendrites are the main neuronal compartment for the reception of synaptic inputs. The spread of synaptic responses through the dendritic tree depends critically on the electrotonic properties of the dendrites. Because dendrites are branching structures, understanding the rules governing dendritic electrotonus and the resulting integration of synaptic responses in dendrites is much more difficult than understanding the rules of simple spread in a single axon.

### Dendritic Electrotonic Spread Depends on Boundary Conditions of Dendritic Termination and Branching

As noted earlier, compared with axons, dendrites are relatively short, and their length becomes an important factor in assessing their electrotonic properties. Consider, in the mammalian nervous system, a moderately thin dendrite of  $1\ \mu\text{m}$  (three orders of magnitude smaller than the squid axon) that has a typical  $R_m$  of  $60,000\ \Omega\text{cm}^{-2}$  (two orders of magnitude larger than that of the squid axon) and an  $R_i$  of  $240\ \Omega\text{cm}$  (three times the squid value). Inserting these values into the equation for characteristic length (Eq. 5.3) gives a  $\lambda$  of approximately  $790\ \mu\text{m}$ . This illustrates that  $\lambda$  tends to be relatively long in comparison with the actual lengths of the dendrites; in other words, because of the relatively high membrane resistance, the electrotonic spread of potentials is relatively effective within a dendritic branching tree.

This essential property underlies the integration of signals in dendrites. The effective spread immediately leads to a second property. The assumption of infinite length no longer holds; dendritic branches are bounded by their terminations on the one hand, and the nature of their branching on the other. These are termed *boundary conditions*. The spread of electrotonic potentials is therefore exquisitely sensitive to the boundary conditions of the dendrites.

This problem is approached most easily by considering two extreme types of termination of a dendritic branch. First, consider that at  $x = \lambda$ ; the branch ends in a sealed end with infinite resistance. In this case, the axial component of the current can spread no further and must therefore seek the only path to ground, which is across the membrane of the cylinder. This current is added to the current already crossing the membrane; in the equation for Ohm's law ( $E = IR$ ),  $I$  is increased, giving a larger  $E$ . The membrane will thus be more depolarized up to the

terminal point  $a$ ; in fact, near point  $a$ , axial current is negligible and almost all the current is across the membrane, which amounts to a virtual space clamp (Fig. 5.7). If at point  $\lambda$  the infinite resistance is replaced by the more realistic assumption of an end that is sealed with surface membrane, only a small amount of current crosses this membrane and attenuation of electrotonic potential is only slightly greater. Infinite resistance is therefore a useful approximation for assessing the effects of a sealed end on electrotonic spread in a terminal dendritic branch.

At the other extreme, consider that at point  $\lambda$ , a small dendritic branch opens out into a very large conductance. Examples are, in the extreme, a hole in the membrane; less extreme are a very small dendritic branch on a large soma and a small twig or spine on a large dendritic branch. Recall that large processes sum their resistances in parallel, which gives low current density and small voltage changes. Therefore, a current spreading through the high resistance of a small branch into a large branch encounters a very low resistance. For steady-state current spread, this situation is referred to as a large conductance load; for a transient current, we refer to it as a low impedance (which includes the effect of the membrane capacitance).

This introduces the key principle of *impedance matching* between interacting compartments, an important principle generally in biological systems. In our example, an impedance mismatch exists between the high impedance thin branch and the lower impedance thick branch. This mismatch reduces any voltage change due to the current and, in the extreme, effectively clamps the membrane to the resting potential ( $E_r$ ) at that point. The electrotonic potential thus is attenuated through the branch much more rapidly than would be predicted by the characteristic length (see Fig. 5.7). This does not invalidate  $\lambda$  as a measure of electrotonic properties; rather, it means that, as with the time constant, each cable property must be assessed within the context of the size and branching of the dendrites.

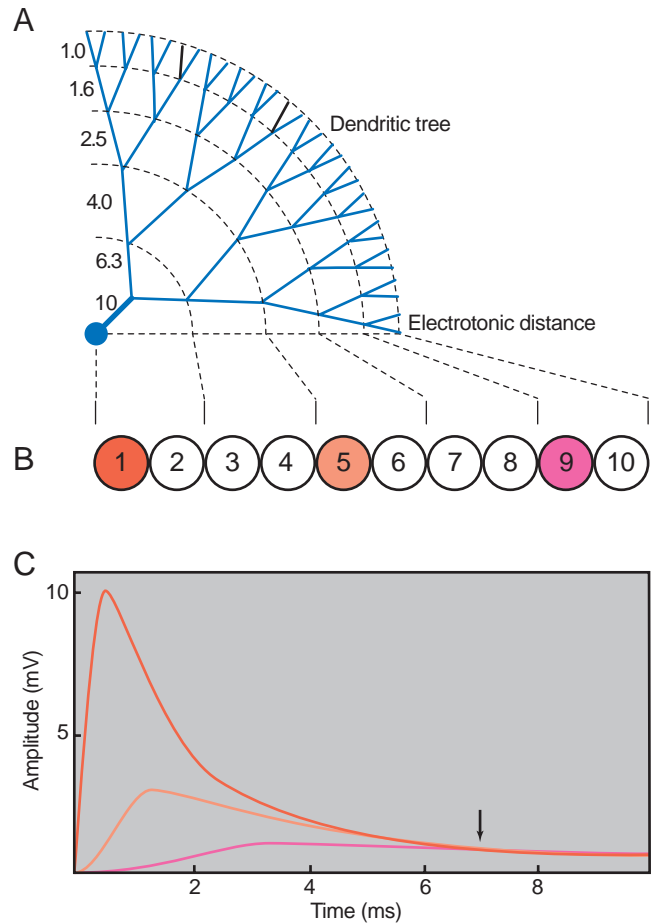

All the different types of branching found in neuronal dendrites lie between these two extremes, with a corresponding range of boundary conditions at  $x = \lambda$ . Consider a segment of dendrite that divides into two branches at  $x = \lambda$ . We can appreciate intuitively that the amount of spread of electrotonic potential into the two branches will be governed by the factors just considered. One possibility is that the two branches have very small diameters, so their input impedance is higher than that of the segment; in this case, the situation will tend toward the sealed end case (Fig. 5.7, top trace). In contrast, the segment may

**FIGURE 5.7** The spread of electrotonic potential through a short nerve cell process such as a dendritic branch is governed by the space constant and by the size of the branches; the latter imposes a boundary condition at the branch point. Curves a–c represent a range of realistic assumptions about the sizes of the branches relative to the size of the stem, together with the limiting conditions of an open circuit (corresponding to an infinite conductance load) and a closed circuit (corresponding to a sealed tip).

give rise to two very fat branches, so the situation will tend toward the large conductance load case (Fig. 5.7, bottom trace).

For many cases of dendritic branching, the input impedance of the branches is between the two extremes (see Fig. 5.7, traces a–c), providing for a reasonable degree of impedance matching between the stem branch and its two daughter branches. This situation thus approximates the infinite cylinder case, in which by definition the input impedance at one site matches that at its neighboring site along the cylinder. The general rules for impedance matching at branch points were worked out by Rall (1959, 1964, 1967), who showed that the input conductance of a dendritic segment varies with the diameter raised to the 3/2 power. There is electrotonic continuity at a branch point equivalent to the infinitely extended cylinder if the diameter of the segment raised to the 3/2 power equals the sum of the diameters raised to the 3/2 power of all the daughter branches. An idealized branching pattern that satisfies this rule is shown in

**FIGURE 5.8** The spread of electrotonic potentials is accompanied by a delay and an attenuation of amplitude. (A) Dendritic diameters (left) satisfy the  $3/2d$  rule so that the tree can be portrayed by an equivalent cylinder. An excitatory postsynaptic potential (EPSP) is generated in compartment 1, 5, or 9 (B) and recordings are made from compartment 1. (C) Short latency, large amplitude, and rapid transient response in compartment 1 at the site of input, as well as the later, smaller, and slower responses recorded in compartment 1 for the same input to compartments 5 and 9. Despite the initial differences in time course, the responses converge at the arrow to decay together. Based on Rall (1967).

Figure 5.8. When the branching tree reduces to a single chain of compartments, as in this case, it is called an “equivalent cylinder.” When the branching pattern departs from the  $3/2$  rule, the compartment chain is referred to as an “equivalent dendrite” (Rall and Shepherd, 1968).

### Dendritic Synaptic Potentials Are Delayed and Attenuated by Electrotonic Spread

We are now in a position to assess the effects of cable properties on the time course of the spread of

synaptic potentials through dendritic branches and trees. Consider in Figure 5.8 the case of recording from a soma while delivering a brief excitatory synaptic conductance change to different locations in the dendritic tree. The response to the nearest site is a rapidly rising synaptic potential that peaks near the end of the conductance change and then decays rapidly toward baseline. When the input is delivered to the middle of the chain of compartments, the response in the soma begins only after a delay, rises more slowly, reaches a much lower peak (which is reached after the end of the conductance change in the soma), and decays slowly toward baseline. For input to the terminal compartment, the voltage delay at the soma is so long that the response has scarcely started by the end of the conductance change in the distal dendrite; the response rises slowly to a delayed (several milliseconds) and prolonged plateau that subsides very slowly (see Fig. 5.8).

Although the synaptic potentials thus decrease in amplitude as they spread, the rate of electrotonic spread can be calculated in terms of the half-amplitude at any point. If distance is expressed in units of  $\lambda$  and time in units of  $\tau$ , then for spread through a semi-infinite cable, we have the simple equation (Jack *et al.*, 1975)

$$\text{Velocity} = 2 \frac{\lambda}{\tau}. \quad (5.9)$$

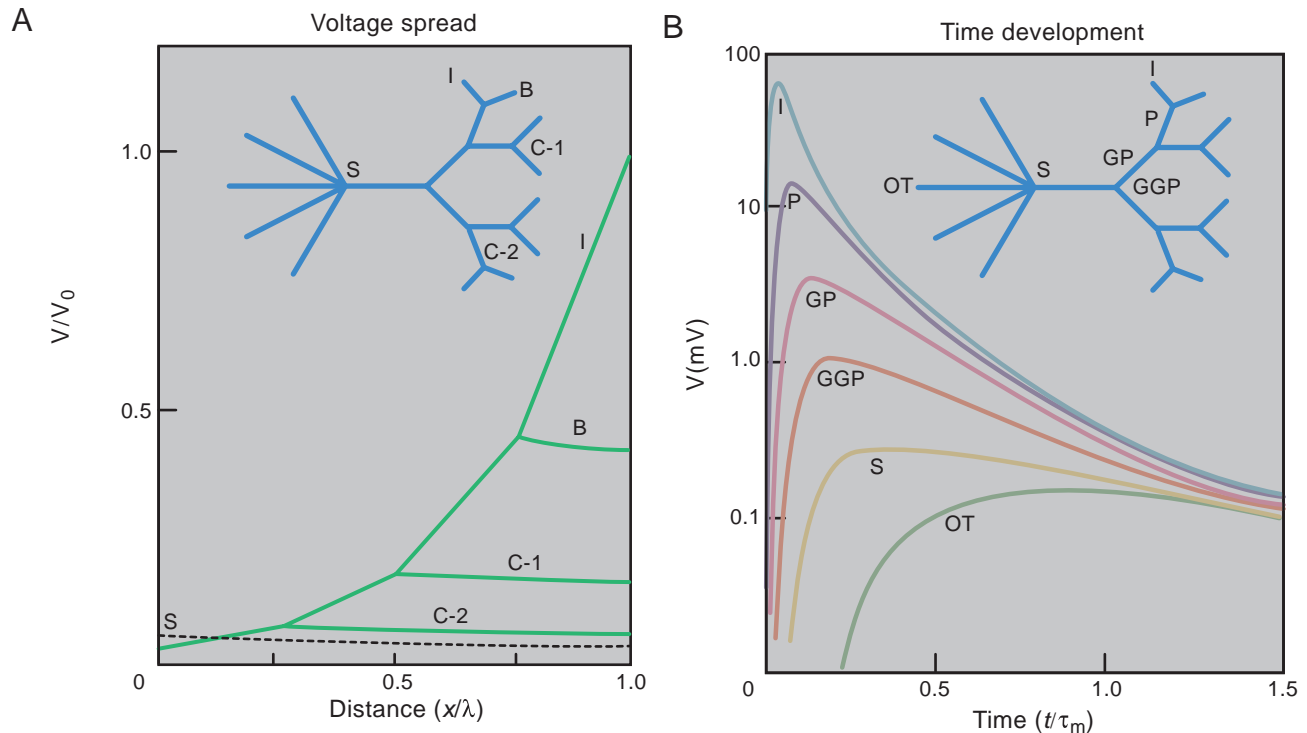

Thus, if we ignore boundary effects, for the 10-mm process mentioned earlier in which  $\lambda = 1500$  and  $\tau = 10$  ms, the velocity of spread would be  $0.3 \text{ ms}^{-1}$ , or  $300 \mu\text{m ms}^{-1}$ . It can be seen that electrotonic spread can be relatively fast over short distances within a dendritic tree but is very slow in comparison with impulse transmission for an axon of this diameter ( $60 \text{ ms}^{-1}$ ). Thus, both the severe decrement and the slow velocity make passive spread by itself ineffective for transmission over long distances.

These general rules of delay and attenuation govern the passive spread of all transient potentials in dendritic branches and trees. As a rule of thumb, spread within one space constant (see the decrement between compartments 1 and 5 in Fig. 5.8) mediates relatively effective linkage for rapid signal integration, whereas spread over one or two space constants (see the decrement between compartments 1 and 9 in Fig. 5.8) is limited to slower background modulation. In real dendrites, these limitations often are overcome through boosting the signals at intermediate sites by voltage-gated properties (see Chapter 12).

The spread of electrotonic potential from a point of input involves the *equalization of charge* on the membrane throughout the system. After cessation of the input, a time is reached when charge has become equalized and the entire system is equipotential; from this time on, the remaining electrotonic potential decays equally at every point in the system. This time is indicated by the vertical arrow in Figure 5.8C. Before this time, the decaying transients are governed by equalizing time constants, indicating electrotonic spread, which can be identified by “peeling” on semi-logarithmic plots of the potentials (Rall, 1977). After this time, the decay of electrotonic potential is governed solely by the membrane time constant. In experimental recordings of synaptic potentials, the overall electrotonic length of the dendritic system, considered as an “equivalent cylinder” or “equivalent dendrite” (see earlier discussion), can be estimated from measurements of the membrane time constant and the equalizing time constants. The electrotonic lengths of the dendritic trees of many neuron types lie between 0.3 and 1.5.

What is the spread of the postsynaptic potential throughout the system when a synaptic input is delivered to only a single terminal dendritic branch (Fig. 5.9) (Rall and Rinzel, 1973; Rinzel and Rall, 1974). Let us begin by considering a steady-state potential. Two main factors are involved. First, in the terminal branch, both the effective membrane resistance and the internal resistance are very large; hence, the branch has a very high input resistance, which produces a very large voltage change for any given synaptic conductance change. Balanced against this high input resistance is a second factor: the small branch has a very large conductance load on it because of the rest of the dendritic tree. As a result, there is a steep decrement in the electrotonic potential spreading from the branch through the tree to the cell body (Fig. 5.9A). For comparison, a direct input to the soma produces only a small potential change there because of the relatively very low input resistance at that site.

For a transient synaptic input, a third factor—membrane capacitance—must be taken into account. The small surface area of a terminal branch has little capacitance, so the amplitude of a transient response differs little from a steady-state response in the branch. However, in spreading out from a small process (such as a distal dendritic twig or spine), the transient synaptic potential is attenuated by the impedance mismatch between the process and the rest of the dendritic tree. Spread of the transient through the dendritic tree is attenuated further by

**FIGURE 5.9** Electrotonic spread from a single small dendritic branch. (A) For steady-state input ( $I$ ), the electrotonic potential ( $V$ ), relative to the initial potential ( $V_0$ ) at the site of input, spreads from the distal branch through the dendritic tree, with a large decrement into the parent branch (due to the large conductance load) but a small decrement into neighboring branches B, C-1, and C-2 (due to the small conductance loads). The resulting potential in the soma (S) is much reduced, as is the response to the same input delivered directly to the soma (because of the low input resistance at the soma and the large conductance load of the dendritic tree). The dashed line indicates the response when the same amount of current is injected into the soma. (B) For transient input ( $I$ ) to a distal branch, transient electrotonic potentials decrease sharply in amplitude and are delayed and slower as they spread toward the soma through the parent (P), grandparent (GP), and great-grandparent (GGP) branches, eventually reaching the soma (S) and output trunk (OT). Modified from Segev (1995) based on Rall and Rinzel (1973, 1974).

the need to charge the capacitance of the dendritic membrane and is slowed by the time taken for the charging.

The amount of slowing is so precise that the relative distance of a synapse in the dendritic tree from the soma can be calculated from experimental measurements in the soma of the time to peak of the recorded synaptic potential (Rall, 1977; Johnston and Wu, 1995). For these reasons, the peak of a synaptic potential transient spreading from distal dendrites toward the soma may be severely attenuated, several-fold more than for the case of steady-state attenuation. This often is referred to as the *filtering effect* of the cable properties. However, the integrated response (the area under the transient voltage) is approximately equivalent to the steady-state amplitude, indicating that there is only a small loss of total charge (see Fig. 5.9B).

## DYNAMIC PROPERTIES OF PASSIVE ELECTROTONIC STRUCTURE

### Electrotonic Structure of the Neuron Changes Dynamically

These considerations show that, compared with the anatomical structure of a dendritic system, which is relatively fixed over short periods of time, the electrotonic structure continually shifts over time, producing complex effects on signal integration. The effects reflect different relations between the electrotonic and signaling properties, such as the direction of signal spread, inhomogeneities in passive properties, rates of signal transfer, and interactions between synaptic or active conductances, to name a few. The effects can be illustrated in graphic fashion for the entire soma-dendritic system by taking a stained neuron and modifying its

size according to its electrotonic properties. This is termed a *morphoelectrotonic transform* (MET) or *neuromorphic transform*.

We illustrate three types of neuromorphic transforms, beginning with the direction of signal spread. Figure 5.10 illustrates a CA1 hippocampal pyramidal cell in which a comparison is made between spread of a signal from the soma to the dendrites (voltage out,  $V_{out}$ ) with spread from the dendrites to the soma (voltage in,  $V_{in}$ ). On the left is the stained neuron, with its long many-branched apical dendrite and shorter basal dendrites and their branches. In the right lower diagram is an electrotonic representation of the neuron for signals spreading from the distal dendrites toward the soma. There is severe decrement from each distal branch (cf. Fig. 5.9) so that apical and basal dendritic trees have electrotonic lengths of approximately 3 and 2, respectively. By comparison, in the right upper diagram is an electrotonic representation of this neuron for a signal spreading from the soma to the dendrites. The basal dendrites have shrunk to almost nothing, indicating that they are nearly isopotential. This is because they are relatively

short compared with their electrotonic lengths and because the sealed end boundary condition greatly reduces the decrement of electrotonic potential through them (cf. Fig. 5.7). The apical dendrite has shrunk to an electrotonic length of approximately 1. Thus, distal synaptic responses decay considerably in spreading all the way to the soma, which active properties help to overcome, as we shall see in Chapter 12, whereas signals at the soma “see” a relatively compact dendritic tree. This, for example, would be the case for a back-propagating action potential.

The analysis in Figure 5.10 applies to spread of steady-state or very slowly changing signals. What about spread of rapid signals? We have seen that membrane capacitance makes the dendrites act as a low-pass filter, further reducing rapid signals. The electrotonic transforms can assess this effect, as shown in Figure 5.11. On the left, the electrotonic representation of a pyramidal neuron is shown for a slow (100 Hz) current injected in the soma. The form is similar to that of the cell in Figure 5.10, with tiny, virtually isopotential basal dendrites and a longer apical dendritic tree of electrotonic length of approximately 1.5. By comparison, a rapid (500 Hz) signal is severely attenuated in spreading into the dendrites, as shown by the basal dendrites with  $L$  of approximately 1 and the apical dendritic tree electrotonic lengths of 4–5. Thus, a somatic action potential could back-propagate into the basal dendrites rather effectively, but would require active properties to invade very far into the apical dendrites. There is direct evidence for these properties underlying back-propagating action potentials in apical dendrites (Chapter 12).

The electrotonic structure of a neuron is not necessarily fixed, but may vary under synaptic control. Our final example is shown in Figure 5.12 for the case of a medium spiny cell in the basal ganglia. During low levels of resting excitatory synaptic input, the electrotonic transform of this cell type is relatively large (left) because of the action of a specific  $K^+$  current (known as  $I_h$ ) in the dendrites that holds them relatively hyperpolarized (see arrow at  $-90$  mV). When synaptic excitation increases, the  $K^+$  current is deactivated, reducing the membrane conductance and thereby increasing the input resistance of the cell; the dendritic tree becomes more compact electrotonically (middle) so that synaptic inputs are more effective in activating the cell. As the cell responds to the synaptic excitation, the resulting depolarization activates other  $K^+$  currents, which expand the electrotonic structure again (right). This example illustrates how cable properties and voltage-gated properties interact to control the integrative actions of the neuron.

**FIGURE 5.10** The electrotonic structure of a neuron varies with the direction of spread of signals. (Left) Stained CA1 pyramidal neuron. (Right) Electrotonic transform of the stained morphology for the case of a voltage spreading toward the cell body (bottom,  $V_{in}$ ) and away from the cell body (top,  $V_{out}$ ). Calibration, 1 electrotonic length. See text. From Carnevale *et al.* (1997).

**FIGURE 5.11** The electrotonic structure of a neuron varies with the rapidity of signals. (Left) Electrotonic transform of a pyramidal neuron in response to a sinusoidal current of 100 Hz injected into the soma (i.e., this is an example of  $V_{out}$ ). (Right) Electrotonic transform of same cell in response to 500 Hz. Calibration, 1 electrotonic length. See text. From Zador *et al.* (1995).

**FIGURE 5.12** The electrotonic structure of a neuron can vary with shifts in the resting membrane potential. In this medium spiny cell, the electrotonic transform varies with the resting membrane potential, which in turn reflects the combination of resting voltage-gated  $K^+$  currents and excitatory synaptic currents. See text. From Wilson (1998).

## Synaptic Conductances in Dendrites Tend to Interact Nonlinearly

Dynamic interactions also occur between synaptic conductances. It often is assumed that synaptic responses sum linearly, but we have already noted that this is not generally true. In an electrical cable, responses to simultaneous current inputs sum linearly (they show “superposition”) because the cable properties remain invariant at all times. However, as noted in relation to Figure 5.6, synaptic responses in real neurons generate current by means of changes in the membrane conductance at the synapse, which alters the overall membrane resistance of that segment and with it the input resistance, thereby changing the electrotonic properties of the whole system. As pointed out by Rall (1964), excitatory and inhibitory conductance changes involve “a change in a conductance which is an element of the system; the system itself is perturbed; the value of a constant coefficient in the linear differential equation is changed; hence the simple superposition rules do not hold.”

This effect is illustrated by the two-compartment model of Figure 5.6. Consider a synaptic input to compartment A, which decreases the membrane resistance of that compartment. Now consider a simultaneous synaptic input to compartment B, which has the same effect on the membrane resistance of that compartment. The internal current flowing between the two compartments encounters a much lower impedance and hence has much less effect on the membrane potential than would have been the case for current injection. The integration of these two responses therefore gives a smaller summed potential than the summation of the two responses taken individually. This effect is referred to as *occlusion*. In essence, each compartment partially short-circuits the other through a larger conductance load, thus reducing the combined response.

These properties mean that, as noted earlier, synaptic integration in dendrites in general is not linear even for purely passive electrotonic properties. The further apart the synaptic sites, the fewer the interactions between the conductances, and the more linear the summation becomes (Fig. 5.13). These nonlinear properties of passive dendrites, combined with the nonlinear properties of voltage-gated channels at local sites on the membrane, contribute to the complexity of signal processing that takes place in dendrites, as will be discussed in Chapter 12. As we shall see, dendritic spines affect these nonlinear properties.

**FIGURE 5.13** Schematic diagram of a dendritic tree to illustrate graded effects of nonlinear interactions between synaptic conductances. (A) Three sites of synaptic input (a–c) are shown, with a recording site in the soma. (B) The voltage response ( $V$ ) is shown for the response to a single input at a, the theoretical linear summation for two inputs at a ( $a \times 2$ ), and the gradual reduction in summation from c to a due to increasing shunting between the conductances. See text. From Shepherd and Koch (1990).

## Significance of Active Conductances in Dendrites Depends on Their Relation to Cable Properties

In electrophysiological recordings from the cell body, dendritic synaptic responses often appear small and slow (cf. Fig. 5.8). However, at their sites of origin in the dendrites, the responses tend to have a large amplitude (because of the high input resistances of the thin distal dendrites) and a rapid time course (because of the small membrane capacitance) (cf. Fig. 5.9). These properties have important implications for the signal processing that takes place in dendrites. In particular, the fact that distal dendrites contain sites of voltage-gated channels means that local integration, local boosting, and local threshold operations can take place. These most distal responses need spread no further than to neighboring local active sites to be boosted by these sites; thus, a rapid integrative sequence of these

actions ultimately produces significant effects on signal integration at the cell body. These properties will be considered further in Chapter 12.

In addition to their role in local signal processing, the cable properties of the neuron are also important for (1) controlling the spread of synaptic potentials from the dendrites through the soma to the site of action potential initiation in the axon hillock initial segment and (2) back-propagation of an action potential into the soma–dendritic compartments, where it can activate dendritic outputs and interact with the active properties involved in signal processing. These properties are discussed further in Chapter 12.

### Dendritic Spines Form Electrotonic and Biochemical Compartments

The rules governing electrotonic interactions within a dendritic tree also apply at the level of a spine, the smallest process of a nerve cell. A spine may vary from a bump on a dendritic branch to a twig to a lollipop-shaped process several micrometers long (Fig. 5.14). A dendritic spine usually receives a single excitatory synapse; an axonal initial segment spine characteristically receives an inhibitory synapse.

Dendritic spines receive most of the excitatory inputs to pyramidal neurons in the cerebral cortex and to Purkinje cells in the cerebellum, as well as to a variety of other neuron types, so an understanding of their properties is critical for understanding brain function (Shepherd, 1996; Araya *et al.*, 2006; Alvarez and Sabatini, 2007). As with the whole dendritic tree, one begins with their electrotonic properties. Given the rules we have built earlier in this chapter, by simple inspection of spine morphology as shown in Figure 5.14, we can postulate several distinctive features that may have important functional implications (see Box 5.3).

In addition to its electrotonic properties, the spine may have interesting biochemical properties. The same cable equations that govern electrotonic properties also have their counterparts in describing the diffusion of substances (as well as the flow of heat). Thus, as already noted, accumulations of only small numbers of ions are needed within the tiny volumes of spine heads to change the driving force on an ion species or to affect significant changes in the concentrations of subsequent second messengers. This interest is intensifying, as the ability to image ion fluxes, such as for  $\text{Ca}^{2+}$ , and to measure other molecular properties of individual spines increases with new technology such as two-photon microscopy. The interpretation of those results for the integrative properties of the neuron will

**FIGURE 5.14** Diagrams illustrating different types of spines and current flows generated by a synaptic input. (A) Stubby spine arising from a thick process. Parallel considerations apply to diffusion between the spine head and dendritic branch. Modified from Shepherd (1974).

require considerations in the biochemical domain that parallel those discussed in the electrotonic domain. The range of properties and possible functions of spines are discussed further in Chapter 12.

### Summary

In addition to membrane properties, the spread of electrotonic potentials in branching dendritic trees is dependent on the boundary conditions set by the modes of branching and termination within the tree. In general, other parts of the dendritic tree constitute a conductance load on activity at a given site; the spread of activity from that site is determined by the impedance match or mismatch between that site and the neighboring sites. Rules governing these impedance relations have been worked out relative to the case in which the sum of the daughter branch diameters raised to the  $3/2$  power is equal to that of the parent branch, in which case the system of branches is an “equivalent cylinder,” resembling a single continuous cable. This provides a starting point in analyzing synaptic integration, which can be adapted for different types of branching patterns in terms of “equivalent dendrites.”

Synchronous synaptic potentials in several branches spread relatively effectively through most dendritic trees. Responses in individual branches may be relatively isolated because of the decrement of passive spread and require local active boosting for effective communication with the rest of the tree. Passive spread

## BOX 5.3

## SOME BASIC ELECTROTONIC PROPERTIES OF DENDRITIC SPINES

a. High input resistance. The smaller the size and the narrower the stem, the higher the input resistance; this gives a large amplitude synaptic potential for a given synaptic conductance. Such a large depolarizing EPSP can have powerful effects on the local environment within the spine.

b. Low total membrane capacitance. The small size also means a small total membrane capacitance, implying that synaptic (and any active) potentials may be rapid; this means that spines on dendrites can potentially be involved in rapid information transmission.

c. Increases in total dendritic membrane capacitance. Although the membrane capacitance of an individual spine is small, the combined spine population increases the total capacitance of its parent dendrite. This increases the filtering effect of the dendrite on transmission of signals through it.

d. Decrement of potentials spreading from the spine. There is an impedance mismatch between the spine head

and its parent dendrite; this means that potentials spreading from the spine to the dendrite will suffer considerable decrement unless there are active properties of the dendrite or of neighboring spines to boost the signal.

e. Ease of potential spread into the spine. The other side of the impedance mismatch is that membrane potential changes within the dendrite spread into the spine with little decrement; thus, the spine tends to follow the potential of its dendrite, except for the transient large-amplitude responses to its own synaptic input. This means that a spine can serve as a *coincidence detector* for nearby synaptic responses or for an action potential back-propagating into the dendritic tree.

f. Linearization of synaptic integration. The spine necks increase the anatomical and electrotonic distance between the spine synapses, thereby decreasing the interactions between their conductances, producing more linear superposition of the postsynaptic responses.

Gordon M. Shepherd

can be characterized in terms of several measures, including characteristic length of the equivalent cylinder. There is scaling within individual branches, such that electrotonic in finer branches spread is relatively effective over their shorter lengths. Integration of synaptic potentials in passive dendrites is fundamentally nonlinear because of interactions between the synaptic conductances. The rules for electrotonic spread in dendrites are the basis for understanding the contributions of active properties of dendrites (see Chapter 12).

## RELATING PASSIVE TO ACTIVE POTENTIALS

We can now begin to gain insight into the relation between passive and active potentials in a neuron. We consider a model, the olfactory mitral cell, in which we apply the principles of this chapter and look forward to the principles underlying active properties in Chapter 12.

A basic problem is to understand the factors that decide where the action potential will be initiated with different levels of excitatory or inhibitory inputs. The possible sites are anywhere from the axon through the soma to the most distal dendrites. The mitral cell is

advantageous for this analysis (1) because all the excitatory synaptic input is through olfactory nerve terminals that make their synapses on the distal dendritic tuft and (2) because the primary dendrite that connects the tuft to the cell body is an unbranched cylinder. Applying depolarizing current to distal dendrite or soma, the experimental findings were counterintuitive: with weak distal inputs the action potential initiation site is far away, in the axon, but with increasing excitation it shifts to the distal dendrite, as illustrated in Figure 5.15A (Chen *et al.*, 1997). How can the weak response spread so far passively, and why does it not excite the active dendrites along the way? Electrotonic spread is the key to the answer.

**FIGURE 5.15** Interactions of passive and active potentials in the olfactory mitral cell. (A) Insets show diagrams of a mitral cell with recording sites at soma and distal dendrite. Curves show fitting of experimental and computed responses to weak and strong depolarizing currents injected into the distal primary dendrite. Note the nearly exact superposition of experimental (solid lines) and computed (dashed lines) responses. (B) Longitudinal distribution of membrane potential changes during responses to weak distal dendritic excitation. (C) Same to strong distal dendritic excitation. Blue lines, predominantly passively generated potentials; red lines, predominantly actively generated potentials. d, dendrite; s, soma; c, passive charging; o, onset of action potential; sp, spike peak; r, recovery. See text. Adapted from Shen *et al.* (1999).

This is much too complex a problem to solve in your head or with “back of the envelope” calculations. The only effective method is a realistic computational simulation. A compartmental model of the mitral cell was therefore constructed, with Na<sup>+</sup> and K<sup>+</sup> conductances scaled to the structure of the mitral cell. Fitting of computed with experimental responses was carried out under stringent constraints, with minimization of eight simultaneous simulations (distal and soma recording sites, distal and soma sites of excitatory current input; strong and weak levels of excitation) (Shen *et al.*, 1999).

We will analyze the active properties in Chapter 12; here we focus on fitting the passive properties. Two steps were essential. First, each experimental recording began with a period of passive charging of the mitral cell membrane (c in Fig. 5.15A). Figure 5.15A shows that the model gave a very accurate simulation, even when the charging was long lasting (left, weak stimulation). This was a critical fit for giving the correct latency of action potential initiation. Second, the longitudinal spread of passive current between the axon and the distal dendrite was calculated. This showed that with weak distal excitation (Fig. 5.15B), the electrotonic current spread with a shallow gradient from the site of injection along the dendrite to the axon (bottom traces); the action potential arose first in the axon because of the much higher density of Na<sup>+</sup> channels there compared with the dendrite. However, with strong distal excitation (Fig. 5.15C), the direct depolarization of the less excitable distal dendrite led the weaker electrotonic depolarization of the more excitable axon, and dendritic action potential initiation occurred first. This can be explored online at [senselab.med.yale.edu/modeldb](http://senselab.med.yale.edu/modeldb).

The computational simulations thus show precisely how the interactions of passive and active potentials control the sites of action potential initiation in the neuron. This is a model for the complex integrative properties of the neuron, which are explored further in Chapter 12.

## Membrane Potential and Action Potential

The communication of information between neurons and between neurons and muscles or peripheral organs requires that signals travel over considerable distances. A number of notable scientists have contemplated the nature of this communication through the ages. In the second century AD, the great Greek physician Claudius Galen proposed that “humors” flowed from the brain to the muscles along hollow nerves. A true electrophysiological understanding of nerve and muscle, however, depended on the discovery and understanding of electricity itself. The precise nature of nerve and muscle action became clearer with the advent of new experimental techniques by a number of European scientists, including Luigi Galvani, Emil Du Bois-Reymond, Carlo Matteucci, and Hermann von Helmholtz, to name a few (Brazier, 1988). Through the application of electrical stimulation to nerves and muscles, these early electrophysiologists demonstrated that the conduction of commands from the brain to the muscle for the generation of movement was mediated by the flow of electricity along nerve fibers.

With the advancement of electrophysiological techniques, electrical activity recorded from nerves revealed that the conduction of information along the axon was mediated by the active generation of an electrical potential, called the action potential. But what precisely was the nature of these action potentials? To know this in detail required not only a preparation from which to obtain intracellular recordings but also one that could survive *in vitro*. The squid giant axon provided precisely such a preparation. Many invertebrates contain unusually large axons for the generation of escape reflexes; large axons conduct more quickly than small ones and so the response time for escape is

reduced (see Chapter 5). The squid possesses an axon approximately 0.5 mm in diameter, large enough to be impaled by even a coarse micropipette (Fig. 6.1). By inserting a glass micropipette filled with a salt solution into the squid giant axon, Alan Hodgkin and Andrew Huxley demonstrated in 1939 that axons at rest are electrically polarized, exhibiting a resting membrane potential of approximately  $-60\text{ mV}$  inside versus outside. In the generation of an action potential, the polarization of the membrane is removed (referred to as depolarization) and exhibits a rapid swing toward, and even past,  $0\text{ mV}$  (Fig. 6.1). This depolarization is followed by a rapid swing in the membrane potential to more negative values, a process referred to as hyperpolarization. The membrane potential following an action potential typically becomes even more negative than the original value of approximately  $-60\text{ mV}$ . This period of increased polarization is referred to as the after-hyperpolarization or the undershoot.

The development of electrophysiological techniques to the point that intracellular recordings could be obtained from the small cells of the mammalian nervous system revealed that action potentials in these neurons are generated through mechanisms similar to that of the squid giant axon.

It is now known that action potential generation in nearly all types of neurons and muscle cells is accomplished through mechanisms similar to those first detailed in the squid giant axon by Hodgkin and Huxley. This chapter considers the cellular mechanisms by which neurons and axons generate a resting membrane potential and how this membrane potential briefly is disrupted for the purpose of propagation of an electrical signal, the action potential.

**FIGURE 6.1** Intracellular recording of the membrane potential and action potential generation in the squid giant axon. (A) A glass micropipette, about  $100\mu\text{m}$  in diameter, was filled with seawater and lowered into the giant axon of the squid after it had been dissected free. The axon is about 1 mm in diameter and is transilluminated from behind. (B) One action potential recorded between the inside and the outside of the axon. Peaks of a sine wave at the bottom provided a scale for timing, with 2 ms between peaks. From Hodgkin and Huxley (1939).

## MEMBRANE POTENTIAL

### Membrane Potential Is Generated by the Differential Distribution of Ions

Through the operation of ionic pumps and special ionic buffering mechanisms, neurons actively maintain precise internal concentrations of several important ions, including  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{2+}$ . The mechanisms by which they do so are illustrated in Figures 6.2 and 6.3. The intracellular and extracellular concentrations of  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{2+}$  differ markedly (Fig. 6.2);  $\text{K}^+$  is actively concentrated inside the cell, and  $\text{Na}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{2+}$  are actively extruded to the extracellular space. However, this does not mean that the cell is filled only with positive charge; anions to which the plasma membrane is impermeant are also present inside the cell and almost balance the high concentration of  $\text{K}^+$ . The osmolarity inside the cell is approximately equal to that outside the cell.

### Electrical and Thermodynamic Forces Determine the Passive Distribution of Ions

Ions tend to move down their concentration gradients through specialized ionic pores, known as ionic channels, in the plasma membrane. Through simple laws of thermodynamics, the high concentration of  $\text{K}^+$  inside glial cells, neurons, and axons results in a tendency for  $\text{K}^+$  ions to diffuse down their concentration gradient and leave the cell or cell process (Fig. 6.3). However, the movement of ions across the membrane also results in a redistribution of electrical charge. As

$\text{K}^+$  ions move down their concentration gradient, the intracellular voltage becomes more negative, and this increased negativity results in an electrical attraction between the negative potential inside the cell and the positively charged,  $\text{K}^+$  ions, thus offsetting the outward flow of these ions. The membrane is selectively permeable; that is, it is impermeable to the large anions inside the cell, which cannot follow the potassium ions across the membrane. At some membrane potential, the “force” of the electrostatic attraction between the negative membrane potential inside the cell and the positively charged  $\text{K}^+$  ions will exactly balance the thermal “forces” by which  $\text{K}^+$  ions tend to flow down their concentration gradient (Fig. 6.3). In this circumstance, it is equally likely that a  $\text{K}^+$  ion exits the cell by movement down the concentration gradient as it is that a  $\text{K}^+$  ion enters the cell due to the attraction between the negative membrane potential and the positive charge of this ion. At this membrane potential, there is no net flow of  $\text{K}^+$  (the same number of  $\text{K}^+$  ions enter the cell as leave the cell per unit time) and these ions are said to be in equilibrium. The membrane potential at which this occurs is known as the equilibrium potential. (See Box 6.1 for calculation of the equilibrium potential.)

To illustrate, let us consider the passive distribution of  $\text{K}^+$  ions in the squid giant axon as studied by Hodgkin and Huxley. The  $\text{K}^+$  concentration  $[\text{K}^+]_i$  inside the squid giant axon is about 400 mM, whereas the  $[\text{K}^+]_o$  outside the axon is about 20 mM. Because  $[\text{K}^+]_i$  is greater than  $[\text{K}^+]_o$ , potassium ions will tend to flow down their concentration gradient, taking positive charge with them. The equilibrium potential (at which the tendency for

**FIGURE 6.2** Differential distribution of ions inside and outside plasma membrane of neurons and neuronal processes, showing ionic channels for  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Cl}^-$ , and  $\text{Ca}^{2+}$ , as well as an electrogenic  $\text{Na}^+$ - $\text{K}^+$  ionic pump (also known as  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase). Concentrations (in millimoles except that for intracellular  $\text{Ca}^{2+}$ ) of the ions are given in parentheses; their equilibrium potentials ( $E$ ) for a typical mammalian neuron are indicated.

$\text{K}^+$  ions to flow down their concentration gradient will be exactly offset by the attraction for  $\text{K}^+$  ions to enter the cell (because of the negative charge inside the cell) at a room temperature of  $20^\circ\text{C}$  can be calculated by the Nernst equation as such:

$$E_K = 58.2 \log_{10} (20/400) = -76 \text{ mV}$$

Therefore, at a membrane potential of  $-76 \text{ mV}$ ,  $\text{K}^+$  ions have an equal tendency to flow either into or out of the axon. The concentrations of  $\text{K}^+$  in mammalian neurons

**FIGURE 6.3** The equilibrium potential is influenced by the concentration gradient and the voltage difference across the membrane. Neurons actively concentrate  $\text{K}^+$  inside the cell. These  $\text{K}^+$  ions tend to flow down their concentration gradient from inside to outside the cell. However, the negative membrane potential inside the cell provides an attraction for  $\text{K}^+$  ions to enter or remain within the cell. These two factors balance one another at the equilibrium potential, which in a typical mammalian neuron is  $-102 \text{ mV}$  for  $\text{K}^+$ .

and glial cells differ considerably from that in the squid giant axon, which is adapted to live in sea water. By substituting  $3.1 \text{ mM}$  for  $[\text{K}^+]_o$  and  $140 \text{ mM}$  for  $[\text{K}^+]_i$  in the Nernst equation, with mammalian body temperature,  $T = 37^\circ\text{C}$ , we obtain

$$E_K = 61.5 \log_{10} (3.1/140) = -102 \text{ mV}$$

### Movements of Ions Can Cause Either Hyperpolarization or Depolarization

In mammalian cells, at membrane potentials positive to  $-102 \text{ mV}$ ,  $\text{K}^+$  ions tend to flow out of the cell. Increasing the ability of  $\text{K}^+$  ions to flow across the membrane (i.e., increasing the conductance of the membrane to  $\text{K}^+$  ( $g_K$ )) causes the membrane potential to become more negative, or hyperpolarized, due to the exiting of positively charged ions from inside the cell (Fig. 6.4).

## BOX 6.1

## NERNST EQUATION

The equilibrium potential is determined by (1) the concentration of the ion inside and outside the cell, (2) the temperature of the solution, (3) the valence of the ion, and (4) the amount of work required to separate a given quantity of charge. The equation that describes the equilibrium potential was formulated by a German physical chemist named Walter Nernst in 1888:

$$E_{\text{ion}} = RT/zF \cdot \ln([\text{ion}]_o/[\text{ion}]_i)$$

Here,  $E_{\text{ion}}$  is the membrane potential at which the ionic species is at equilibrium,  $R$  is the gas constant [8.315 J per Kelvin per mole ( $\text{J K}^{-1} \text{mol}^{-1}$ )],  $T$  is the temperature in Kelvins ( $T_{\text{Kelvin}} = 273.16 + T_{\text{Celsius}}$ ),  $F$  is Faraday's constant

[96,485 coulombs per mole ( $\text{C mol}^{-1}$ )],  $z$  is the valence of the ion, and  $[\text{ion}]_o$  and  $[\text{ion}]_i$  are the concentrations of the ion outside and inside the cell, respectively. For a monovalent, positively charged ion (cation) at room temperature ( $20^\circ\text{C}$ ), substituting the appropriate numbers and converting natural log ( $\ln$ ) into log base 10 ( $\log_{10}$ ) results in

$$E_{\text{ion}} = 58.2 \log_{10}([\text{ion}]_o/[\text{ion}]_i);$$

at a body temperature of  $37^\circ\text{C}$ , the Nernst equation is

$$E_{\text{ion}} = 61.5 \log_{10}([\text{ion}]_o/[\text{ion}]_i).$$

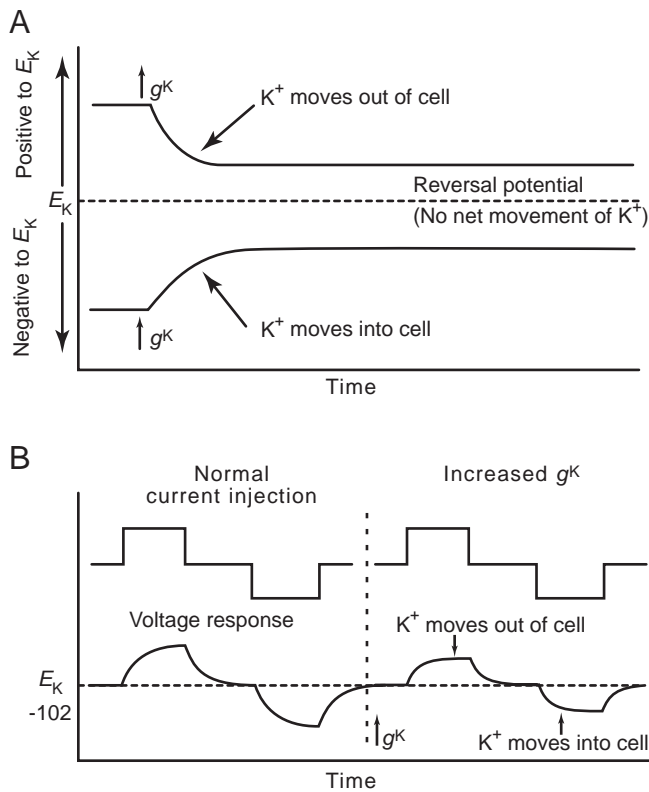

*David A. McCormick*

At membrane potentials negative to  $-102\text{mV}$ ,  $\text{K}^+$  ions tend to flow into the cell; increasing the membrane conductance to  $\text{K}^+$  causes the membrane potential to become more positive, or depolarized, due to the flow of positive charge into the cell. The membrane potential at which the net current "flips" direction is referred to as the reversal potential. If the channels conduct only one type of ion (e.g.,  $\text{K}^+$  ions), then the reversal potential and the Nernst equilibrium potential for that ion coincide (Fig. 6.4A). Increasing the membrane conductance to  $\text{K}^+$  ions while the membrane potential is at the equilibrium potential for  $\text{K}^+$  ( $E_K$ ) does not change the membrane potential because no net driving force causes  $\text{K}^+$  ions to either exit or enter the cell. However, this increase in membrane conductance to  $\text{K}^+$  decreases the ability of other species of ions to change the membrane potential because any deviation of the potential from  $E_K$  increases the drive for  $\text{K}^+$  ions to either exit or enter the cell, thereby drawing the membrane potential back toward  $E_K$  (Fig. 6.4B). This effect is known as a "shunt" and is important for some effects of inhibitory synaptic transmission.

The exiting and entering of the cell by  $\text{K}^+$  ions during generation of the membrane potential gives rise to a curious problem. When  $\text{K}^+$  ions leave the cell to generate a membrane potential, the concentration of  $\text{K}^+$  changes both inside and outside the cell. Why does this change in concentration not alter the equilibrium potential, thus changing the tendency for  $\text{K}^+$  ions to flow down their concentration gradient? The reason is that the number of  $\text{K}^+$  ions required to leave the cell to

achieve the equilibrium potential is quite small. For example, if a cell were at  $0\text{mV}$  and the membrane suddenly became permeable to  $\text{K}^+$  ions, only about  $10^{-12}\text{mol}$  of  $\text{K}^+$  ions per square centimeter of membrane would move from inside to outside the cell in bringing the membrane potential to the equilibrium potential for  $\text{K}^+$ . In a spherical cell of  $25\mu\text{m}$  diameter, this would amount to an average decrease in intracellular  $\text{K}^+$  of only about  $4\mu\text{M}$  (e.g., from  $140$  to  $139.996\text{mM}$ ). However, there are instances when significant changes in the concentrations of  $\text{K}^+$  may occur, particularly during the generation of pronounced activity, such as an epileptic seizure. During the occurrence of a tonic-clonic generalized (grand mal) seizure, large numbers of neurons discharge throughout the cerebral cortex in a synchronized manner. This synchronous discharge of large numbers of neurons significantly increases the extracellular  $\text{K}^+$  concentration, by as much as a couple of millimoles, resulting in a commensurate positive shift in the equilibrium potential for  $\text{K}^+$ . This shift in the equilibrium potential can increase the excitability of affected neurons and neuronal processes and thus promote the spread of the seizure activity. Fortunately, the extracellular concentration of  $\text{K}^+$  is tightly regulated and is kept at normal levels through uptake by glial cells, as well as by diffusion through the fluid of the extracellular space.

As is true for  $\text{K}^+$  ions, each of the membrane-permeable species of ions possesses an equilibrium potential that depends on the concentration of that ion inside and outside the cell. Thus, equilibrium potentials may

**FIGURE 6.4** Increases in  $K^+$  conductance can result in hyperpolarization, depolarization, or no change in membrane potential. (A) Opening  $K^+$  channels increases the conductance of the membrane to  $K^+$ , denoted  $g_K$ . If the membrane potential is positive to the equilibrium potential (also known as the reversal potential) for  $K^+$ , then increasing  $g_K$  will cause some  $K^+$  ions to leave the cell, and the cell will become hyperpolarized. If the membrane potential is negative to  $E_K$  when  $g_K$  is increased, then  $K^+$  ions will enter the cell, therefore making the inside more positive (more depolarized). If the membrane potential is exactly  $E_K$  when  $g_K$  is increased, then there will be no net movement of  $K^+$  ions. (B) Opening  $K^+$  channels when the membrane potential is at  $E_K$  does not change the membrane potential; however, it reduces the ability of other ionic currents to move the membrane potential away from  $E_K$ . For example, a comparison of the ability of the injection of two pulses of current, one depolarizing and one hyperpolarizing, to change the membrane potential before and after opening  $K^+$  channels reveals that increases in  $g_K$  decrease the responses of the cell noticeably.

vary between different cell types, such as those found in animals adapted to live in salt water versus mammalian neurons. In mammalian neurons, the equilibrium potential is approximately 56 mV for  $Na^+$ , approximately  $-76$  mV for  $Cl^-$ , and about 125 mV for  $Ca^{2+}$  (Fig. 6.2). Thus, increasing the membrane conductance to  $Na^+$  ( $g_{Na}$ ) through the opening of  $Na^+$  channels depolarizes the membrane potential toward 56 mV; increasing the membrane conductance to  $Cl^-$  brings the membrane potential closer to  $-76$  mV; and finally increasing the membrane conductance to  $Ca^{2+}$  depolarizes the cell toward 125 mV.

## $Na^+$ , $K^+$ , and $Cl^-$ Contribute to the Determination of the Resting Membrane Potential

If a membrane is permeable to only one ion and no electrogenic ionic pumps are operating (see next section), then the membrane potential is necessarily at the equilibrium potential for that ion. At rest, the plasma membrane of most cell types is not at the equilibrium potential for  $K^+$  ions, indicating that the membrane is also permeable to other types of ions. For example, the resting membrane of the squid giant axon is permeable to  $Cl^-$  and  $Na^+$ , as well as  $K^+$ , due to the presence of ionic channels that not only allow these ions to pass but also are open at the resting membrane potential. Because the membrane is permeable to  $K^+$ ,  $Cl^-$ , and  $Na^+$ , the resting potential of the squid giant axon is not equal to  $E_K$ ,  $E_{Na}$ , or  $E_{Cl}$ , but is somewhere in between these three. A membrane permeable to more than one ion has a steady-state membrane potential whose value is between those of the equilibrium potentials for each of the permeant ions (Box 6.2).

## Different Types of Neurons Have Different Resting Potentials

Intracellular recordings from neurons in the mammalian central nervous system (CNS) reveal that different types of neurons exhibit different resting membrane potentials. Indeed, some types of neurons do not even exhibit a true “resting” membrane potential; they spontaneously and continuously generate action potentials even in the total lack of synaptic input. In the visual system, intracellular recordings have shown that photoreceptor cells of the retina—the rods and cones—have a membrane potential of approximately  $-40$  mV at rest and are hyperpolarized when activated by light. Cells in the dorsal lateral geniculate nucleus, which receive axonal input from the retina and project to the visual cortex, have a resting membrane potential of approximately  $-70$  mV during sleep and  $-55$  mV during waking, whereas pyramidal neurons of the visual cortex have a resting membrane potential of about  $-75$  mV. Presumably, the resting membrane potentials of different cell types in the central and peripheral nervous system are highly regulated and are functionally important. For example, the depolarized membrane potential of photoreceptors presumably allows the membrane potential to move in both negative and positive directions in response to changes in light intensity. The hyperpolarized membrane potential of thalamic neurons during sleep ( $-70$  mV) dramatically decreases the flow of information from the sensory periphery to the cerebral cortex,

## BOX 6.2

## GOLDMAN-HODGKIN-KATZ EQUATION

An equation developed by Goldman and later used by Alan Hodgkin and Bernard Katz describes the steady-state membrane potential for a given set of ionic concentrations inside and outside the cell and the relative permeabilities of the membrane to each of those ions:

$$V_m \frac{RT}{F} \cdot \ln \left( \frac{(p_K [K^+]_o + p_{Na} [Na^+]_o + p_{Cl} [Cl^-]_i)}{(p_K [K^+]_i + p_{Na} [Na^+]_i + p_{Cl} [Cl^-]_o)} \right)$$

The relative contribution of each ion is determined by its concentration differences across the membrane and the relative permeability ( $p_K$ ,  $p_{Na}$ ,  $p_{Cl}$ ) of the membrane to each type of ion. If a membrane is permeable to only one ion, then the Goldman-Hodgkin-Katz equation reduces to the Nernst equation. In the squid giant axon, at resting membrane potential, the permeability ratios are

$$p_K : p_{Na} : p_{Cl} = 1.00 : 0.04 : 0.45.$$

The membrane of the squid giant axon, at rest, is most permeable to  $K^+$  ions, less so to  $Cl^-$ , and least permeable to  $Na^+$ . (Chloride appears to contribute considerably less to the determination of the resting potential of mammalian neurons.) These results indicate that the resting membrane potential is determined by the resting permeability of the membrane to  $K^+$ ,  $Na^+$ , and  $Cl^-$ . In theory, this resting membrane potential may be anywhere between  $E_K$  (e.g.,  $-76$  mV) and  $E_{Na}$  ( $55$  mV). For the three ions at  $20^\circ\text{C}$ , the equation is

$$V_m = \frac{58.2 \log_{10} \{(1 \cdot 20 + 0.04 \cdot 440 + 0.45 \cdot 40)\}}{(1 \cdot 400 + 0.04 \cdot 50 + 0.45 \cdot 560)} = -62 \text{ mV}.$$

This suggests that the squid giant axon should have a resting membrane potential of  $-62$  mV. In fact, the resting membrane potential may be a few millivolts hyperpolarized to this value through the operation of the electrogenic  $Na^+-K^+$  pump.

David A. McCormick

presumably to allow the cortex to be relatively undisturbed during sleep, and the 20-mV membrane potential between the resting potential and the action potential threshold in cortical pyramidal cells allows these cells to be strongly influenced by subthreshold barrages of synaptic potentials from other cortical neurons (see Chapters 5 and 12).

### Ionic Pumps Actively Maintain Ionic Gradients

Because the resting membrane potential of a neuron is not at the equilibrium potential for any particular ion, ions constantly flow down their concentration gradients. This flux becomes considerably larger with the generation of electrical and synaptic potentials because ionic channels are opened by these events. Although the absolute number of ions traversing the plasma membrane during each action potential or synaptic potential may be small in individual cells, the collective influence of a large neural network of cells, such as in the brain, and the presence of ion fluxes even at rest can substantially change the distribution of ions inside and outside neurons. Cells have solved this problem with the use of active transport of ions against their concentration gradients. The proteins that actively transport ions are referred to as ionic pumps, of which

the  $Na^+-K^+$  pump is perhaps the most thoroughly understood (Lauger, 1991). The  $Na^+-K^+$  pump is stimulated by increases in the intracellular concentration of  $Na^+$  and moves  $Na^+$  out of the cell while moving  $K^+$  into it, achieving this task through the hydrolysis of ATP (Fig. 6.2). Three  $Na^+$  ions are extruded for every two  $K^+$  ions transported into the cell. Because of the unequal transport of ions, the operation of this pump generates a hyperpolarizing electrical potential and is said to be electrogenic. The  $Na^+-K^+$  pump typically results in the membrane potential of the cell being a few millivolts more negative than it would be otherwise.

The  $Na^+-K^+$  pump consists of two subunits,  $\alpha$  and  $\beta$ , arranged in a tetramer ( $\alpha\beta$ )<sub>2</sub>. The  $Na^+-K^+$  pump is believed to operate through conformational changes that alternatively expose a  $Na^+$ -binding site to the interior of the cell (followed by the release of  $Na^+$ ) and a  $K^+$  binding site to the extracellular fluid (Fig. 6.2). Such a conformation change may be due to the phosphorylation and dephosphorylation of the protein.

The membranes of neurons and glia contain multiple types of ionic pumps, used to maintain the proper distribution of each ionic species important for cellular signaling. Many of these pumps are operated by the  $Na^+$  gradient across the cell, whereas others operate through a mechanism similar to that of the  $Na^+-K^+$

pump (i.e., the hydrolysis of ATP). For example, the calcium concentration inside neurons is kept to very low levels (typically 50–100 nM) through the operation of both types of ionic pumps, as well as special intracellular  $\text{Ca}^{2+}$  buffering mechanisms.  $\text{Ca}^{2+}$  is extruded from neurons through both a  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ -ATPase, and a  $\text{Na}^{+}$ - $\text{Ca}^{2+}$  exchanger. The  $\text{Na}^{+}$ - $\text{Ca}^{2+}$  exchanger is driven by the  $\text{Na}^{+}$  gradient across the membrane and extrudes one  $\text{Ca}^{2+}$  ion for each  $\text{Na}^{+}$  ion allowed to enter the cell.

The  $\text{Cl}^{-}$  concentration in neurons is actively maintained at a low level through operation of a chloride-bicarbonate exchanger, which brings in one ion of  $\text{Na}^{+}$  and one ion of  $\text{HCO}_3^{-}$  for each ion of  $\text{Cl}^{-}$  extruded. Intracellular pH can also markedly affect neuronal excitability and is therefore tightly regulated, in part by a  $\text{Na}^{+}$ - $\text{H}^{+}$  exchanger that extrudes one proton for each  $\text{Na}^{+}$  allowed to enter the cell.

## Summary

The membrane potential is generated by the unequal distribution of ions, particularly  $\text{K}^{+}$ ,  $\text{Na}^{+}$ , and  $\text{Cl}^{-}$ , across the plasma membrane. This unequal distribution of ions is maintained by ionic pumps and exchangers.  $\text{K}^{+}$  ions are concentrated inside the neuron and tend to flow down their concentration gradient, leading to a hyperpolarization of the cell. At the equilibrium potential, the tendency of  $\text{K}^{+}$  ions to flow out of the cell will be exactly offset by the tendency of  $\text{K}^{+}$  ions to enter the cell due to the attraction of the negative potential inside the cell. The resting membrane is also permeable to  $\text{Na}^{+}$  and  $\text{Cl}^{-}$  and therefore the resting membrane potential is approximately  $-75$  to  $-40$  mV, in other words, substantially positive to  $E_{\text{K}}$ .

## ACTION POTENTIAL

### An Increase in $\text{Na}^{+}$ and $\text{K}^{+}$ Conductance Generates Action Potentials

Hodgkin and Huxley not only recorded the action potential with an intracellular microelectrode (Fig. 6.1), but also went on to perform a remarkable series of experiments that explained qualitatively and quantitatively the ionic mechanisms by which the action potential is generated (Hodgkin and Huxley, 1952a, b). As mentioned earlier, these investigators found that during the action potential, the membrane potential of the cell rapidly overshoots 0 mV and approaches the equilibrium potential for  $\text{Na}^{+}$ . After generation of the action potential, the membrane potential repolar-

izes and becomes more negative than before, generating an after-hyperpolarization. These changes in membrane potential during generation of the action potential were associated with a large increase in conductance of the plasma membrane, but to what does the membrane become conductive in order to generate the action potential? The prevailing hypothesis was that there was a nonselective increase in conductance causing the negative resting potential to increase toward 0 mV. Since publication of the experiments of E. Overton in 1902, the action potential had been known to depend on the presence of extracellular  $\text{Na}^{+}$ . Reducing the concentration of  $\text{Na}^{+}$  in the artificial seawater bathing the axon resulted in a marked reduction in the amplitude of the action potential. On the basis of these and other data, Hodgkin and Katz proposed that the action potential is generated through a rapid increase in the conductance of the membrane to  $\text{Na}^{+}$  ions. A quantitative proof of this theory was lacking, however, because ionic currents could not be observed directly. Development of the voltage-clamp technique by Kenneth Cole at the Marine Biological Laboratory in Massachusetts resolved this problem and allowed quantitative measurement of the  $\text{Na}^{+}$  and  $\text{K}^{+}$  currents underlying the action potential (Cole, 1949; Box 6.3).

Hodgkin and Huxley (1952) used the voltage-clamp technique to investigate the mechanisms of generation of the action potential in the squid giant axon. Axons and neurons have a threshold for the initialization of an action potential of about  $-45$  to  $-55$  mV. Increasing the voltage from  $-60$  to 0 mV produces a large, but transient, flow of positive charge into the cell (known as inward current). This transient inward current is followed by a sustained flow of positive charge out of the cell (the outward current). By voltage clamping the cell and substituting different ions inside or outside the axon or both, Hodgkin, Huxley, and colleagues demonstrated that the transient inward current is carried by  $\text{Na}^{+}$  ions flowing into the cell and the sustained outward current is mediated by a sustained flux of  $\text{K}^{+}$  ions moving out of the cell (Fig. 6.6) (Hodgkin and Huxley, 1952a, 1952b; Hille, 1977).

$\text{Na}^{+}$  and  $\text{K}^{+}$  currents ( $I_{\text{Na}}$  and  $I_{\text{K}}$ , respectively) can be blocked, allowing each current to be examined in isolation (Fig. 6.6B). Tetrodotoxin (TTX), a powerful poison found in the puffer fish *Spherooides rubripes*, selectively blocks voltage-dependent  $\text{Na}^{+}$  currents (the puffer fish remains a delicacy in Japan and must be prepared with the utmost care by the chef). Using TTX, one can selectively isolate  $I_{\text{K}}$  and examine its voltage dependence and time course (Fig. 6.6B).

Another compound, tetraethylammonium (TEA), is a useful pharmacological tool for selectively blocking

## BOX 6.3

## VOLTAGE-CLAMP TECHNIQUE

In the voltage-clamp technique, two independent electrodes are inserted into the squid giant axon: one for recording the voltage difference across the membrane and the other for intracellularly injecting the current (Fig. 6.5). These electrodes are then connected to a feedback circuit that compares the measured voltage across the membrane with the voltage desired by the experimenter. If these two values differ, then current is injected into the axon to compensate for this difference. This continuous feedback cycle, in which the voltage is measured and current is injected, effectively “clamps” the membrane at a particular voltage. If ionic channels were to open, then the resultant flow of ions into or out of the axon would be compensated for by the injection of positive or negative current into the axon through the current-injection electrode. The current injected through this electrode is

necessarily equal to the current flowing through the ionic channels. It is this injected current that is measured by the experimenter. The benefits of the voltage-clamp technique are twofold. First, the current injected into the axon to keep the membrane potential “clamped” is necessarily equal to the current flowing through the ionic channels in the membrane, thereby giving a direct measurement of this current. Second, ionic currents are both voltage and time dependent; they become active at certain membrane potentials and do so at a particular rate. Keeping the voltage constant in the voltage clamp allows these two variables to be separated; the voltage dependence and the kinetics of the ionic currents flowing through the plasma membrane can be measured directly.

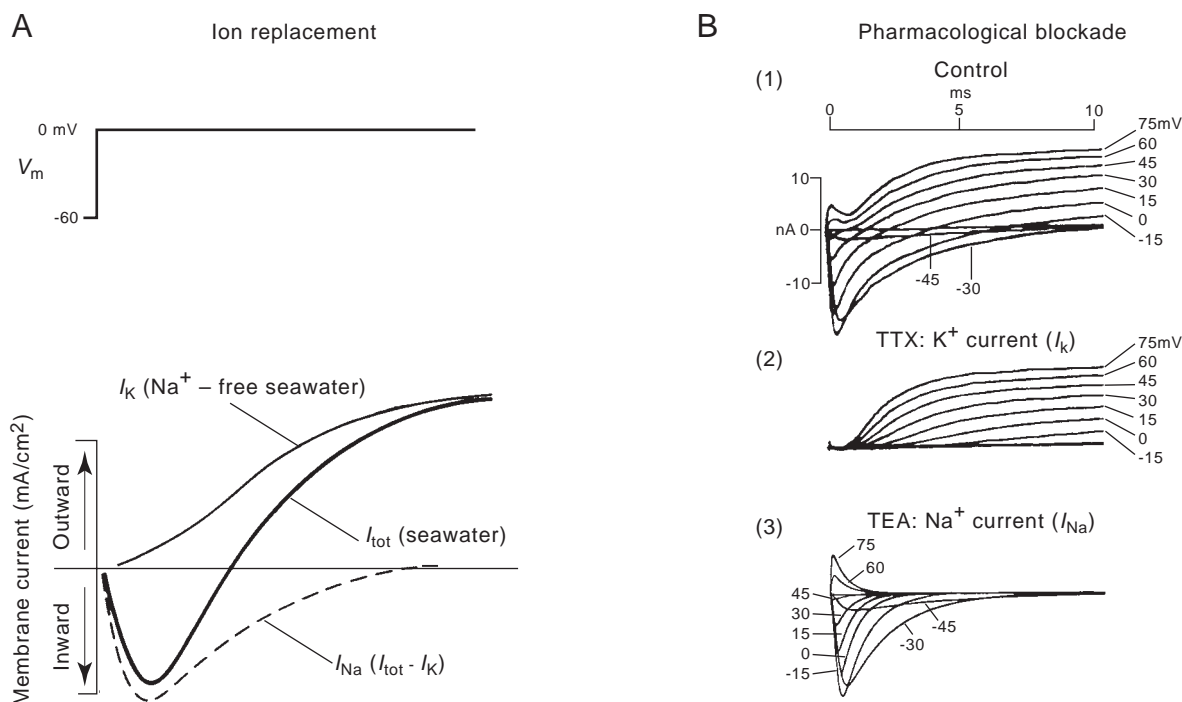

*David A. McCormick*

**FIGURE 6.5** The voltage-clamp technique keeps the voltage across the membrane constant so that the amplitude and time course of ionic currents can be measured. In the two-electrode voltage-clamp technique, one electrode measures the voltage across the membrane while the other injects current into the cell to keep the voltage constant. The experimenter sets a voltage to which the axon or neuron is to be stepped (the command potential). Current is then injected into the cell in proportion to the difference between the present membrane potential and the command potential. This feedback cycle occurs continuously, thereby clamping the membrane potential to the command potential. By measuring the amount of current injected, the experimenter can determine the amplitude and time course of the ionic currents flowing across the membrane.

$I_K$  (Fig. 6.6B). The use of TEA to examine the voltage dependence and time course of the  $Na^+$  current underlying action-potential generation (Fig. 6.6B) reveals some fundamental differences between  $Na^+$  and  $K^+$  currents. First, the inward  $Na^+$  current activates, or “turns on,” much more rapidly than the  $K^+$  current (giving rise to the name “delayed rectifier” for this  $K^+$  current). Second, the  $Na^+$  current is transient; it inactivates, even if the membrane potential is maintained at 0 mV (Fig. 6.6A). In contrast, the outward  $K^+$  current, once activated, remains “on” as long as the membrane potential is clamped to positive levels; that is, the  $K^+$  current does not inactivate, it is sustained. Remarkably, from one experiment, we see that the  $Na^+$  current both activates and inactivates rapidly, whereas the  $K^+$  current only activates slowly. These fundamental properties of the underlying  $Na^+$  and  $K^+$  channels allow the generation of action potentials.

Hodgkin and Huxley proposed that  $K^+$  channels possess a voltage-sensitive “gate” that opens by depolarization and closes by the subsequent repolarization of the membrane potential. This process of “turning on” and “turning off” the  $K^+$  current came to be known as activation and deactivation. The  $Na^+$  current also exhibits voltage-dependent activation and deactivation (Fig. 6.6), but the  $Na^+$  channels also become inactive despite maintained depolarization. Thus, the  $Na^+$  current not only activates and deactivates, but also exhibits a separate process known as inactivation, whereby the channels become blocked even though

**FIGURE 6.6** Voltage-clamp analysis reveals ionic currents underlying action potential generation. (A) Increasing the potential from  $-60$  to  $0$  mV across the membrane of the squid giant axon activates an inward current followed by an outward current. If the  $\text{Na}^+$  in seawater is replaced by choline (which does not pass through  $\text{Na}^+$  channels), then increasing the membrane potential from  $-60$  to  $0$  mV results in only the outward current, which corresponds to  $I_K$ . Subtracting  $I_K$  from the recording in normal seawater illustrates the amplitude–time course of the inward  $\text{Na}^+$  current,  $I_{\text{Na}}$ . Note that  $I_K$  activates more slowly than  $I_{\text{Na}}$  and that  $I_{\text{Na}}$  inactivates with time. From Hodgkin and Huxley (1952). (B) These two ionic currents can also be isolated from one another through the use of pharmacological blockers. (1) Increasing the membrane potential from  $-45$  to  $75$  mV in  $15$ -mV steps reveals the amplitude–time course of inward  $\text{Na}^+$  and outward  $\text{K}^+$  currents. (2) After the block of  $I_{\text{Na}}$  with the poison tetrodotoxin (TTX), increasing the membrane potential to positive levels activates  $I_K$  only. (3) After the block of  $I_K$  with tetraethylammonium (TEA), increasing the membrane potential to positive levels activates  $I_{\text{Na}}$  only. From Hille (1977).

they are activated. Removal of this inactivation is achieved by removal of depolarization and is a process known as deinactivation. Thus,  $\text{Na}^+$  channels possess two voltage-sensitive processes: activation–deactivation and inactivation–deinactivation. The kinetics of these two properties of  $\text{Na}^+$  channels are different: inactivation takes place at a slower rate than activation. The functional consequence of the two mechanisms is that  $\text{Na}^+$  ions are allowed to flow across the membrane only when the current is activated but not inactivated. Accordingly,  $\text{Na}^+$  ions do not flow at resting membrane potentials because the activation gate is closed (even though the inactivation gate is not). Upon depolarization, the activation gate opens, allowing  $\text{Na}^+$  ions to flow into the cell. However, this depolarization also results in closure (at a slower rate) of the inactivation gate, which then blocks the flow of  $\text{Na}^+$  ions. Upon repolarization of the membrane potential, the activation gate once again closes and the inactivation gate once again opens, preparing the axon for generation of the next action potential (Fig. 6.7). Depolarization allows ionic current to flow by virtue of activation of the channel. The rush of  $\text{Na}^+$  ions into

the cell further depolarizes the membrane potential and more  $\text{Na}^+$  channels become activated, forming a positive feedback loop that rapidly (within  $100 \mu\text{s}$  or so) brings the membrane potential toward  $E_{\text{Na}}$ . However, the depolarization associated with generation of the action potential also inactivates  $\text{Na}^+$  channels, and, as a larger and larger percentage of  $\text{Na}^+$  channels become inactivated, the rush of  $\text{Na}^+$  into the cell diminishes. This inactivation of  $\text{Na}^+$  channels and the activation of  $\text{K}^+$  channels result in the repolarization of the action potential. This repolarization deactivates the  $\text{Na}^+$  channels. Then, the inactivation of the channel is slowly removed, and the channels are ready, once again, for the generation of another action potential (Fig. 6.7).

By measuring the voltage sensitivity and kinetics of these two processes, activation–deactivation and inactivation–deinactivation of the  $\text{Na}^+$  current, as well as the activation–deactivation of the delayed rectifier  $\text{K}^+$  current, Hodgkin and Huxley generated a series of mathematical equations that quantitatively described the generation of the action potential (calculation of the propagation of a single action potential required

**FIGURE 6.7** Generation of the action potential is associated with an increase in membrane  $\text{Na}^+$  conductance and  $\text{Na}^+$  current followed by an increase in  $\text{K}^+$  conductance and  $\text{K}^+$  current. Before action potential generation,  $\text{Na}^+$  channels are neither activated nor inactivated (illustrated at the bottom of the figure). Activation of  $\text{Na}^+$  channels allows  $\text{Na}^+$  ions to enter the cell, depolarizing the membrane potential. This depolarization also activates  $\text{K}^+$  channels. After activation and depolarization, the inactivation particle on the  $\text{Na}^+$  channels closes and the membrane potential repolarizes. The persistence of the activation of  $\text{K}^+$  channels (and other membrane properties) generates an after-hyperpolarization. During this period, the inactivation particle of the  $\text{Na}^+$  channel is removed and the  $\text{K}^+$  channels close.

an entire week of cranking a mechanical calculator). According to these early experimental and computational neuroscientists, the action potential is generated as follows. Depolarization of the membrane potential increases the probability of  $\text{Na}^+$  channels being in the activated, but not yet inactivated, state. At a particular membrane potential, the resulting inflow of  $\text{Na}^+$  ions tips the balance of the net ionic current from outward to inward (remember that depolarization will also increase  $\text{K}^+$  and  $\text{Cl}^-$  currents by moving the membrane potential away from  $E_{\text{K}}$  and  $E_{\text{Cl}}$ ). At this membrane potential, known as the action potential threshold (typically about  $-55\text{ mV}$ ), the movement of  $\text{Na}^+$  ions into the cell depolarizes the axon and opens more  $\text{Na}^+$  channels, causing yet more depolarization of the membrane; repetition of this process yields a rapid, positive feedback loop that brings the axon close to  $E_{\text{Na}}$ .

However, even as more and more  $\text{Na}^+$  channels are becoming activated, some of these channels are also inactivating and therefore no longer conducting  $\text{Na}^+$

ions. In addition, the delayed rectifier  $\text{K}^+$  channels are also opening, due to the depolarization of the membrane potential, and allowing positive charge to exit the cell. At some point, close to the peak of the action potential, the inward movement of  $\text{Na}^+$  ions into the cell is exactly offset by the outward movement of  $\text{K}^+$  ions out of the cell. After this point, the outward movement of  $\text{K}^+$  ions dominates, and the membrane potential is repolarized, corresponding to the fall of the action potential. The persistence of the  $\text{K}^+$  current for a few milliseconds following the action potential generates the after-hyperpolarization. During this after-hyperpolarization, which is lengthened by the membrane time constant, inactivation of the  $\text{Na}^+$  channels is removed, preparing the axon for generation of the next action potential (Fig. 6.7).

The occurrence of an action potential is not associated with substantial changes in the intracellular or extracellular concentrations of  $\text{Na}^+$  or  $\text{K}^+$ , as shown earlier for the generation of the resting membrane potential. For example, generation of a single action potential in a  $25\text{-}\mu\text{m}$ -diameter hypothetical spherical cell should increase the intracellular concentration of  $\text{Na}^+$  by only approximately  $6\text{ }\mu\text{M}$  (from about  $18$  to  $18.006\text{ mM}$ ). Thus, the action potential is an electrical event generated by a change in the distribution of charge across the membrane and not by a marked change in the intracellular or extracellular concentration of  $\text{Na}^+$  or  $\text{K}^+$ .

### Action Potentials Typically Initiate in the Axon Initial Segment and Propagate Down the Axon and Backward through the Dendrites

Neurons have complex morphologies including dendritic arbors, a cell body, and typically one axonal output, which branches extensively. In many cells, all these parts of the neuron are capable of independently generating action potentials. The activity of most neurons is dictated by barrages of synaptic potentials generated at each moment by a variable subset of the thousands of synapses impinging upon the cell's dendrites and soma. Where then is the action potential initiated? In most cells, each action potential is initiated in the initial portion of the axon, known as the axon initial segment (Coombs *et al.*, 1957; Stuart *et al.*, 1997; Shu *et al.*, 2007). The initial segment of the axon has the lowest threshold for action potential generation because it typically contains a moderately high density of  $\text{Na}^+$  channels and it is a small compartment that is easily depolarized by the in-rush of  $\text{Na}^+$  ions. Once a spike is initiated (e.g., about  $30\text{--}50$  microns down the axon from the cell body in cortical pyramidal cells), this action potential then propagates ortho-

dromically down the axon to the synaptic terminals, where it causes release of transmitter, as well as antidromically back through the cell body and into the cells dendrites, where it can modulate intracellular processes.

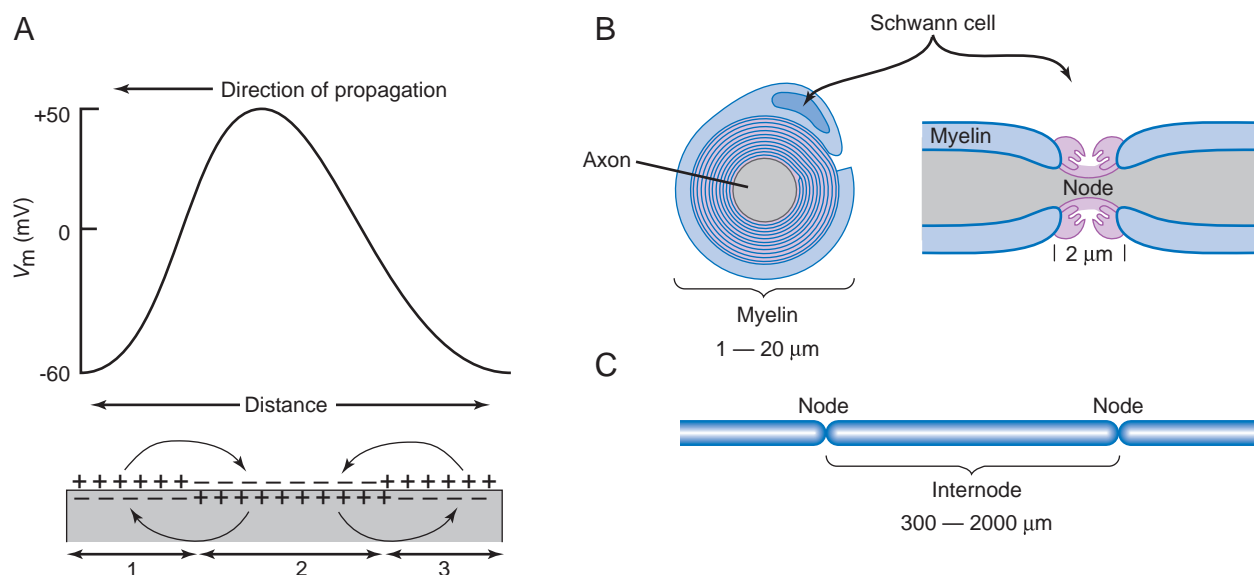

### Refractory Periods Prevent “Reverberation”

The ability of depolarization to activate an action potential varies as a function of the time since the last generation of an action potential, due to the inactivation of  $\text{Na}^+$  channels and the activation of  $\text{K}^+$  channels. Immediately after the generation of an action potential, another action potential usually cannot be generated regardless of the amount of current injected into the axon. This period corresponds to the absolute refractory period and largely is mediated by the inactivation of  $\text{Na}^+$  channels. The relative refractory period occurs during the action potential after-hyperpolarization and follows the absolute refractory period. The relative refractory period is characterized by a requirement for the increased injection of ionic current into the cell to generate another action potential and results from persistence of the outward  $\text{K}^+$  current. The practical implication of refractory periods is that action potentials are not allowed to “reverberate” between the axon initial segment and axon terminals.

### The Speed of Action Potential Propagation Is Affected by Myelination

Axons may be either myelinated or unmyelinated. Invertebrate axons or small vertebrate axons are typically unmyelinated, whereas larger vertebrate axons are often myelinated. As described in Chapter 4, sensory and motor axons of the peripheral nervous system are myelinated by specialized cells (Schwann cells) that form a spiral wrapping of multiple layers of myelin around the axon (Fig. 6.8). Several Schwann cells wrap around an axon along its length; between the ends of successive Schwann cells are small gaps (nodes of Ranvier). In the central nervous system, a single oligodendrocyte, a special type of glial cell, typically ensheaths several axonal processes.

In unmyelinated axons, the  $\text{Na}^+$  and  $\text{K}^+$  channels taking part in action potential generation are distributed along the axon, and the action potential propagates along the length of the axon through local depolarization of each neighboring patch of membrane, causing that patch of membrane also to generate an action potential (Fig. 6.8). In myelinated axons, however, the  $\text{Na}^+$  channels are concentrated at the nodes of Ranvier. The generation of an action potential at each node results in depolarization of the next node and subsequently generation of an action potential

**FIGURE 6.8** Propagation of the action potential in unmyelinated and myelinated axons. (A) Action potentials propagate in unmyelinated axons through the depolarization of adjacent regions of membrane. In the illustrated axon, region 2 is undergoing depolarization during the generation of the action potential, whereas region 3 already has generated the action potential and is now hyperpolarized. The action potential will propagate further by depolarizing region 1. (B) Vertebrate myelinated axons have a specialized Schwann cell that wraps around them in many spiral turns. The axon is exposed to the external medium at the nodes of Ranvier (Node). (C) Action potentials in myelinated fibers are regenerated at the nodes of Ranvier, where there is a high density of  $\text{Na}^+$  channels. Action potentials are induced at each node through the depolarizing influence of the generation of an action potential at an adjacent node, thereby increasing conduction velocity.

with an internode delay of only about  $20\ \mu\text{s}$  (see Chapter 5), referred to as saltatory conduction (from the Latin *saltare*, “to leap”). Growing evidence indicates that, near the nodes of Ranvier and underneath the myelin covering,  $\text{K}^+$  channels may play a role in determining the resting membrane potential and repolarization of the action potential. A cause of some neurological disorders, such as multiple sclerosis and Guillain–Barre syndrome, is the demyelination of axons, resulting in a block of conduction of the action potentials.

### Ion Channels Are Membrane-Spanning Proteins with Water-Filled Pores

The generation of ionic currents useful for the propagation of action potential requires the movement of

significant numbers of ions across the membrane in a relatively short time. The rate of ionic flow during the generation of an action potential is far too high to be achieved by an active transport mechanism and results instead from the opening of ion channels. Although the existence of ionic channels in the membrane has been postulated for decades, their properties and structure only recently have become known in detail. The powerful combination of electrophysiological and molecular techniques has enhanced our knowledge of the structure–function relations of ionic channels greatly (Box 6.4).

Various neural toxins were particularly useful in the initial isolation of ionic channels. For example, three subunits ( $\alpha$ ,  $\beta_1$ ,  $\beta_2$ ) of the voltage-dependent  $\text{Na}^+$  channel were isolated with the use of a derivative of a scorpion toxin. The  $\alpha$  subunit of the  $\text{Na}^+$  channel is a

#### BOX 6.4

### ION CHANNELS AND DISEASE

Cells cannot survive without functional ion channels. It is therefore not surprising that an ever-increasing number of diseases have been found to be associated with defective ion channel function. There are a number of different mechanisms by which this may occur.

1. Mutations in the coding region of ion channel genes may lead to gain or loss of channel function, either of which may have deleterious consequences. For example, mutations producing enhanced activity of the epithelial  $\text{Na}^+$  channel are responsible for Liddle’s syndrome, an inherited form of hypertension, whereas other mutations in the same protein that cause reduced channel activity give rise to hypotension. The most common inherited disease in Caucasians is also an ion channel mutation. This disease is cystic fibrosis (CF), which results from mutations in the epithelial chloride channel, known as CFTR. The most common mutation, deletion of a phenylalanine at position 508, results in defective processing of the protein and prevents it from reaching the surface membrane. CFTR regulates chloride fluxes across epithelial cell membranes, and this loss of CFTR activity leads to reduced fluid secretion in the lung, resulting in potentially fatal lung infections.

2. Mutations in the promoter region of the gene may cause under- or overexpression of a given ion channel.

3. Other diseases result from defective regulation of channel activity by cellular constituents or extracellular

ligands. This defective regulation may be caused by mutations in the genes encoding the regulatory molecules themselves or defects in the pathways leading to their production. Some forms of maturity-onset diabetes of the young (MODY) may be attributed to such a mechanism. ATP-sensitive potassium (K-ATP) channels play a key role in the glucose-induced insulin secretion from pancreatic  $\beta$  cells, and their defective regulation is responsible for one form of MODY.

4. Autoantibodies to channel proteins may cause disease by downregulating channel function—often by causing internalization of the channel protein itself. Well-known examples are myasthenia gravis, which results from antibodies to skeletal muscle acetylcholine channels, and Lambert–Eaton myasthenic syndrome, in which patients produce antibodies against presynaptic  $\text{Ca}^{2+}$  channels.

5. Finally, a number of ion channels are secreted by cells as toxic agents. They insert into the membrane of the target cell and form large nonselective pores, leading to cell lysis and death. The hemolytic toxin produced by the bacterium *Staphylococcus aureus* and the toxin secreted by the protozoan *Entamoeba histolytica*, which causes amebic dysentery, are examples.

Natural mutations in ion channels have been invaluable for studying the relationship between channel structure and function. In many cases, genetic analysis of a

### BOX 6.4 (cont'd)

disease has led to the cloning of the relevant ion channel. The first  $K^+$  channel to be identified (Shaker), for example, came from the cloning of the gene that caused *Drosophila* to shake when exposed to ether. Likewise, the gene encoding the primary subunit of a cardiac potassium channel (KCNQ1) was identified by positional cloning in families carrying mutations that caused a cardiac disorder known as long QT syndrome (see later). Conversely, the large number of studies on the relationship between  $Na^+$  channel structure and function has greatly assisted our understanding of how mutations in  $Na^+$  channels produce their clinical phenotypes.

Many diseases are genetically heterogeneous, and the same clinical phenotype may be caused by mutations in different genes. Long QT syndrome is a relatively rare inherited cardiac disorder that causes abrupt loss of consciousness, seizures, and sudden death from ventricular arrhythmia in young people. Mutations in five different genes, two types of cardiac muscle  $K^+$  channels (HERG, KCNQ1, KCNE1, KCNE2) and the cardiac muscle sodium channel (SCN1A), give rise to long QT syndrome. The disorder is characterized by a long QT interval in the electrocardiogram, which reflects the delayed repolarization of the cardiac action potential. As therefore might be expected, mutations in the cardiac  $Na^+$  channel gene that cause long QT syndrome enhance the  $Na^+$  current (by reducing  $Na^+$  channel inactivation), whereas those in

potassium channel genes cause loss of function and reduce the  $K^+$  current.

Mutations in many different types of ion channels have been shown to cause human diseases. In addition to the examples listed earlier, mutations in water channels cause nephrogenic diabetes insipidus; mutations in gap junction channels cause Charcot–Marie–Tooth disease (a form of peripheral neuropathy) and hereditary deafness; mutations in the skeletal muscle  $Na^+$  channel cause a range of disorders known as periodic paralyses; mutations in intracellular  $Ca^{2+}$ -release channels cause malignant hyperthermia (a disease in which inhalation anesthetics trigger a potentially fatal rise in body temperature); and mutations in neuronal voltage-gated  $Ca^{2+}$  channels cause migraine and episodic ataxia. The list increases daily. As is the case with all single gene disorders, the frequency of these diseases in the general population is very low. However, the insight they have provided into the relationship between ion channel structure and function, and into the physiological role of the different ion channels, has been invaluable. As William Harvey said in 1657 “nor is there any better way to advance the proper practice of medicine than to give our minds to the discovery of the usual form of nature, by careful investigation of the rarer forms of disease.”

*Frances M. Ashcroft*

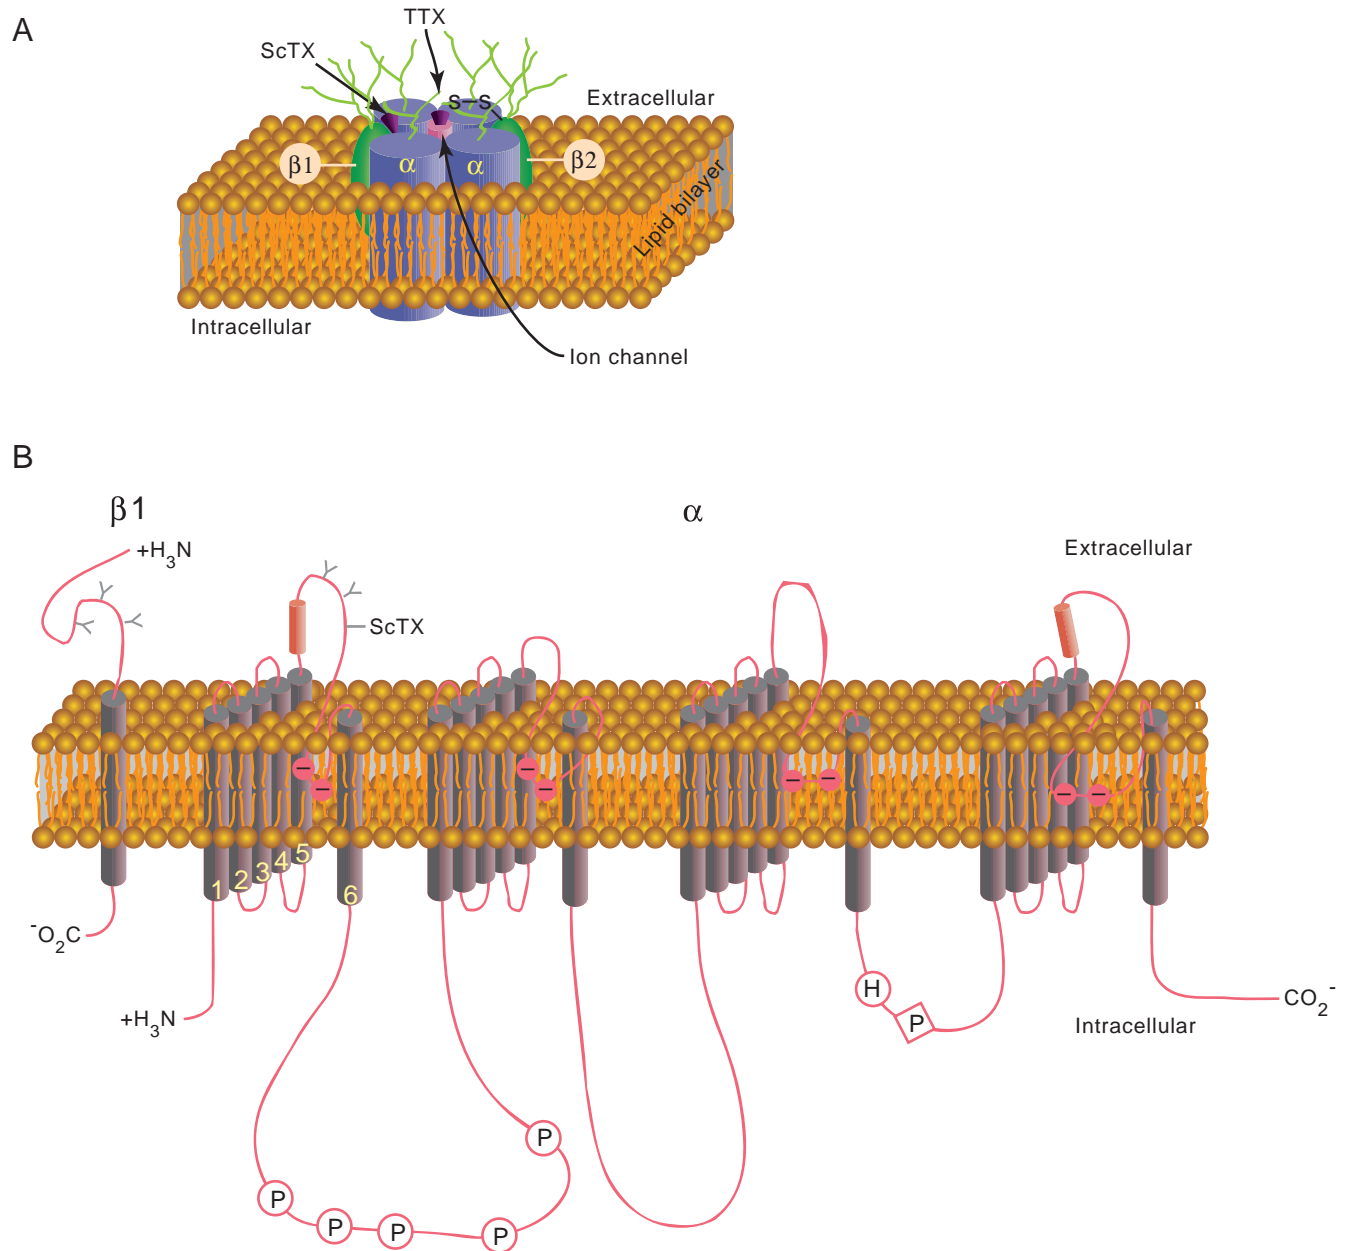

large glycoprotein with a molecular mass of 270 kDa, whereas the  $\beta 1$  and  $\beta 2$  subunits are smaller polypeptides of molecular masses 39 and 37 kDa, respectively (Fig. 6.9). The  $\alpha$  subunit, of which there are at least nine different isoforms, is the building block of the water-filled pore of the ionic channel, whereas the  $\beta$  subunits have some other role, such as in the regulation or structure of the native channel (Catterall, 2000a).

The  $\alpha$  subunit of the  $Na^+$  channel contains four internal repetitions (Fig. 6.9B). Hydrophobicity analysis of these four components reveals that each contains six hydrophobic domains that may span the membrane as an  $\alpha$ -helix. Of these six membrane-spanning components, the fourth (S4) has been proposed to be critical to the voltage sensitivity of the  $Na^+$  channels. Voltage-sensitive gating of  $Na^+$  channels is accomplished by the redistribution of ionic charge (“gating charge”) in the channel. Positive charges in the S4 region may act as voltage sensors such that an increase

in the positivity of the inside of the cell results in a conformational change of the ionic channel. In support of this hypothesis, site-directed mutagenesis of the S4 region of the  $Na^+$  channel to reduce the positive charge of this portion of the pore also reduces the voltage sensitivity of activation of the ionic channel.

The mechanisms of inactivation of ionic channels have been analyzed with a combination of molecular and electrophysiological techniques. The most convincing hypothesis is that inactivation is achieved by a block of the inner mouth of the aqueous pore. Ionic channels are inactivated without detectable movement of ionic current through the membrane; thus inactivation is probably not directly gated by changes in the membrane potential alone. Rather, inactivation is triggered or facilitated as a secondary consequence of activation. Site-directed mutagenesis or the use of antibodies has shown that the part of the molecule between regions III and IV may be allowed to move to

block the cytoplasmic side of the ionic pore after the conformational change associated with activation.

### Neurons of the Central Nervous System Exhibit a Wide Variety of Electrophysiological Properties

The first intracellular recordings of action potentials in mammalian neurons by Sir John Eccles and col-

leagues revealed a remarkable similarity to those of the squid giant axon and gave rise to the assumption that the electrophysiology of neurons in the CNS was really rather simple: when synaptic potentials brought the membrane potential positive to action potential threshold, action potentials were produced through an increase in  $\text{Na}^+$  conductance followed by an increase in  $\text{K}^+$  conductance, as in the squid giant axon. The assumption, therefore, was that the complicated pat-

terns of activity generated by the brain during the resting, sleeping, or active states were brought about as an interaction of the very large numbers of neurons present in the mammalian CNS. However, intracellular recordings of invertebrate neurons revealed that different cell types exhibit a wide variety of different electrophysiological behaviors, indicating that neurons may be significantly more complicated than the squid giant axon.

Elucidation of the basic electrophysiology and synaptic physiology of different types of neurons and neuronal pathways within the mammalian CNS was facilitated by the *in vitro* slice technique, in which thin (~0.5 mm) slices of brain can be maintained for several hours. Intracellular recordings from identified cells revealed that neurons of the mammalian nervous system, such as those of invertebrate networks, can generate complex patterns of action potentials entirely through intrinsic ionic mechanisms and without synaptic interaction with other cell types. For example, Rodolfo Llinás and colleagues discovered that Purkinje cells of the cerebellum can generate high-frequency trains (>200 Hz) of Na<sup>+</sup>- and K<sup>+</sup>-mediated action potentials interrupted by Ca<sup>2+</sup> spikes in the dendrites, whereas a major afferent to these neurons, the inferior olivary cell, can generate rhythmic sequences of broad action potentials only at low frequencies (<15 Hz) through an interaction between various Ca<sup>2+</sup>, Na<sup>+</sup>, and K<sup>+</sup> conductances (Fig. 6.10). These *in vitro* recordings confirmed a major finding obtained with earlier intracellular recordings *in vivo*: each morphologically distinct class of neuron in the brain exhibits distinct electrophysiological features. Just as cortical pyramidal cells are morphologically distinct from cerebellar Purkinje cells, which are distinct from thalamic relay cells, the electrophysiological properties of each of these different cell types are also markedly distinct (Llinás, 1988).

Although no uniform classification scheme has been formulated in which all the different types of neurons of the brain can be classified, a few characteristic patterns of activity seem to recur. The first general class of action potential generation is characterized by those cells that generate trains of action potentials one spike at a time. The more prolonged the depolarization of these cells, the more prolonged their discharge. The more intensely these cells are depolarized, the higher the frequency of action potential generation. This type of relatively linear behavior is typical for brain stem and spinal cord motor neurons functioning in muscle contraction. A modification of this basic pattern of "regular firing" is characterized by the generation of trains of action potentials that exhibit a marked tendency to slow down in frequency with time, a process

known as spike frequency adaptation. Examples of cells that discharge in this manner are cortical and hippocampal pyramidal cells.

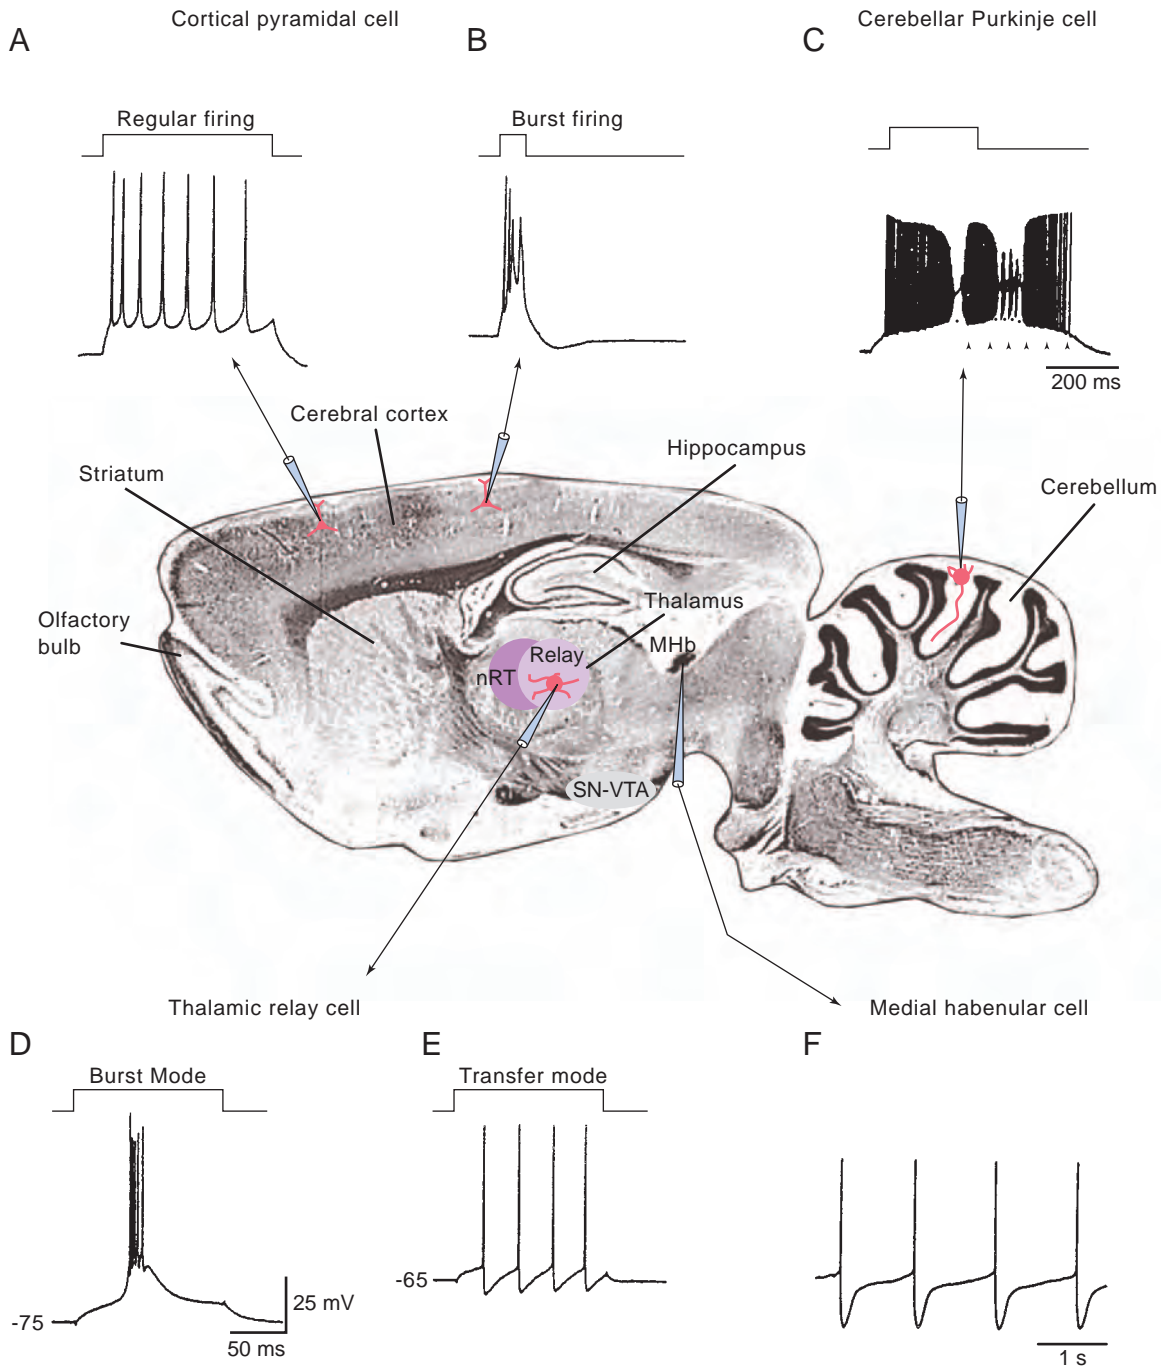

In addition to these regular firing cells, many neurons in the central nervous system exhibit the intrinsic propensity to generate rhythmic bursts of action potentials (Fig. 6.10). Examples of such neurons are thalamic relay neurons, inferior olivary neurons, and some types of cortical and hippocampal pyramidal cells. In these cells, clusters of action potentials can occur together when the membrane is brought above the firing threshold. These clusters of action potentials typically are generated through the activation of specialized Ca<sup>2+</sup> currents that, through their slower kinetics, allow the membrane potential to be depolarized for a sufficient period to result in the generation of a burst of regular, Na<sup>+</sup>- and K<sup>+</sup>-dependent action potentials (discussed in the next section).

Yet another general category of neurons in the brain comprises cells that generate relatively short duration (<1 ms) action potentials and can discharge at relatively high frequencies (>300 Hz). Such electrophysiological properties often are found in neurons that release the inhibitory amino acid  $\gamma$ -aminobutyric acid (Fig. 6.10) including some types of interneurons in the cerebral cortex, thalamus, and hippocampus. Finally, the last general category of neurons consists of those that spontaneously generate action potentials at relatively slow frequencies (e.g., 1–10 Hz). This type of electrophysiological behavior often is associated with neurons that release neuromodulatory transmitters, such as acetylcholine, norepinephrine, serotonin, and histamine. Neurons that release these neuromodulatory substances often innervate wide regions of the brain and appear to set the "state" of the different neural networks of the CNS in a manner similar to the modulation of the different organs of the body by the sympathetic and parasympathetic nervous systems.

Each of these unique intrinsic patterns of activity in the nervous system is due to the presence of a distinct mixture and distribution of different ionic currents in the cells. As in classical studies of the squid giant axon, these different ionic currents have been characterized, at least in part, with voltage-clamp and pharmacological techniques, and the basic electrophysiological properties have been replicated with computational simulations (Figs. 6.7 and 6.12).

## Neurons Have Multiple Active Conductances

The search for the electrophysiological basis of the varying intrinsic properties of different types of neurons of vertebrates and invertebrates revealed a wide variety of ionic currents. Each type of ionic

**FIGURE 6.10** Neurons in the mammalian brain exhibit widely varying electrophysiological properties. (A) Intracellular injection of a depolarizing current pulse in a cortical pyramidal cell results in a train of action potentials that slow down in frequency. This pattern of activity is known as “regular firing.” (B) Some cortical cells generated bursts of three or more action potentials, even when depolarized only for a short period of time. (C) Cerebellar Purkinje cells generate high-frequency trains of action potentials in their cell bodies that are disrupted by the generation of  $\text{Ca}^{2+}$  spikes in their dendrites. These cells can also generate “plateau potentials” from the persistent activation of  $\text{Na}^+$  conductances (arrowheads). Thalamic relay cells may generate action potentials either as bursts (D) or as tonic trains of action potentials (E) due to the presence of a large low-threshold  $\text{Ca}^{2+}$  current. (F) Medial habenular cells generate action potentials at a steady and slow rate in a “pacemaker” fashion.

current is characterized by several features: (1) the type of ions conducted by the underlying ionic channels (e.g.,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Cl}^-$ , or mixed cations), (2) their voltage and time dependence, and (3) their sensitivity to second messengers. In vertebrate neurons, two distinct  $\text{Na}^+$  currents have been identified and six distinct  $\text{Ca}^{2+}$  currents and more than seven distinct  $\text{K}^+$  currents are known (Fig. 6.11). This is a minimal number, as these currents are formed from a much greater pool of channel subunits. The following sections briefly review these classes of ionic currents and their ionic channels, relating them to the different patterns of behavior mentioned earlier for neurons in the mammalian CNS.

### $\text{Na}^+$ Currents Are Both Transient and Persistent

Depolarization of many different types of vertebrate neurons results not only in the activation of the rapidly activating and inactivating  $\text{Na}^+$  current ( $I_{\text{Nat}}$ ) underlying action potential generation, but also in the rapid activation of a  $\text{Na}^+$  current that does not inactivate and is therefore known as the “persistent”  $\text{Na}^+$  current ( $I_{\text{Nap}}$ ). The threshold for activation of the persistent  $\text{Na}^+$  current is typically about  $-65\text{mV}$ ; that is, below the threshold for the generation of action potentials. This property gives this current the interesting ability to enhance or facilitate the response of the neuron to depolarizing, yet subthreshold, inputs. For example, synaptic events that depolarize the cell will activate  $I_{\text{Nap}}$ , resulting in an extra influx of positive charge and

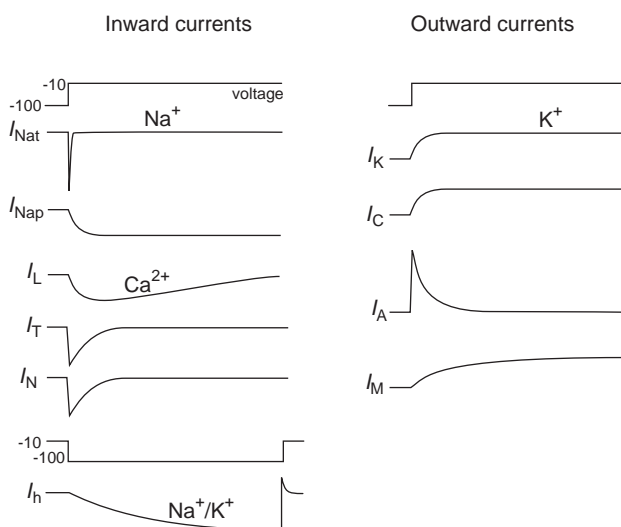

therefore a larger depolarization than otherwise would occur. Likewise, hyperpolarizations may result in deactivation of  $I_{\text{Nap}}$ , again resulting in larger hyperpolarizations than otherwise would occur. In this manner, the persistent  $\text{Na}^+$  current may play an important regulatory function in the control of the functional responsiveness of the neuron to synaptic inputs and may contribute to the dynamic coupling of the dendrites to the soma.

Persistent activation of  $I_{\text{Nap}}$  may also contribute to another electrophysiological feature of neurons: the generation of plateau potentials. A plateau potential refers to the ability of many different types of neurons to generate, through intrinsic ionic mechanisms, a prolonged (from tens of milliseconds to seconds) depolarization and action potential discharge in response to a short-lasting depolarization (Fig. 6.10C). One can wonder whether such plateau potentials contribute to persistent firing in neurons during the performance of working memory tasks, where groups of neurons have to retain information for brief (seconds) periods of time.

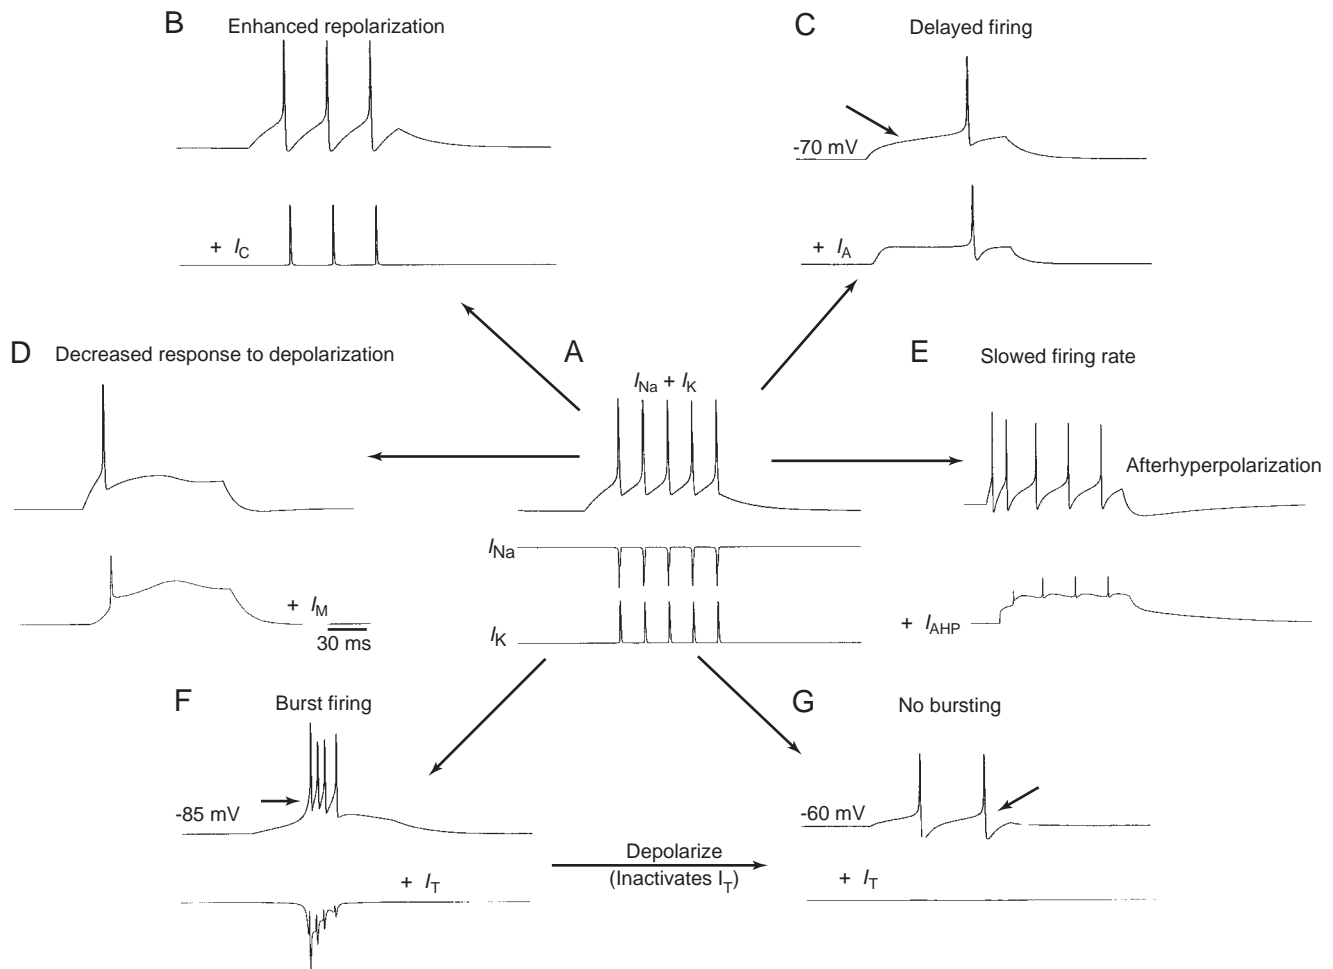

### $\text{K}^+$ Currents Vary in Their Voltage Sensitivity and Kinetics

Potassium currents that contribute to the electrophysiological properties of neurons are numerous and exhibit a wide range of voltage-dependent and kinetic properties (reviewed in Coetzee *et al.*, 1999). Perhaps the simplest  $\text{K}^+$  current is that characterized by Hodgkin and Huxley: this  $\text{K}^+$  current,  $I_{\text{K}}$ , activates rapidly on depolarization and does not inactivate (Fig. 6.11). Other  $\text{K}^+$  currents activate with depolarization but also inactivate with time. For example, the rapid activation and inactivation of  $I_{\text{A}}$  give this current a transient appearance (Fig. 6.11), and  $I_{\text{A}}$  is believed to be important in controlling the rate of action potential generation, particularly at low frequencies (Fig. 6.12). Like the  $\text{Na}^+$  channel,  $I_{\text{A}}$  channels are inactivated by the plugging of the inner mouth of the pore through movement of an inactivation particle.

Another broad class of  $\text{K}^+$  channels consists of those that are sensitive to changes in the intracellular concentration of  $\text{Ca}^{2+}$ . These  $\text{K}^+$  currents collectively are referred to as  $I_{\text{KCa}}$  (Fig. 6.11). Still other  $\text{K}^+$  channels are not only activated by voltage, but are also modulated by the activation of various modulatory neurotransmitter receptors (e.g.,  $I_{\text{M}}$ ; Fig. 6.11). Between these classic examples of  $\text{K}^+$  currents are a variety of other types that have not been fully characterized, including  $\text{K}^+$  currents that vary from one another in their voltage sensitivity, kinetics, and response to various second messengers.

**FIGURE 6.11** Voltage dependence and kinetics of different ionic currents in the mammalian brain. Depolarization of the membrane potential from  $-100$  to  $-10\text{mV}$  results in the activation of currents entering or leaving neurons.

**FIGURE 6.12** Simulation of the effects of the addition of various ionic currents to the pattern of activity generated by neurons in the mammalian CNS. (A) The repetitive impulse response of the classical Hodgkin–Huxley model (voltage recordings above, current traces below). With only  $I_{Na}$  and  $I_K$ , the neuron generates a train of five action potentials in response to depolarization. Addition of  $I_C$  (B) enhances action potential repolarization. Addition of  $I_A$  (C) delays the onset of action potential generation. Addition of  $I_M$  (D) decreases the ability of the cell to generate a train of action potentials. Addition of  $I_{AHP}$  (E) slows the firing rate and generates a slow after-hyperpolarization. Finally, addition of the transient  $Ca^{2+}$  current  $I_T$  results in two states of action potential firing: (F) burst firing at  $-85$  mV and (G) tonic firing at  $-60$  mV. From Huguenard and McCormick (1994).

Molecular biological studies of voltage-sensitive  $K^+$  channels, first done in *Drosophila* and later in mammals, have revealed the presence of a large number of genes that generate  $K^+$  channels. The voltage-gated  $K^+$  channel subunits are contained within nine distinct subfamilies: Kv1-9 (reviewed in Coetzee *et al.*, 1999). These genes generate a wide variety of different  $K^+$  channels, not only due to the large number of genes involved, but also due to alternative RNA splicing, gene duplication, and other posttranslational mechanisms. Functional expression of different  $K^+$  channels reveals remarkable variation in the rate of inactivation, such that some are rapidly inactivating (A current like), whereas others inactivate more slowly and, finally, some  $K^+$  channels do not inactivate, such as  $I_K$ .

One of the largest subfamilies of  $K^+$  channels are those that give rise to the resting membrane potential, so-called “leak channels.” Interestingly, these channels appear to be opened by gaseous anesthetics, indicating that hyperpolarization of central neurons is a major component of general anesthesia. It is now clear that each type of neuron in the nervous system contains a unique set of functional voltage-sensitive  $K^+$  channels, selected, modified, and placed in particular spatial locations in the cell in a manner that facilitates the unique role of that cell type in neuronal processing.

An additional current that also regulates the responsiveness of neurons to depolarizing inputs is the voltage-sensitive  $K^+$  current known as the M current (Figs. 6.11 and 6.12D). By investigating the ionic mech-

anisms by which the release of acetylcholine from preganglionic neurons in the brain results in prolonged changes in the excitability of neurons of the sympathetic ganglia, Brown and Adams (1980) discovered a unique  $K^+$  current that slowly (over tens of milliseconds) turns on with depolarization of the neuron (Fig. 6.12D). The slow activation of this  $K^+$  current results in a decrease in the responsiveness of the cell to depolarization, and therefore regulates how the cell responds to excitation. This  $K^+$  current, like  $I_{AHP}$ , is reduced by the activation of a wide variety of receptors, including muscarinic receptors, for which it is named. Reduction of  $I_M$  results in a marked increase in responsiveness of the affected cell to depolarizing inputs and again may contribute to the mechanisms by which neuromodulatory systems control the state of activity in cortical and hippocampal networks (reviewed in McCormick, 1992).

### Ca<sup>2+</sup> Currents Control Electrophysiological Properties and Ca<sup>2+</sup>-Dependent Second-Messenger Systems

Ionic channels that conduct Ca<sup>2+</sup> are present in all neurons. These channels are special in that they serve two important functions. First, Ca<sup>2+</sup> channels are present throughout the different parts of the neuron (dendrites, soma, synaptic terminals) and contribute greatly to the electrophysiological properties of these processes. Second, Ca<sup>2+</sup> channels are unique in that Ca<sup>2+</sup> is an important second messenger in neurons, and entry of Ca<sup>2+</sup> into the cell can affect numerous physiological functions, including neurotransmitter release, synaptic plasticity, neurite outgrowth during development, and even gene expression. On the bases of their voltage sensitivity, their kinetics of activation and inactivation, and their ability to be blocked by various pharmacological agents, Ca<sup>2+</sup> currents can be separated into at least six separate categories, three of which are  $I_T$  ("transient"),  $I_L$  ("long lasting"), and  $I_N$  ("neither"), illustrated in Fig. 6.11A. A fourth,  $I_P$ , is found in Purkinje cells of the cerebellum, as well as in many different cell types of the CNS. These Ca<sup>2+</sup> channels are formed from at least 10 different  $\alpha$  subunits as well as a variety of  $\beta$  and  $\gamma$  subunits, indicating that there are an even greater number of Ca<sup>2+</sup> currents yet to be characterized.

### Neurons Possess Multiple Subtypes of High-Threshold Ca<sup>2+</sup> Currents

High voltage-activated Ca<sup>2+</sup> channels are activated at membrane potentials positive to approximately

–40 mV and include the currents  $I_L$ ,  $I_N$ , and  $I_P$ . L-type calcium currents exhibit a high threshold for activation (about –10 mV) and give rise to rather persistent, or long-lasting, ionic currents (Fig. 6.11A). Dihydropyridines, Ca<sup>2+</sup> channel antagonists, are clinically useful for their effects on the heart and vascular smooth muscle (e.g., for the treatment of arrhythmias, angina, and migraine headaches) and selectively block L-type Ca<sup>2+</sup> channels. In contrast with  $I_L$ ,  $I_N$  is not blocked by dihydropyridines: it is blocked selectively by a toxin found in Pacific cone shells ( $\omega$ -conotoxin-GVIA). N-type Ca<sup>2+</sup> channels have a threshold for activation of about –20 mV, inactivate with maintained depolarization, and are modulated by a variety of neurotransmitters. In some cell types,  $I_N$  has a role in the Ca<sup>2+</sup>-dependent release of neurotransmitters at presynaptic terminals. The P-type calcium channel is distinct from N and L types in that it is not blocked by either dihydropyridines or  $\omega$ -conotoxin-GVIA but is blocked by a toxin ( $\omega$ -agatoxin-IVA) present in the venom of the Funnel web spider. This type of calcium channel activates at relatively high thresholds and does not inactivate. Prevalent in Purkinje cells as well as other cell types, as mentioned earlier, the P-type Ca<sup>2+</sup> channel participates in the generation of dendritic Ca<sup>2+</sup> spikes, which can strongly modulate the firing pattern of the neuron in which it resides (Fig. 6.10C; Llinás, 1988).

Collectively, high threshold-activated Ca<sup>2+</sup> channels contribute to the generation of action potentials in mammalian neurons. The activation of Ca<sup>2+</sup> currents adds somewhat to the depolarizing part of the action potential, but, more importantly, these channels allow Ca<sup>2+</sup> to enter the cell, which has the secondary consequence of activation of various Ca<sup>2+</sup>-activated  $K^+$  currents and protein kinases (see Chapter 10). As mentioned earlier, activation of these  $K^+$  currents modifies the pattern of action potentials generated in the cell (Figs. 6.10 and 6.12).

High-threshold Ca<sup>2+</sup> channels are similar to the Na<sup>+</sup> channel in that they are composed of a central  $\alpha 1$  subunit that forms the aqueous pore and several regulatory or auxiliary subunits. As in the Na<sup>+</sup> channel, the primary structure of the  $\alpha 1$  subunit of the Ca<sup>2+</sup> channel consists of four homologous domains (I–IV), each containing six regions (S1–S6) that may generate transmembrane  $\alpha$ -helices. Genes for at least 10 different Ca<sup>2+</sup> channel  $\alpha$  subunits have been cloned and are separated into three subfamilies (Cav1, Cav2, and Cav3). The properties of the products of these genes indicate that  $I_L$  is likely to correspond to the Cav1 subfamily, whereas  $I_N$  corresponds to Cav2.2 and  $I_T$  is formed from the Cav3 subfamily (see Catterall, 2000b).

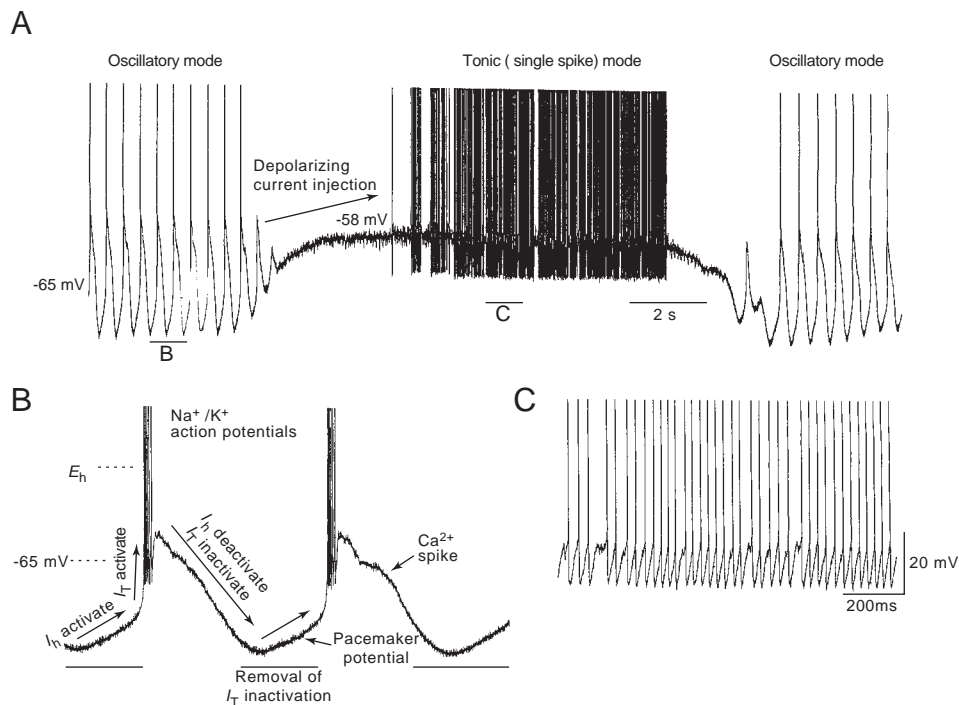

## Low-Threshold $\text{Ca}^{2+}$ Currents Generate Bursts of Action Potentials

Low-threshold  $\text{Ca}^{2+}$  currents (Fig. 6.11A) often take part in the generation of rhythmic bursts of action potentials (Figs. 6.10 and 6.12). The low-threshold  $\text{Ca}^{2+}$  current is characterized by a threshold for activation of about  $-65\text{mV}$ , which is below the threshold for generation of typical  $\text{Na}^+\text{-K}^+$ -dependent action potentials ( $-55\text{mV}$ ). This current inactivates with maintained depolarization. Because of these properties, the role of low-threshold  $\text{Ca}^{2+}$  currents differs markedly from that of the high-threshold  $\text{Ca}^{2+}$  currents. Through activation and inactivation of the low-threshold  $\text{Ca}^{2+}$  current, neurons can generate slow (about  $100\text{ms}$ )  $\text{Ca}^{2+}$  spikes, which can result, due to their prolonged duration, in generation of a high-frequency "burst" of short-duration  $\text{Na}^+\text{-K}^+$  action potentials (Fig. 6.10).

In the mammalian brain, this pattern is especially well exemplified by the activity of thalamic relay neurons; in the visual system, these neurons receive direct input from the retina and transmit this information to the visual cortex. During periods of slow wave

sleep, the membrane potential of these relay neurons is relatively hyperpolarized, resulting in the removal of inactivation (deinactivation) of the low-threshold  $\text{Ca}^{2+}$  current. This deinactivation allows these cells to spontaneously generate low-threshold  $\text{Ca}^{2+}$  spikes and bursts of from two to five action potentials (Fig. 6.13). The large number of thalamic relay cells bursting during sleep in part gives rise to the spontaneous synchronized activity that early investigators were so surprised to find during recordings from the brains of sleeping animals. It has even proved possible to maintain one of the sleep-related brain rhythms (spindle waves) intact in slices of thalamic tissue maintained *in vitro*, due to the generation of this rhythm by the interaction of a local network of thalamic cells and their electrophysiological properties.

The transition to waking or the period of sleep when dreams are prevalent (rapid eye movement sleep) is associated with a maintained depolarization of thalamic relay cells to membrane potentials ranging from about  $-60$  to  $-55\text{mV}$ . The low-threshold  $\text{Ca}^{2+}$  current is inactivated and therefore the burst discharges are abolished. In this way, the properties of a single ionic current ( $I_T$ ) help explain in part the remarkable changes

**FIGURE 6.13** Two different patterns of activity generated in the same neuron, depending on membrane potential. (A) The thalamic neuron spontaneously generates rhythmic bursts of action potentials due to the interaction of the  $\text{Ca}^{2+}$  current  $I_T$  and the inward "pacemaker" current  $I_h$ . Depolarization of the neuron changes the firing mode from rhythmic burst firing to tonic action potential generation in which spikes are generated one at a time. Removal of this depolarization reinstates rhythmic burst firing. This transition from rhythmic burst firing to tonic activity is similar to that which occurs in the transition from sleep to waking. (B) Expansion of detail of rhythmic burst firing. (C) Expansion of detail of tonic firing. From McCormick and Pape (1990).

in brain activity taking place in the transition from sleep to waking (Fig. 6.13).

### Hyperpolarization-Activated Ionic Currents Are Involved in Rhythmic Activity

In most types of neurons, hyperpolarization negative to approximately  $-60$  mV activates an ionic current, known as  $I_h$ , that conducts both  $\text{Na}^+$  and  $\text{K}^+$  ions (Fig. 6.11). This current typically has very slow kinetics, turning on with a time constant on the order of tens of milliseconds to seconds. Because the channels underlying this current allow the passage of both  $\text{Na}^+$  and  $\text{K}^+$  ions, the reversal potential of  $I_h$  is typically about  $-35$  mV—between  $E_{\text{Na}}$  and  $E_{\text{K}}$ . Because this current is activated by hyperpolarization below approximately  $-60$  mV, it is typically dominated by the inward movement of  $\text{Na}^+$  ions and is therefore depolarizing. For what purpose could neurons use a depolarizing current that activates when the cell is hyperpolarized? A clue comes from cardiac cells in which this current, known as  $I_f$  for “funny,” is important for determining heart rate. Activation of  $I_f$  results in a slow depolarization of the membrane potential between adjacent cardiac action potentials. The more that  $I_f$  is activated, the faster the membrane depolarizes between beats and therefore the sooner the threshold for the next action potential is reached and the next beat is generated. In this manner, the amplitude, or sensitivity to voltage, of  $I_f$  can modify the heart rate. Interestingly, the sensitivity of  $I_f$  to voltage is adjusted by the release of noradrenaline and acetylcholine; the activation of adrenoceptors by noradrenaline increases  $I_f$  and therefore increases the heart rate, whereas the activation of muscarinic receptors decreases  $I_f$ , thereby decreasing the heart rate (see DiFrancesco, 2005). This continual adjustment of  $I_f$  results from a push-pull arrangement between  $\beta$ -adrenergic and muscarinic cholinergic receptors and is mediated by the adjustment of intracellular levels of cyclic AMP. Indeed, the recent cloning of h-channels reveals that their structure is similar to that of cyclic nucleotide-gated channels.

Could  $I_h$  play a role in neurons similar to that of  $I_f$  in the heart? Possibly. Synchronized rhythmic oscillations in the membrane potential of large numbers of neurons, in some respects similar to those of the heart, are characteristic of the mammalian brain. Oscillations of this type are particularly prevalent in thalamic relay neurons during some periods of sleep, as mentioned earlier. Intracellular recordings from these thalamic neurons reveal that they often generate rhythmic “bursts” of action potentials mediated by the activation of a slow spike that is generated through the activation of the low-threshold, or transient,  $\text{Ca}^{2+}$  current,

$I_T$  (Fig. 6.13). Between the occurrence of each low-threshold  $\text{Ca}^{2+}$  spike is a slowly depolarizing membrane potential generated by activation of the mixed  $\text{Na}^+$ - $\text{K}^+$  current  $I_h$ , as with  $I_f$  in the heart. The amplitude, or voltage sensitivity, of  $I_h$  adjusts the rate at which the thalamic cells oscillate, and, as with the heart, this sensitivity is adjusted by the release of modulatory neurotransmitters. In a sense, the thalamic neurons are “beating” in a manner similar to that of the heart.

### Summary

An action potential is generated by the rapid influx of  $\text{Na}^+$  ions followed by a slightly slower efflux of  $\text{K}^+$  ions. Although the generation of an action potential does not disrupt the concentration gradients of these ions across the membrane, the movement of charge is sufficient to generate a large and brief deviation in the membrane potential. Action potentials typically are initiated in the axon initial segment and the propagation of the action potential along the axon allows communication of the output of the cell to its distant synapses. Neurons possess many different types of ionic channels in their membranes, allowing complex patterns of action potentials to be generated and complex synaptic computations to occur within single neurons.

# Neurotransmitters

A century ago the as yet unnamed field of neuroscience was having growth pains. It was a time marked by claim and counterclaim, confusion, and recrimination—not unlike politics today, or for that matter, science. One major reason for the tumult was the heretical idea that the brain is not one continuous network (a syncytium), with each cell in physical contact with its neighbors. The pioneering studies of Santiago Ramon y Cajal revealed a very different picture from the dogma, with each cell (neuron) of the brain being an independent structure (see Shepherd, 1991). Although final confirmation of this view awaited electron microscopic verification a half century later, a general acceptance of neurons as the independent building blocks of the nervous system emerged much more quickly. In turn, this resulted in a new debate: how do these neurons communicate? The answer to this question has evolved continuously, and become increasingly complex, with different modes of communication identified. In this chapter we will explore how neurons communicate by chemical messengers.

Neurons vary widely in function but share certain structural characteristics. They have a cell body (soma) from which processes emerge. Axons can be short or long and can be local or project to distant areas. In contrast, dendrites are exclusively local structures. The identification of long (axon) and short (dendrite) processes led to the idea that the long axonal projections served to transmit information between neurons, often over long distances, and dendrites were the receptive elements of neurons, responding to the long information sent via axons. The gap over which information between neurons must be conveyed was termed the synapse by Charles Sherrington (see Shepherd, 1991), and came to identify pre- and postsynaptic cells. This general conceptual framework remains in place today,

although there are many exceptions, including dendrites that release neuroactive substances and axons that receive inputs from other neurons. One other characteristic proposed by Sherrington that is central to the concept of chemical communication between neurons is that synaptic transmission does not follow all-or-none rules, but is graded in strength and is flexible.

## SEVERAL MODES OF NEURONAL COMMUNICATION EXIST

Over the first half of the twentieth century there was a vigorous debate on the nature of neuronal communication: as one review of this debate described, it was a war of sparks (electrical communication) and soups (chemical messengers) (see Valenstein, 2005). This debate raged despite the fact some evidence was marshaled in support of chemical transmission in the mid-nineteenth century. In 1849, Claude Bernard noted that curare, the active constituent of a poison that was applied to arrows in South America, blocked nerve-to-muscle signaling. This effect subsequently was shown to be due to the binding of curare to postsynaptic (muscle) receptors for acetylcholine (ACh), thus blocking neuromuscular transmission. About 50 years later Thomas Elliott found that epinephrine caused the contraction of smooth muscle that had been deprived of its nerve inputs, suggesting that muscle contraction depended on the action of chemical molecules liberated from nerves. In a key series of studies using isolated frog hearts, Otto Loewi provided firm evidence in support of chemical neurotransmission by showing that ACh was released upon nerve stimulation and activated a target muscle.

These and other data suggested that the major means of interneuronal communication is chemical in nature, but that neurons also use other processes for intercellular communication. Among these are electrical synaptic transmission, ephaptic interactions, and autocrine, paracrine, and long-range signaling, to which molecules produced by both neural and non-neural cells contribute. The nonsynaptic mode of intercellular communication with the longest range (distance) is hormonal signaling. For example, some hormones made outside of the brain can enter the central nervous system (CNS) to exert effects on neurons that express receptors for the hormones. These hormone actions may occur over the short term (changes in neuronal activity) or, more often, over a longer period (long-lasting changes in gene expression).

Molecules released from neurons can also be used in intercellular signaling that does not require synaptic specializations. There are a host of molecules that are secreted by neurons or diffuse passively from cells, ranging from conventional neurotransmitters to gases such as nitric oxide. These factors may act through autocrine mechanisms (activating receptors on the same cell that releases them) or paracrine pathways to influence nearby cells. Some of these compounds can be retrograde signaling molecules, providing chemically-coded information to the presynaptic neuron, thus reversing the more common forward (anterograde) direction of information flow. The role of such molecules is thought to be primarily in modulating neural activity, although they may also provide guidance cues for neurons that are growing toward their final targets in the brain as well as for the establishment and maintenance of synaptic connections (see Chapter 19).

## CHEMICAL TRANSMISSION

Chemically-mediated transmission is the major mode of neuronal communication. The general acceptance of chemical neurotransmission as the means of conveying information between neurons resulted in the establishment of specific criteria for designation of a compound as a neurotransmitter. A relatively small number of compounds have been designated as neurotransmitters based on these “classical” criteria. However, over the past generation it has become apparent that there is a large number of chemical messengers that broadly qualify as intercellular transmitters, although these compounds often do not meet—and even stand in sharp contrast to—the classical criteria.

### Several Criteria Have Been Established for a Neurotransmitter

Neurotransmitters usually are considered to be endogenous substances that are released from neurons, act on receptor sites that are typically present on membranes of postsynaptic cells, and produce a functional change in the properties of the target cell. Over the years general agreement evolved that several criteria should be met for a substance to be designated a neurotransmitter:

1. A neurotransmitter must be synthesized by and released from neurons. This means that the presynaptic neuron should contain a transmitter and the appropriate enzymes need to synthesize that neurotransmitter. Synthesis in the *axon terminal* is not an absolute requirement. For example, peptide transmitters are synthesized in the *cell body* and transported to distant sites, where they are released.
2. The substance should be released from nerve terminals in a chemically- or pharmacologically-identifiable form. Thus, one should be able to isolate the transmitter and characterize its structure using biochemical or other techniques.
3. A neurotransmitter should reproduce at the postsynaptic cell the specific events (such as changes in membrane properties) that are seen after stimulation of the presynaptic neuron.
4. The effects of a putative neurotransmitter should be blocked by competitive antagonists of the receptor for the transmitter in a dose-dependent manner. In addition, treatments that inhibit synthesis of the transmitter candidate should block the effects of presynaptic stimulation.
5. There should be active mechanisms to terminate the action of the putative neurotransmitter. Among such mechanisms are uptake of the transmitter by the presynaptic neuron or glial cells through specific transporter molecules, or alternatively enzymatic inactivation of the chemical messenger.

### The Process of Chemical Neurotransmission Can Be Divided into Five Steps

Synaptic transmission consists of a number of steps. The general mechanisms of chemical synaptic transmission are depicted in Figure 7.1.

1. *Synthesis of the neurotransmitter in the presynaptic neuron.* In order for the transmitter to be synthesized, precursors should be present in appropriate places within neurons. Enzymes

**FIGURE 7.1** Schematic representation of the life cycle of a classical neurotransmitter. After accumulation of a precursor amino acid into the neuron (1), the amino acid precursor is metabolized sequentially (2) to yield the mature transmitter. The transmitter is then accumulated into vesicles by the vesicular transporter (3), where it is poised for release and protected from degradation. Once released, the transmitter can interact with postsynaptic receptors (4) or autoreceptors (5) that regulate transmitter release, synthesis, or firing rate. Transmitter actions are terminated by means of a high-affinity membrane transporter (6) that usually is associated with the neuron that released the transmitter. Alternatively, transmitter actions may be terminated by diffusion from the active sites (7) or accumulation into glia through a membrane transporter (8). When the transmitter is taken up by the neuron, it is subject to metabolic inactivation (9).

taking part in the conversion of the precursor(s) into the transmitter should be present in an active form and localized to the appropriate compartment in the neuron. For example, one would not expect synthetic enzymes for the transmitter to be found in the nucleus or the mitochondrion. In addition, any cofactors that are required for enzyme activity should be present. Drugs affecting the synthesis of neurotransmitters have long been of value in medicine. An example is  $\alpha$ -methyl-*p*-tyrosine, a drug used to treat an adrenal gland tumor that causes very high blood pressure by releasing massive amounts of norepinephrine (NE).  $\alpha$ -Methyl-*p*-tyrosine prevents the synthesis of NE, thereby lowering blood pressure.

2. *Storage of the neurotransmitter and/or its precursor in the presynaptic nerve terminal.* Classical and peptide transmitters are stored in synaptic vesicles, where they are sequestered and protected from enzymatic degradation and are ready for quick release. In the case of classical neurotransmitters such as acetylcholine, the synaptic vesicles are small (~50 nm in diameter), in contrast to the large dense-core vesicles (~100 nm in diameter) in which neuropeptide transmitters are stored. Vesicles are often found adjacent to the presynaptic membrane, where they are poised to be released in response to stimulation of the neuron. Because most neurotransmitters are synthesized in the cytosol of neurons, there must be some mechanism through which the

transmitter enters the vesicle. This mechanism is the vesicular transporter protein, which actively accumulates the transmitter through an energy-dependent process.

3. *Release of the neurotransmitter into the synaptic cleft.* The vesicle in which the transmitter is stored fuses with the cell membrane and releases the transmitter. Neurons use two pathways to secrete proteins. The release of most neurotransmitters occurs by a regulated pathway that is controlled by extracellular signals. The neurotransmitter release process is discussed more fully in Chapter 8. A second (constitutive) pathway of release is not triggered by extracellular stimulation and is used to secrete membrane components, viral proteins, and extracellular matrix molecules; some unconventional transmitters (such as growth factors) may be synthesized and released by both constitutive and regulated pathways.
4. *Binding and recognition of the neurotransmitter by target receptors.* Neurotransmitters that are released interact with receptors located on the target cell. Most transmitter receptors fall into two broad classes. The first are membrane proteins called metabotropic receptors, which are coupled to intracellular G proteins as effectors (see Chapter 9). Ionotropic receptors form channels through which ions such as Na<sup>+</sup> and Ca<sup>2+</sup> flow. Receptors can be found on neurons that are postsynaptic to the cell releasing the transmitter. Receptors can also be located on the presynaptic neuron, where they can respond to the transmitter released from the same cell in the case of classical transmitters, or respond to a retrograde signal elaborated from the postsynaptic neuron; this latter process has not been described for classical or peptide transmitters. Presynaptic receptors that respond to the transmitter released by the same neuron are termed autoreceptors, and regulate transmitter release, synthesis, or impulse flow; these autoreceptors can be thought of as homeostatic feedback mechanisms.
5. *Termination of the action of the released transmitter.* If a cell cannot terminate the actions of neurotransmitters, dysfunction occurs: sustained activation of postsynaptic targets can result in tetanus (in muscles) or seizures (in the brain). If one thinks of chemical transmission as being the flow of information, continuous unregulated transmitter release is not conveying to the target cell temporal data, such as the rate of firing of the presynaptic neuron or the pattern of firing of the presynaptic neuron. Neurotransmitter actions may be terminated

actively or passively. Among the active termination processes is reuptake of the neurotransmitter through specific transporter proteins on the presynaptic neuron or on glial cells. Another common means of the termination of action of a transmitter is by enzymatic degradation to an inactive substance. Finally, inactivation can occur by diffusion of the transmitter from the synaptic region. All three processes probably work cooperatively to terminate the action of a neurotransmitter.

These five steps form a logical scaffold for understanding classical and peptide chemical neurotransmission. There are, however, differences across the various transmitters, and our knowledge of the different transmitters varies widely. We discuss in detail one class of neurotransmitters, the catecholamines, to illustrate the process of chemical neurotransmission, and then examine more briefly other classical neurotransmitters. We also discuss differences between classical and nonclassical transmitters or chemical messengers, including peptide transmitters, and unconventional transmitters such as nitric oxide, growth factors, and endocannabinoids.

## CLASSICAL NEUROTRANSMITTERS

The term classical is used to differentiate acetylcholine, the biogenic amines, and the amino acid transmitters from other transmitters. The designation is somewhat arbitrary, although these compounds were all accepted as neurotransmitters by the late 1950s. Several criteria can be used to distinguish classical from other transmitters, such as the peptide transmitters. First, storage vesicles for classical transmitters are smaller. Second, classical transmitters are subject to active reuptake by the presynaptic cell and thus can be viewed as homeostatically conserved; in contrast, there is no energy-dependent, high-affinity reuptake process for nonclassical transmitters. Third, most classical transmitters are synthesized in the nerve terminal by enzymatic action, and peptides are synthesized in the soma from a precursor protein and are then transported to the nerve terminal. The remainder of this chapter deals with the biochemistry of several different transmitter groups, discussing their synthesis, storage, and release. Other aspects of chemical transmission, including detailed discussions of transmitter release and the receptors for various transmitters is presented in Chapters 8 and 9.

## Catecholamine Neurotransmitters

Catecholamines are organic compounds that contain a catechol nucleus (a benzene ring with two adjacent hydroxyl substitutions) and an amine group. In general practice the term normally is used to describe the three transmitters: dopamine (DA), NE, and epinephrine (Epi). These three neurotransmitters are formed by successive enzymatic steps requiring distinct enzymes (see Fig. 7.2). The presence of specific synthesizing enzymes in different cells results in separate groups of DA-, NE-, and Epi-containing neurons in the brain.

Catecholamines also have transmitter roles in the peripheral nervous system and certain hormonal functions. In the peripheral nervous system, DA has significant biological activity in the kidney but is mainly present as a NE precursor. NE is the transmitter of the sympathetic nervous system in mammals, whereas Epi is the sympathetic transmitter in frogs. Despite this species difference, biochemical aspects of neurotransmission are remarkably constant across different vertebrate species and even invertebrates.

## Biosynthesis of Catecholamines

The amino acids phenylalanine and tyrosine are precursors for catecholamines. Both amino acids are found in high concentrations in the plasma and brain. In mammals, tyrosine can be formed from dietary phenylalanine by the enzyme phenylalanine hydroxylase, found in large amounts in the liver. Insufficient amounts of phenylalanine hydroxylase result in phenylketonuria, a metabolic disorder that leads to intellectual deficits unless treated by dietary manipulation.

Catecholamine synthesis usually is considered to begin with tyrosine. The enzyme tyrosine hydroxylase (TH) converts the amino acid L-tyrosine into 3,4-dihydroxyphenylalanine (L-DOPA). The hydroxylation of L-tyrosine by TH results in the formation of the DA precursor L-DOPA, which is metabolized by L-aromatic amino acid decarboxylase (AADC; see Cooper *et al.*, 2002) to the transmitter dopamine. This step occurs so rapidly that it is difficult to measure L-DOPA in the brain without first inhibiting AADC. In neurons that use DA as the transmitter, the decarboxylation of L-DOPA to DA is the final step in transmitter synthesis. However, in those neurons using norepinephrine (also known as noradrenaline) or epinephrine (adrenaline) as transmitters, the enzyme dopamine  $\beta$ -hydroxylase (DBH), which converts DA to yield NE, is also present. In still other neurons in which epinephrine is the transmitter, a third enzyme (phenylethanolamine N-methyltransferase, PNMT) converts NE into

Epi. Thus, a cell that uses Epi as its transmitter contains four enzymes (TH, AADC, DBH, and PNMT), whereas NE neurons contain only three enzymes (lacking PNMT) and DA cells only two (TH and AADC).

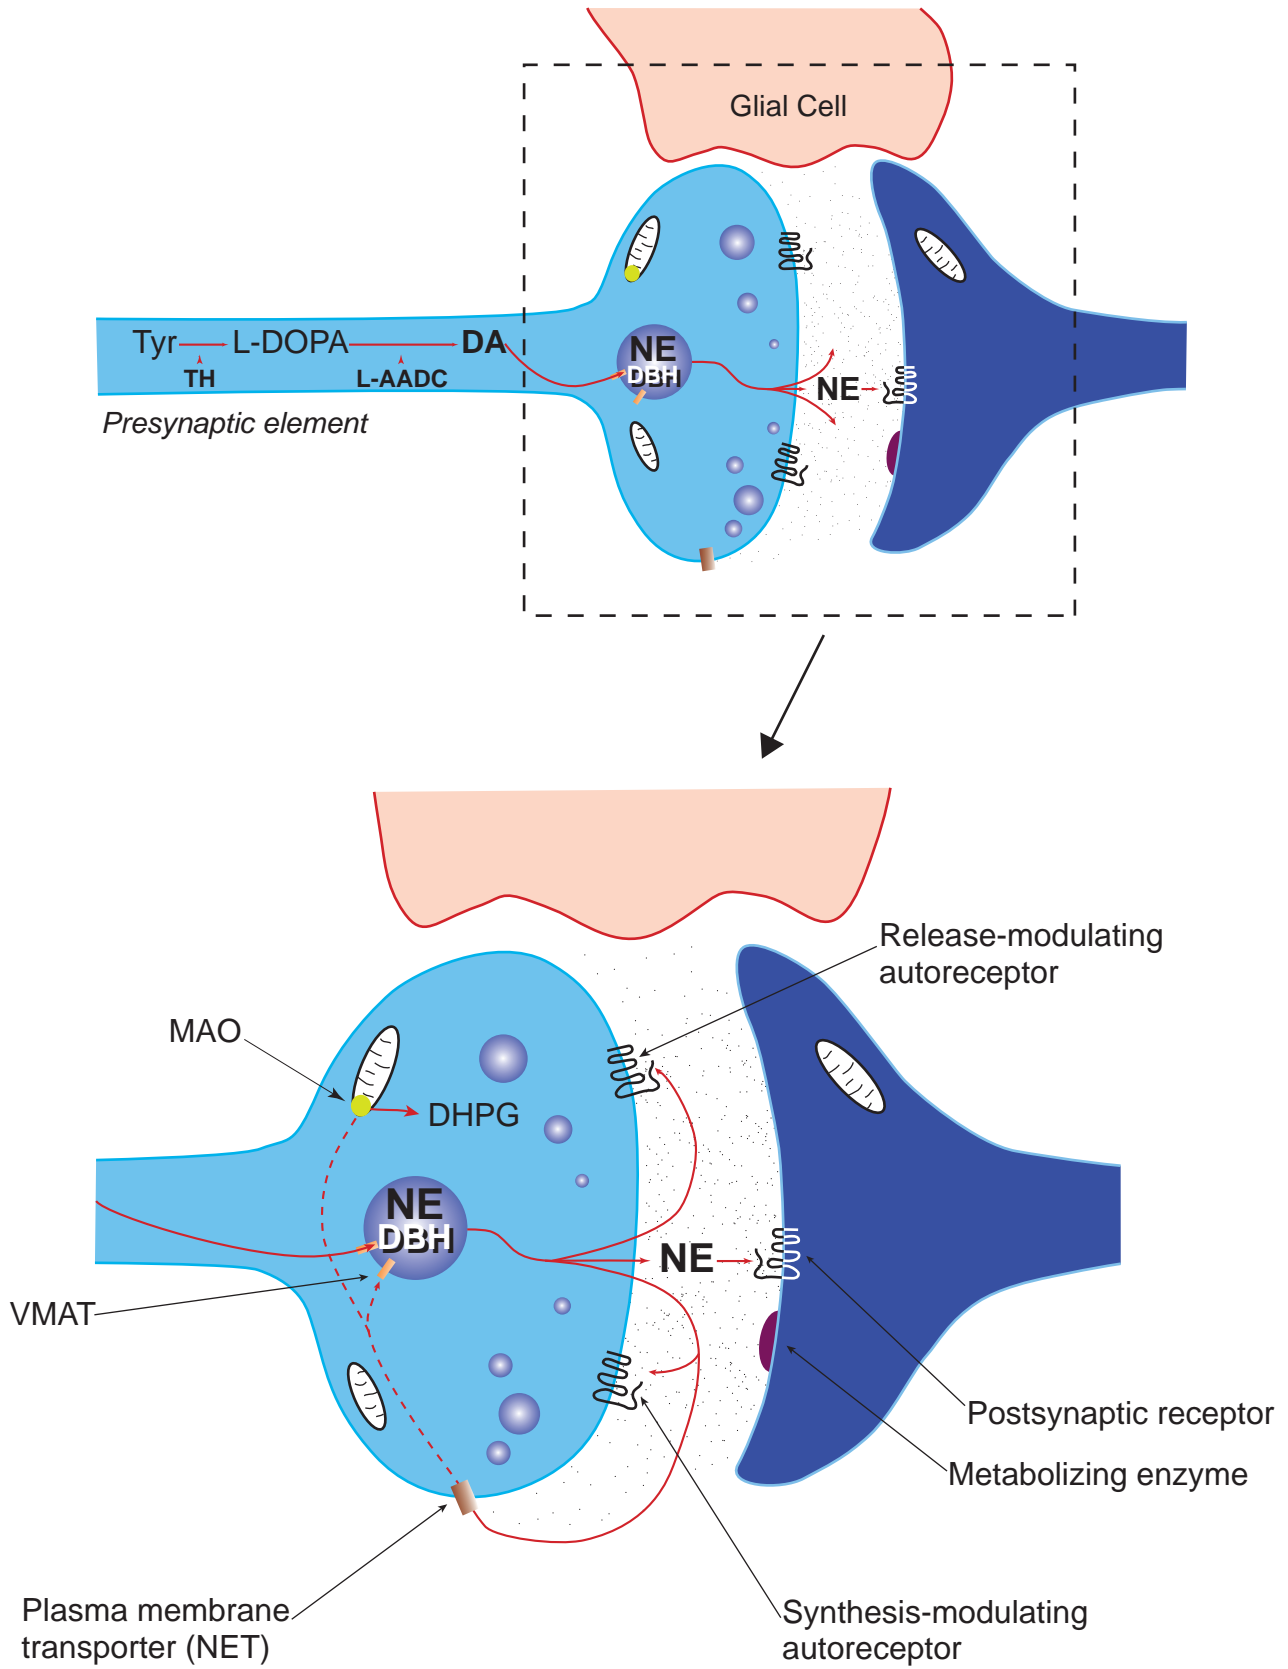

## Tyrosine Hydroxylase

In human beings, a single TH gene is alternatively spliced to yield four TH mRNAs and four distinct TH protein isoforms. However, in most primates, only two TH isoforms are present, and the rat possesses but a single form of TH. It has been speculated that different TH forms in primates are associated with differences in activity of the enzyme, but conclusive data addressing this point are lacking.

The function of TH and other enzymes is determined by two factors: changes in enzyme activity (the rate at which the enzyme converts precursor into its product) and changes in the amount of enzyme protein. The major determinant of TH activity is phosphorylation of the enzyme. Another means of regulating enzyme activity is through end product inhibition: catecholamines can inhibit the activity of TH by competing for a required cofactor for the enzyme (Cooper *et al.*, 2002).

Increased neuronal demand for catecholamines to be released can be accomplished by synthesizing new TH protein or increasing the activity of the TH activity. The degree to which increases in catecholamine synthesis depend on *de novo* synthesis of new enzyme protein or changes in the activity of existing enzymes differs across brain regions. For example, in most NE neurons, increases in TH gene expression and synthesis of the enzyme are readily seen when conditions require more catecholamine synthesis, but in midbrain DA neurons phosphorylation of TH is much more important.

The synthesis of catecholamines starts with the entry of tyrosine (or phenylalanine) into the brain. This process is an energy-dependent one in which tyrosine competes with large neutral amino acids as a substrate for a transporter. Because brain tyrosine levels are high enough to saturate TH, catecholamine synthesis cannot usually be increased by administration of tyrosine. Exceptions to this rule are catecholamine synthesis in cells that are very active, such as DA neurons that project to the prefrontal cortex, and under certain pathological conditions. Because TH is saturated by tyrosine, tyrosine hydroxylation is the rate-limiting step in catecholamine synthesis under basal conditions. However, when NE- or Epi-containing cells are activated, dopamine- $\beta$ -hydroxylase (the enzyme responsible for NE and Epi synthesis) becomes rate-limiting, and thus tyrosine availability can regulate catecholamine synthesis under certain conditions.

**FIGURE 7.2** Characteristics of a norepinephrine (NE)-containing catecholamine neuron. Tyrosine (Tyr) is accumulated by the neuron and then is metabolized sequentially by tyrosine hydroxylase (TH) and L-aromatic amino acid decarboxylase (L-AADC) to dopamine (DA). The DA is then taken up through the vesicular monoamine transporter into vesicles. In DA neurons, this is the final step. However, in this NE-containing cell, DA is metabolized to NE by dopamine- $\beta$ -hydroxylase (DBH), which is found in the vesicle. Once NE is released, it can interact with postsynaptic noradrenergic receptors or presynaptic noradrenergic autoreceptors. The accumulation of NE by the high-affinity membrane NE transporter (NET) terminates the actions of NE. Once taken back up by the neuron, NE can be metabolized to inactive compounds (DHPG) by degradative enzymes such as monoamine oxidase (MAO) or taken back up by the vesicle.

TH is a mixed function oxidase with moderate substrate specificity, hydroxylating phenylalanine as well as tyrosine. The actions of TH require the cofactor tetrahydrobiopterin (BH<sub>4</sub>) and iron (Fe<sup>2+</sup>); BH<sub>4</sub> is also an essential cofactor for tryptophan hydroxylase, the enzyme that synthesizes another transmitter, serotonin. Because BH<sub>4</sub> is not present in saturating concentrations under basal conditions, it is crucial in regulating TH activity. Intracellular levels of BH<sub>4</sub> are determined by its own synthesizing enzyme, GTP cyclohydrolase. Mutations in the gene encoding GTP cyclohydrolase result in DOPA-responsive dystonia, a movement disorder that is treated by administering L-DOPA (bypassing the disruption at the level of TH) to increase central DA levels.

#### *L-Aromatic Amino Acid Decarboxylase*

The hydroxylation of tyrosine by TH generates L-DOPA, which is then decarboxylated to dopamine (DA) by L-aromatic amino acid decarboxylase (AADC; also sometimes referred to as DOPA decarboxylase). AADC has low substrate specificity and decarboxylates tryptophan as well as tyrosine. Because AADC is found in both catecholamine and serotonin neurons, it plays an important role in the synthesis of both transmitters. In dopaminergic neurons, AADC is the final enzyme of the synthetic pathway.

DA does not cross the blood-brain barrier, but its precursor L-DOPA enters the brain readily. L-DOPA has achieved fame as a means of treating Parkinson's disease, which is due to loss of DA in the striatum (see Chapter 31). Although DOPA freely enters the brain, it is readily metabolized in the liver and bloodstream. It is therefore necessary to administer L-DOPA together with an inhibitor of decarboxylases that does not enter the brain but blocks metabolism in the liver and blood.

#### *Dopamine $\beta$ -Hydroxylase*

Noradrenergic and adrenergic neurons contain the enzyme dopamine- $\beta$ -hydroxylase (DBH), which converts DA into NE. In noradrenergic neurons, this is the final step in catecholamine synthesis. Humans have two different DBH mRNAs that are generated from a single gene. DBH lacks a high degree of substrate specificity and *in vitro* it oxidizes almost any phenylethylamine to its corresponding phenylethanolamine. For example, in addition to forming NE from DA, DBH converts tyramine into octopamine. Interestingly, receptors that have a high affinity for the trace amines tyramine and octopamine recently have been discovered (see Zucchi *et al.*, 2006) and may be involved in certain psychiatric disorders.

#### *Phenylethanolamine N-Methyltransferase*

Phenylethanolamine N-methyltransferase (PNMT) is present at high levels in a restricted number of brainstem neurons that use epinephrine as a transmitter, and in the inner portion (medulla) of the adrenal gland, where it methylates NE to form Epi, the major adrenal catecholamine. There is a single PNMT gene. The regulation of PNMT activity in the brain has not been as extensively studied as in the adrenal gland, where glucocorticoids and nerve growth factor regulate the enzyme.

#### **Storage of Catecholamines and Their Enzymes**

Catecholamines are stored in specialized subcellular organelles called vesicles. Accordingly, a specialized vesicular transporter protein is required in order for dopamine that is formed in the cytosol to enter the vesicle.

#### *Vesicular Storage*

The vesicle serves as a depot for the transmitter until it is released by appropriate physiological stimuli (see Chapter 8). In addition, vesicles isolate transmitters and protect them from metabolic inactivation by intraneuronal enzymes found in the cytosol, and from attack by toxins that have gained entry to the cell vesicle.

The NE-synthesizing enzyme DBH differs from the other enzymes in catecholamine synthesis by being localized to the vesicle rather than the cytosol. This means that only *after* DA is taken up by vesicles through the vesicular monoamine transporter (VMAT) is it metabolized to NE. This vesicular storage of DBH has an interesting consequence: DBH and dopamine can both be released into the synapse along with NE.

### *Vesicular Monoamine Transporters*

The ability of vesicles to accumulate DA and other compounds depends on VMAT (Weihe and Eiden, 2000). The vesicular transporter differs from the neuronal membrane transporter that terminates the action of catecholamines in terms of substrate affinity and localization. Two VMAT genes have been cloned: VMAT1 is found in adrenal gland cells that synthesize and release catecholamines, and VMAT2 is found in the catecholamine and serotonin-containing neurons of the brain. VMAT2 is not very specific and transports catecholamines, indoleamines such as serotonin, and histamine into vesicles.

The VMATs are inhibited by reserpine. This drug has been used for centuries in India as a folk medicine to treat high blood pressure and psychoses. These uses of reserpine were reported in international journals in the early 1930s, but these therapeutic actions were not appreciated in Western medicine until a generation later; the unpleasant side effects of reserpine initially garnered more attention. In the 1950s Bernard Brodie and coworkers discovered that reserpine depleted brain serotonin. The contemporaneous discovery that the hallucinogen LSD is structurally similar to serotonin led to the proposal that the antipsychotic actions of reserpine were due to its ability to deplete serotonin in the brain. However, it was soon realized that reserpine depletes both serotonin and catecholamines in the brain; thus, antipsychotic effects of reserpine might be due to serotonin or catecholamine depletion, or both.

To determine if serotonin or catecholamines were more important for the antipsychotic effect of reserpine, Arvid Carlsson and colleagues administered catecholamine and serotonin precursors to rats treated with reserpine in an attempt to replenish the levels of the transmitters. They then examined locomotor activity, which is severely depressed by reserpine. Motor function was restored by the DA precursor L-DOPA but not by the serotonin precursor 5-hydroxytryptophan. This work led to the characterization of DA as a neurotransmitter. The demonstration that L-DOPA increases brain DA concentrations in reserpinized animals suggested that the primary mechanism through which reserpine exerts antipsychotic effects was through its ability to disrupt DA transmission. This idea led directly to the hypothesis that the dysfunction of central DA systems underlies schizophrenia. Interestingly, studies have suggested that drugs that are antagonists at both certain DA and serotonin receptors may be better than DA antagonists in treating schizophrenia.

VMATs have significant homology with a group of bacterial antibiotic drug resistance transporters, sug-

gesting a role of VMAT in detoxification. This is indeed the case: VMAT sequesters the transmitter in vesicles where it is protected from various toxins. This is perhaps best illustrated by studies of heterozygous mice with one copy of VMAT2. In these mice, the parkinsonian toxin MPTP (see Chapter 31) causes a greater loss of DA neurons than in wildtype control mice because there is less VMAT to package the toxin into vesicles and thus permits the toxin to disrupt mitochondrial function.

### **Release of Catecholamines**

Catecholamine release usually operates through the same calcium-dependent exocytotic process used by other transmitters (see Chapter 8), but can also occur through at least two other mechanisms. First, catecholamines can be released by a reversal of the direction of transport through the membrane transporters DAT and NET. For example, this occurs in response to certain drugs (such as amphetamine). Second, DA and perhaps other catecholamines can be released from dendrites through a process that does not appear to involve  $Ca^{2+}$ .

### *Regulation of Catecholamine Synthesis and Release by Autoreceptors*

Enzymes that control catecholamine synthesis can be regulated at both the transcriptional level and by post-translational modifications that alter enzymatic activity. In addition, DA and NE can be regulated by the interaction of released catecholamine with specific DA or NE "autoreceptors" located on the nerve terminal.

Autoreceptors are found on most parts of the neuron and are defined functionally by the events that they regulate. Thus, synthesis-, release-, and impulse-modulating DA autoreceptors have been described (see Cooper *et al.*, 2002). All three types of DA autoreceptors belong to the D2 family of DA receptors, which includes three different receptors ( $D_2$ ,  $D_3$ , and  $D_4$ ). It is clear that  $D_2$  autoreceptors exist, but considerable controversy surrounds the presence of  $D_3$  autoreceptors and there is no evidence for  $D_4$  autoreceptors. The presence of three functionally different DA autoreceptors suggests that a single  $D_2$  protein may have different autoreceptor roles that occur through distinct transduction mechanisms.

The autoreceptor can be thought of as a key part of a feedback mechanism. Thus, DA that is released from a neuron stimulates an autoreceptor to inhibit further DA release. *Release-modulating* autoreceptors are a common regulatory feature of all neurons that use classical transmitters. Because *intracellular* DA levels regulate tyrosine hydroxylase activity by interfering with the binding of TH to its cofactor, changes in the release

of DA may also alter transmitter synthesis. *Synthesis-modulating* autoreceptors directly regulate DA synthesis: DA release decreases DA synthesis whereas DA antagonists that block the autoreceptor increase synthesis. Interestingly, synthesis-modulating autoreceptors are not found on all DA neurons: some mid-brain and hypothalamic DA neurons lack synthesis-modulating autoreceptors. Finally, *impulse-modulating* autoreceptors found on the soma and dendrites of DA neurons and regulate the firing rates of these cells. Because the release of DA can alter synthesis of the transmitter by changing feedback inhibition on TH, it follows that impulse-modulating autoreceptors also change DA synthesis. Thus, all three types of DA autoreceptors may ultimately regulate synthesis. The interdependence of regulatory processes governing DA cells is characteristic of monoaminergic neurons.

Constant levels of a neurotransmitter in the synapse will not accurately convey information about the dynamic state of the presynaptic neuron to its follower cell. In addition, continuous stimulation of certain receptors is pathological and can damage postsynaptic cells. For example, when certain receptors for the transmitter glutamate are activated continuously, the result is "excitotoxic" cell death.

In order to prevent continuous presynaptic signaling, different mechanisms for terminating the actions of a transmitter have evolved. The simplest is diffusion of the transmitter and its subsequent dilution in extracellular fluid to subthreshold concentrations. Believed to be more important are active modes of halting transmitter action, including enzymatic inactivation of the transmitter and uptake of the transmitter by membrane-associated transporter proteins.

### *Enzymatic Inactivation of Catecholamines*

Enzymatic inactivation originally was thought to be the major means of terminating catecholamine actions in the CNS, although it now appears that reuptake of the transmitter is the primary mode of inactivation. Two enzymes contribute to catecholamine catabolism: monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). These enzymes can act independently or can act on the products generated by the other enzyme, leading to catecholamine metabolites that are deaminated, *O*-methylated, or both. COMT is a relatively nonspecific enzyme that transfers methyl groups from the donor *S*-adenosylmethionine to the *m*-hydroxy group of catechols. COMT is found in both peripheral tissues and central nervous system and is the major means of inactivating catecholamines that are released from the adrenal gland.

MAOs oxidatively deaminates catecholamines and their *O*-methylated derivatives to form inactive and

unstable derivatives that can be further degraded by other enzymes. Two forms of MAO have been identified. MAO<sub>A</sub> has high affinities for NE and serotonin and is selectively inhibited by drugs such as clorgyline. In contrast, MAO<sub>B</sub> has a higher affinity for *o*-phenylethylamines and is selectively inhibited by different compounds, such as deprenyl. The MAOs are important targets of drugs used to treat several neuropsychiatric disorders (Box 7.1).

### *Neuronal Catecholamine Transporters*

The reuptake of a transmitter released by a neuron is the major mode of transmitter inactivation in the brain. Accumulation of the transmitter also allows intracellular enzymes that degrade the transmitter to act, thus bolstering the actions of extracellular enzymes.

Several characteristics define the high-affinity neuronal reuptake of transmitters (Clark and Amara, 1993). The process is energy dependent and saturable, depends on Na<sup>+</sup> cotransport, and requires extracellular Cl<sup>-</sup>. Because reuptake depends on coupling to the Na<sup>+</sup> gradient across the neuronal membrane, toxins that inhibit Na<sup>+</sup>, K<sup>+</sup>-ATPase inhibit reuptake. Under certain conditions, the coupling of transporter function to Na<sup>+</sup> flow may cause local changes in membrane Na<sup>+</sup> gradients and thereby paradoxically cause the transporter to operate in "reverse" to extrude ("release") the transmitter from the cell to the extracellular space.

Membrane catecholamine transporters are not Mg<sup>2+</sup> dependent and are not inhibited by reserpine, which distinguishes neuronal and vesicular membrane transporters. Catecholamine transporters are localized to neurons: although there appears to be a reuptake process that accumulates catecholamines into glia, this is not a high affinity process and its functional significance is unclear.

Two distinct mammalian catecholamine transporters, one for dopamine (dopamine transporter, DAT) and one for norepinephrine (NET), have been identified. The two are closely related members of a class of transporter proteins (including serotonin and amino acid transmitter transporters) with 12 transmembrane domains. Neither transporter is specific, with each accumulating both DA and NE. In fact, NET has a higher affinity for dopamine than for NE. An epinephrine transporter has been identified in the frog but not in mammals.

The regional distribution of DAT and NET largely follows the expected localization to DA and NE neurons, respectively. However, DAT does not appear to be expressed in all DA cells. Certain hypothalamic cells that release DA into the blood system of the pituitary lack detectable DAT mRNA and protein. Because

## BOX 7.1

## MAO AND COMT INHIBITORS IN THE TREATMENT OF NEUROPSYCHIATRIC DISORDERS

One hypothesis of the pathophysiology of depression posits a decrease in noradrenergic levels in the brain. MAO<sub>A</sub> inhibitors, such as tranylcypromine, effectively increase NE levels (as well as DA and 5-HT concentrations) and were once a mainstay in the treatment of depression. However, the use of MAO inhibitors in depression largely has been supplanted by the introduction of drugs that increase extracellular NE levels by blocking the NE transporter (tricyclic antidepressants) and other agents that increase 5-HT or DA levels by blocking SERT or DAT (such as Prozac and Welbutrin). The treatment of depression with MAO<sub>A</sub> inhibitors, although still useful for certain patients who do not respond to other antidepressants, is marred by a large number of side effects. Among the most serious is hypertensive crisis. Patients treated with MAO<sub>A</sub> inhibitors cannot metabolize tyramine efficiently, which is present in large amounts in certain foods, such as aged cheeses and red wines. Because tyramine releases catecholamines peripherally, small amounts of tyramine increase blood pressure significantly and may lead to a high risk for stroke.

Deprenyl, a specific inhibitor of MAO<sub>B</sub>, has been used as an initial treatment for Parkinson's disease (PD; see Chapter 31). The use of deprenyl in the treatment of PD and the rationale for its use were based on data from studies of a neurotoxin, 1-methyl-4-phenyl 1-1,2,3,6-tetrahydropyridine (MPTP). MPTP results in the degeneration of midbrain DA neurons and a parkinsonian syndrome. MPTP-induced parkinsonism was first noted in a group of opiate addicts. In an attempt to synthesize a designer drug, the structurally related MPTP was inadvertently produced; addicts who injected this drug developed a severe parkinsonian syndrome. Subsequent animal studies showed that MPTP itself is not toxic, but that its active metabolite, MPP<sup>+</sup>, is highly toxic. The formation of MPP<sup>+</sup> from MPTP is catalyzed by MAO<sub>B</sub>, and treatment

with MAO inhibitors such as deprenyl can prevent MPTP toxicity. The realization that MPTP administration rather faithfully reproduces the cardinal signs and symptoms of PD reawakened interest in environmental toxins as a cause of PD. The MPTP saga also led to the idea that deprenyl treatment might slow the progression of PD by preventing metabolism of an environmental compound to an active toxin such as MPP<sup>+</sup>. Although clinical studies initially were interpreted to suggest that there was a slowing of clinical progression of Parkinson's disease in response to deprenyl, later studies showed that deprenyl increases DA levels slightly and thus gives some symptomatic relief.

Catechol O-methyl transferase, which together with MAO degrades catecholamines, also plays a role in the treatment of PD. Two COMT inhibitors are used to prevent the enzymatic inactivation of DOPA. By inhibiting COMT, these drugs prolong the therapeutic action of DOPA and may smooth out fluctuations in the therapeutic response to DOPA.

Changes in catecholamine function also have been the object of intense scrutiny in schizophrenia, with recent attention focusing on possible changes in dopamine. One allelic variant of the COMT gene results in a much reduced activity of the enzyme. Data have examined COMT alleles for full vs. low COMT activity in normal subjects and schizophrenics. Individuals bearing the allele that confers lower COMT activity display improved performance on cognitive tasks that involve DA actions in the prefrontal cortex; the performance of schizophrenic persons on these tasks is impaired. It therefore has been proposed that high COMT activity may confer an increased risk to schizophrenia.

*Ariel Y. Deutch and Robert H. Roth*

DA released from these neurons is carried away in the blood, the existence of a transporter protein on these DA cells would be superfluous.

Immunohistochemical studies of the subcellular localization of DAT led to an unexpected finding. DAT is not found at the synaptic junction, but just outside of this region. Thus, the transporter may be used to accumulate and therefore inactivate DA that has

escaped from the synaptic cleft. This suggests that diffusion is the initial process by which DA is removed from the synapse. The extrasynaptic localization of the catecholamine transporters, coupled with a similar extrasynaptic localization of dopamine receptors, suggests that extrasynaptic ("volume") neurotransmission may be of major importance in catecholamine signaling.

Mice in which the gene encoding DAT has been deleted have been particularly useful in clarifying the function of transporters. Transgenic mice that lack DAT have a remarkable number of changes in DA function, ranging from increased extracellular DA levels and delayed clearance of released DA to a striking decrease in tissue concentrations of DA in the face of increased DA synthesis (Gainetdinov *et al.*, 1998). There is also a complete loss of autoreceptor-mediated tone, including deficits in release-, synthesis-, and impulse-modulating autoreceptor function. These deficits in DAT knockout mice have been suggested to reflect a disinhibition of tyrosine hydroxylase due to a lack of intraneuronal DA (removing feedback inhibition of the enzyme), resulting in a marked increase in DA synthesis and release.

The catechoamine transporters are important targets of many drugs. Cocaine and amphetamine both increase extracellular levels of catecholamines by blocking transporters. In particular, cocaine shows a very high affinity for DAT; amphetamine is a less potent inhibitor but also induces "release" (via transporter reversal) of catecholamines. Drugs used in the treatment of attention deficit disorder, including amphetamine, methylphenidate, and atomoxetine also act by blocking catecholamine transporters. NET is the molecular target of tricyclic antidepressant drugs, which potently inhibit NE reuptake.

## Serotonin

Well over a century ago scientists were aware of a substance in the blood that induced powerful contractions of smooth muscle organs. In the mid-twentieth century, Page and collaborators succeeded in isolating the compound, which they suggested to be a possible cause of high blood pressure, from platelets. At the same time, Italian researchers were studying a substance in intestinal mucosa that caused contractions of intestinal smooth muscle. The material isolated from platelets was called "serotonin," and the substance isolated from the intestinal tract was named "enteramine." Studies soon revealed that the two substances were the same compound, 5-hydroxytryptamine (5-HT), which now is commonly referred to as serotonin.

Serotonin is found in neurons and in several other types of cells in the body. In fact, the brain accounts for only about 1% of total body stores of serotonin. Although the isolation and identification of serotonin were from peripheral tissues, much of the subsequent interest in serotonin was based on its potential involvement in psychiatric disorders. The finding that serotonin's chemical structure is similar to that of LSD led

to theories that associated abnormalities in serotonin function to schizophrenia and depression.

The basic process of serotonin biosynthesis is very similar to that of catecholamine transmitters: a peripheral amino acid (tryptophan) gains entry into the brain and is metabolized in serotonergic neurons via a series of enzymatic steps. Once tryptophan enters the serotonergic neuron, it is hydroxylated by tryptophan hydroxylase, the rate-limiting step in serotonin synthesis, giving rise to 5-hydroxytryptophan (5-HTP), which is then decarboxylated by L-aromatic amino acid decarboxylase to the transmitter serotonin. Thus, only two critical enzymes (tryptophan hydroxylase and AADC) are involved in the synthesis of 5-HT (Cooper *et al.*, 2002).

### *Alternative Tryptophan Metabolic Pathways*

Although serotonin is usually the endpoint of tryptophan metabolism in brain, serotonin can be metabolized further to yield active products. In the pineal gland, 5-HT is metabolized to form 5-methoxy-N-acetyltryptamine (melatonin), a hormone thought to play an important role in sleep. In peripheral tissues, most tryptophan is not metabolized to 5-HT but instead is metabolized by the kynurenine pathway. This kynurenine shunt is also present in the brain and leads to the accumulation of several interesting active substances (see Schwarcz, 2004). The two major tryptophan metabolites generated by the kynurenine shunt are quinolinic and kynurenic acids. Quinolinic acid is a potent agonist at certain glutamate receptors, and acts through glutamate receptors to cause cell loss and convulsions; in contrast, kynurenine is an antagonist at these receptors. These compounds are the focus of considerable clinical interest in various neuropsychiatric disorders.

### *Inactivation of Released Serotonin*

Serotonin is inactivated primarily by reuptake through SERT, the serotonin transporter that belongs to the same family of transporters as the catecholamine transporters. The most commonly used antidepressants today are a class of compounds known as serotonin selective reuptake inhibitors, or SSRIs; the prototypic SSRI is fluoxetine (Prozac). Because antidepressant drugs increase serotonin or norepinephrine levels, or both, current theories of depression posit critical modulatory roles for NE and 5-HT.

The enzymatic degradation of 5-HT is catalyzed by monoamine oxidase (MAO). The product of this reaction, 5-hydroxyindole acid aldehyde, is oxidized further to 5-hydroxyindoleacetic acid. MAO inhibitors increase 5-HT levels and have been widely used as antidepressants (Box 7.1).

## Acetylcholine

Our basic ideas about chemical synaptic transmission are based on early studies of acetylcholine (ACh). Both pharmacological and electrophysiological studies at the neuromuscular junction led to key findings on ACh that remain the cornerstone for today's understanding of chemical neurotransmission. For example, electrophysiological studies revealed fast excitatory responses of muscle fibers to the stimulation of nerves innervating the muscle. The presence of miniature end plate potentials (mEPPs) in muscle fiber was noted, and in the early 1950s, Fatt and Katz demonstrated that these mEPPs resulted from the slow "leakage" of ACh, with each mEPP representing the release of transmitter in one vesicle (termed a quantum). Overt depolarization generated an increase in the number of quanta released over a given period of time (see Chapter 8). Over the past half century many of the rules that govern ACh neurotransmission have been found to be general principles that apply to many transmitters.

In large part the general principles that govern catecholamine and serotonin synthesis also apply to acetylcholine synthesis. The synthesis of ACh is simple, with only a single step: the acetyl group from acetyl-coenzyme A is transferred to choline by the enzyme choline acetyltransferase (ChAT). There are correspondingly few requirements for ACh synthesis: the presence of the substrate choline, the donor acetyl-coenzyme A, and ChAT. The acetyl-CoA that serves as the donor is derived from pyruvate generated by glucose metabolism. There is one interesting twist on ACh synthesis: acetyl-CoA is localized to mitochondria, but the synthetic enzyme ChAT is cytoplasmic, dictating that acetyl-CoA must exit the mitochondria to gain access to ChAT. Despite the fact that ChAT is the only enzyme involved in ACh synthesis, it is not the rate-limiting step in synthesis of the transmitter. The full enzymatic activity of ChAT is not expressed *in vivo*: ChAT activity measured *in vitro* is much greater than would be expected on the basis of ACh synthesis *in vivo*. The reason for this discrepancy has been suggested to be related to the requirement that acetyl-CoA be transported from the mitochondria to the cytoplasm. Alternatively, intracellular choline concentrations may determine the rate of ACh synthesis. This latter idea has led to the use of choline precursors in attempts to enhance ACh synthesis in Alzheimer disease, in which there is a marked decrease of cortical ACh levels. Unfortunately, these attempts have not proven very successful.

ACh is taken up into storage vesicles by the vesicular cholinergic transporter (VAChT). Cloning of human VAChT revealed that the gene is localized to chromo-

some 10, near the ChAT gene for ChAT. Additional studies then demonstrated that the entire VAChT coding **region** is contained in the first intron of the ChAT gene. This suggested that both genes are coordinately regulated, a suspicion that subsequently was confirmed.

The primary mode of inactivation of ACh appears to be enzymatic, which is simply the hydrolysis of ACh to choline. Two groups of cholinesterases have been defined on the basis of substrate specificity: acetylcholinesterases (AChEs) and butyrylcholinesterases (Taylor and Brown, 2006). The former are relatively specific for ACh and are found in high concentration in the brain, whereas butyrylcholinesterases are enriched in the liver and are present in lower levels in the brain.

AChE is found in high concentrations in cholinergic neurons. However, AChE also is found in moderately high concentrations in some noncholinergic neurons that receive cholinergic inputs. This observation is consistent with the fact that AChE is a secreted enzyme that is associated with the cell membrane. Thus, ACh hydrolysis takes place extracellularly, and the choline generated is conserved by the high-affinity reuptake process. In addition to its role in inactivating acetylcholine, AChE has been proposed to be a chemical messenger in the CNS (Greenfield, 1991).

## $\gamma$ -Aminobutyric Acid: The Major Inhibitory Neurotransmitter

Several amino acids fulfill most of the criteria for consideration as neurotransmitters. The best studied of these are  $\gamma$ -aminobutyric acid (GABA), the major inhibitory transmitter in brain, and glutamate, which is the major excitatory transmitter in brain. Many of the principles concerning transmitter synthesis and inactivation that were previously discussed apply to amino acid transmitters, however there are some key differences between the amino acid and other classical transmitters. The most obvious difference is that GABA is derived from glucose metabolism (Fig. 7.3). Accordingly, mechanisms must exist to segregate the transmitter and general metabolic pools of the amino acid transmitters (Olsen and Betz, 2006). A second difference between amino acid and catecholamine transmitters is that the former are taken up readily by glia as well as neurons.

## GABA Synthesis

### *The GABA Shunt and GABA Transaminase*

GABA ultimately is derived from glucose metabolism.  $\alpha$ -Ketoglutarate formed by the Krebs cycle is

**FIGURE 7.3** Schematic depiction of the life cycle of a GABAergic neuron.  $\alpha$ -Ketoglutarate formed in the Krebs cycle is transaminated to glutamate (Glu) by GABA transaminase (GABA-T). The transmitter GABA is formed from the Glu by glutamic acid decarboxylase (GAD). GABA that is released is taken by high-affinity GABA transporters (GAT) present on neurons and glia.

transaminated to the amino acid glutamate by the enzyme GABA-transaminase (GABA-T). In those cells in which GABA is used as a transmitter, the presence of another enzyme, glutamic acid decarboxylase (GAD), generates GABA from glutamate. The presence of GAD therefore serves as an unambiguous marker of a neuron that uses GABA as a transmitter.

An unusual feature of GABA synthesis is that intraneuronal GABA is inactivated by the actions of GABA-T, which appears to be associated with mitochondria (Fig. 7.3). Thus, GABA-T is both a key synthetic enzyme and a degradative enzyme! GABA-T metabolizes GABA to succinic semialdehyde, but only if  $\alpha$ -ketoglutarate is present to receive the amino group that is removed from GABA. This unusual GABA shunt serves to maintain supplies of GABA.

### *How Are Transmitter and Metabolic Pools Separate?*

A major question concerning amino acid transmitters is how the transmitter pool is separately maintained from the general metabolic roles of amino acids. The GABA synthetic enzyme GAD is a cytosolic enzyme, but GABA-T, which converts  $\alpha$ -ketoglutarate into the GAD substrate glutamate, is present in mitochondria. Thus, the metabolic pool is present in mitochondria, and glutamate destined for the transmitter pool must be exported from mitochondria to the cytosol. This process is poorly understood.

Glutamate is not only a precursor to GABA, but is also the major excitatory neurotransmitter. Why GABA neurons fail to use the precursor glutamate as a transmitter may involve different biosynthetic enzymes for

the transmitter and metabolic pools of glutamate, as well as different vesicular transporters that accumulate glutamate and GABA into vesicles. A neuronal enzyme that is localized to vesicles has been proposed to be responsible for the synthesis of the transmitter pool of glutamate.

## Storage and Release of GABA

### *Vesicular Inhibitory Amino Acid Transporter*

A vesicular GABA transporter has been cloned on the basis of homology to a protein in the worm *Caenorhabditis elegans*. The strategy of moving from invertebrate to mammalian species has been very useful in identifying a variety of mammalian transmitter-related genes. The vesicular GABA transporter shares with the vesicular monoamine transporters a lack of substrate specificity, and will transport the inhibitory transmitter glycine as well as GABA. Some rare GABA cells may lack the transporter, raising the specter of a related transporter or some unique functional attribute of these cells.

### *Autoreceptor Regulation of GABA Release*

As is the case with other classical transmitters, GABAergic cells have autoreceptors that regulate release of the transmitter. There are two major classes of GABA receptors. One type of GABA receptor forms ion channels, which are found mainly on cells postsynaptic to GABA terminals; the second class are G protein-coupled receptors. Pharmacological studies indicate that the autoreceptor-mediated regulation of GABA neurons takes place mainly through G protein-coupled GABA<sub>B</sub> receptors located on GABAergic axon terminals. Anatomical studies have revealed that GABA<sub>B</sub> receptors sometimes also are found on postsynaptic non-GABAergic neurons. It is possible that these postsynaptic GABA<sub>B</sub> sites respond to GABA released from a neuron that is presynaptic to another GABA neuron. Interestingly, when one GABA neuron terminates on another GABA cell, the inhibition of the second (postsynaptic cell) will have the same functional consequence as an autoreceptor (decreasing subsequent transmitter release) on the third cell in the chain.

## Inactivation of GABA

Reuptake is the primary mode of inactivation of the transmitter GABA. There are four GABA transporters (GATs), providing a diverse means of regulating GABA neurons. Early studies defined the different GABA transporters as neuronal or glial based on phar-

macological criteria. However, anatomical studies found that one GAT that had been defined on pharmacological grounds as a glial transporter is present in both neurons and glia. The reason for multiple GABA transporters is not clear. GATs are expressed in both GABAergic and non-GABAergic cells (presumably cells that receive a GABA innervation). Consistent with the promiscuous uptake of transmitters by other transporters, GATs also appear to take up amino acids other than GABA.

## Glutamate and Aspartate: Excitatory Amino Acid Transmitters

Excitatory amino acid transmitters account for most of the fast synaptic transmission that occurs in the mammalian brain. Glutamate and aspartate are the major excitatory amino acid neurotransmitters, and several related amino acids, such as N-acetylaspartylglutamate, are also thought to have neurotransmitter roles. Excitatory amino acids such as glutamate participate in both intermediary metabolism and neuronal communication.

Neither glutamate nor aspartate crosses the blood-brain barrier, and in the brain these transmitters are derived only by local synthesis from glucose. Two processes lead to glutamate synthesis in the nerve terminal. As discussed earlier, glutamate is formed from glucose through the Krebs cycle and transamination of  $\alpha$ -ketoglutarate. In addition, glutamate can be formed directly from glutamine. Because glutamine is synthesized in glial cells, both neurons and glia are important in determining the transmitter pool of glutamate. Glutamine is exported from glia and is transported into nerve terminals before being converted into glutamate by a glutaminase enzyme (Hassel and Dingledine, 2006).

Because of the intermingling of glial and neuronal contributions to glutamate synthesis, and the lack of specific enzymes or other proteins to distinguish the metabolic pool of glutamate from the transmitter glutamate, it was difficult to clearly identify a neuron as using glutamate as a transmitter. The identification of three vesicular glutamate transporters, VGluT1, 2, and 3, has resulted in a simple means of marking glutamatergic neurons. However, anatomical studies over the past several years have revealed that many glutamate neurons also contain one or more other transmitters (Fremeau *et al.*, 2004), with some even containing the inhibitory amino acid transmitter GABA. Because GABA hyperpolarizes cells in adult neurons, while glutamate depolarizes neurons, one would expect that the transmitter pools of GABA and glutamate are not found in the same neurons. The

functional significance of such an arrangement is not clear.

Just as there are several vesicular glutamate receptors, there are several glutamate transporters that terminate the action of glutamate. An unusual aspect is that one of these transporters is expressed by astrocytes and is the major accumulator of glutamate from the extracellular space. Moreover, relatively new data point to glia as releasing glutamate in a signaling capacity. These findings have led to an increasing awareness of glia as being far more than structural support cells and argue for a much broader contribution of glia to neuronal communication (Volterra *et al.*, 2002).

## NONCLASSICAL NEUROTRANSMITTERS

We have discussed classical transmitters, of which there are relatively few. Many more transmitters are peptides. There are some clear differences between peptide and classical transmitters, but the two groups have more in common. For example, both classical and peptide transmitters usually are very well conserved across species; many of the peptide transmitters initially were isolated from amphibians. In addition, both classical and peptide transmitters are synthesized in neurons, where they are stored in vesicles and released in a  $\text{Ca}^{2+}$ -dependent manner. However, the biosynthetic mechanisms and the modes of inactivation of peptide and classical transmitters differ. We will first consider the question of the significance of multiple neurotransmitters, and then turn to the general principles of peptide transmitter biosynthesis and inactivation.

### Why Do Neurons Have So Many Transmitters?

About a dozen classical transmitters and dozens of neuropeptides function as transmitters. There are still more "unconventional" transmitters, which we will address later in this chapter. If transmitters simply serve as a chemical bridge that conveys information between two spatially distinct cells, why have so many chemical messengers?

#### *Convergence of Different Transmitter-containing Axons on a Common Neuron*

Perhaps the simplest explanation for multiple transmitters is that many nerve terminals synapse onto a single neuron. How can a neuron distinguish

between multiple inputs that carry different information? One way is to segregate the place on the neuron at which an input arrives, such as the soma, axon, or dendrite. However, because many afferents terminate in close proximity, another means of distinguishing inputs and their information is necessary: chemical coding of the inputs by neurotransmitters.

#### *Colocalization of Neurotransmitters*

The idea that a neuron is limited to one transmitter can be traced to Henry Dale, or more accurately, to an informal restatement of what is termed Dale's principle. In the 1940s, Dale posited that a metabolic process that takes place in the cell body can reach or influence events in all processes of the neuron. Sir John Eccles restated Dale's view to suggest that a neuron releases the same transmitter at all its processes. Illustrating the dangers of scientific sound bites, this principle was soon misinterpreted to indicate that only a single transmitter can be present in a given neuron. This view held sway for about 40 years, when it was no longer possible to dismiss as artifact the data in support of peptide transmitters. We now know that neurons can contain multiple transmitters, including both a classical transmitter (such as DA) and a peptide transmitter (such as neurotensin). Indeed, it appears that few, if any, neurons contain only one transmitter, and in many cases three or more transmitters are found in a single neuron.

The presence of multiple transmitters in single neurons suggests that different transmitters are used by a neuron to signal different functional states to its target cell. For example, the firing rates of the neurons differ considerably, and it may be useful to encode fast firing by one transmitter and slower firing by a different transmitter. The firing *pattern* of neurons also conveys information. For example, a neuron may discharge five times every second on average. This may mean that the cell regularly discharges every 200 ms, but can also represent a cell that has a burst of five discharges during an initial 100-ms period followed by 900 ms of silence. Peptide transmitters often are released at higher firing rates and particularly under burst-firing patterns.

The different synthetic steps in peptides and classical transmitters lead to differential release. Classical transmitters can be replaced rapidly because their synthesis occurs in nerve terminals. In contrast, peptide transmitters must be synthesized in the cell body and transported to the terminal. Thus, it is useful to conserve peptide transmitters for situations of high demand because they would otherwise be depleted rapidly.

### *Transmitter Release from Different Processes*

The restatement of Dale's principle by Eccles held that a transmitter is found in all processes of a neuron. In invertebrate species a transmitter can be localized to different parts of a neuron, and it is clear that many proteins in mammalian neurons are distributed in a highly specialized manner. Although differential targeting of transmitters to different processes in mammalian neurons remains to be demonstrated conclusively, if a transmitter were restricted to a particular part of a neuron, the neuron would need multiple transmitters to account for different release sites. Receptors are very specific in their locations on neurons, and certain receptors are recruited to "hot spots" on neuronal processes by the activity patterns of presynaptic inputs.

### *Synaptic Specializations versus Nonjunctional Appositions between Neurons*

The anatomical relations between one cell and its follower may contribute to the need for different transmitters. We typically think of synaptic specializations as the physical substrate of communication between two neurons. However, there may also be nonsynaptic communication between two neurons. This could occur across distances that are larger than conventional synaptic arrangements. In such a situation the requirements for transmitter action would differ from those discussed previously because the distance traversed by the transmitter molecule would be farther than at a synaptic apposition. Thus, transmitters that lack an efficient reuptake system, such as peptide transmitters, might be favored at nonsynaptic sites. Because a single neuron can form both synaptic and nonsynaptic specializations, a single neuron may require more than one neurotransmitter.

### *Fast versus Slow Responses of Target Neurons to Neurotransmitters*

Different firing rates or patterns may be accompanied by changes in the type or relative amounts of a transmitter being released from a neuron. For example, stimulation of receptors that form ion channels leads to very rapid changes, whereas actions at metabotropic receptors that are coupled to intracellular events through specific transduction molecules have slower response characteristics. Differences in temporal response characteristics allow the receptive neuron to respond differently to a stimulus depending on the antecedent activity in the cell. A transmitter can change the response characteristics of a particular cell to subsequent stimuli by seconds or even minutes, and thus short-term changes can occur independent of changes in gene expression.

## PEPTIDE TRANSMITTERS

### Synthesis and Storage of Peptide Transmitters

Classical transmitters typically are synthesized in the axon from which they are released. In contrast, genes encoding peptide transmitters give rise to a prohormone, which is incorporated into secretory granules, after which the prohormone is acted on by peptidases to form the peptide transmitter (Fig. 7.4). This process typically occurs in the cell body, and the peptide-containing vesicles then are transported to the axon; a small number of peptide transmitters are synthesized enzymatically.

In neurons that use classical transmitters, demands for increased amounts of transmitter are met by increasing local transmitter synthesis. However, increasing the amount of a peptide transmitter requires an increase in gene expression to yield a prohormone, with a subsequent delay in delivery to the axon terminal of the peptide. Thus, classical transmitters respond to increased demand rapidly, but peptide transmitters cannot.

The storage of peptides and classical transmitters also differs. Classical neurotransmitters generally are stored in small (approximately 50 nm) synaptic vesicles. In contrast, neuropeptide transmitters are stored in large (approximately 100 nm) dense core vesicles. Because peptide transmitters typically are released at a high neuronal firing frequency or in a burst-firing pattern, it is reasonable to assume that there are different mechanisms for the exocytosis and subsequent release of peptide and classical transmitter vesicles. Although the release of peptide transmitters, like that of classical transmitters, is calcium-dependent, distinct but related molecular mechanisms subserve the release of small and large dense core vesicles (Sieburth *et al.*, 2007).

### Inactivation of Peptide Transmitters

There are also differences in the inactivation of peptide and classical transmitters. Classical transmitters have high-affinity reuptake processes to remove the transmitter from the extracellular space. Peptide transmitters are inactivated enzymatically or by diffusion, but lack a high-affinity active reuptake process. Enzymatic inactivation of peptide transmitters also differs from that of classical transmitters. Peptide transmitters are short chains of amino acids, but the inactivating enzymes are specific for certain dipeptide sequences and are not specific to any single peptide. For example, an enzyme that inactivates opioid-like peptide transmitters called enkephalins usually is

referred to as enkephalinase, but also cleaves other peptide transmitters.

A final difference between the inactivation of peptide and classical transmitters is in the final product. When classical transmitters are broken down enzymatically, the metabolites are inactive at the transmitter's receptor. However, certain peptide fragments derived from the enzymatic "inactivation" of peptide transmitters are biologically active. An example is angiotensin, in which the angiotensin I is metabolized to yield angiotensin II and III, each successively more active than the parent angiotensin I. It can therefore sometimes be difficult to distinguish between transmitter synthesis and transmitter inactivation. The peptide that is stored in vesicles and then released is therefore considered the transmitter, although the actions of certain peptidases may lead to other biologically active fragments.

### Neurotensin Synthesis

Neurotensin (NT) is widely expressed in the central nervous system and in certain peripheral tissues, such as the small intestine. A related peptide, neuromedin N (NMN), is also transcribed from the mammalian gene that encodes NT (Fig. 7.4). A 170 amino acid prohormone precursor of NT is the product of a single gene that is transcribed to yield two mRNAs. The smaller transcript is the major form in the intestine; the two mRNA species are equally abundant in most brain areas. The precursor contains one copy each of NT and NMN. The molar ratios of NT/NMN differ across different tissues, suggesting different enzymatic processing of the prohormone or, alternatively, the generation of different transcripts. Because NT and NMN are contained in the same exon of the NT-NMN gene, differences in relative abundance of the two are due to differential processing of the precursor.

NT and other peptide transmitters are stored in large dense core vesicles, but the general characteristics of NT release are similar to those of classical transmitters. Thus, depolarization evokes the  $\text{Ca}^{2+}$ -dependent release of both NT and NMN (Kitabgi *et al.*, 1992). The impulse-dependent release of NT varies as a function of frequency and pattern of impulses, with higher frequencies of firing or burst firing patterns eliciting greater peptide release (Bean and Roth, 1992).

### Inactivation of Neurotensin

Peptides are inactivated by enzymatic actions or diffusion. NT is degraded by three endopeptidases, known with great flair as 24.11, 24.15, and 24.16 (Kitabgi *et al.*, 1992). Endopeptidase 24.11 cleaves NT at two

specific sites to yield a decapeptide, and endopeptidase 24.16 acts at the same two sites (Fig. 7.4); the other endopeptidase acts at a different set of amino acid residues. Because these enzymes act at dipeptides that are found in many peptides and proteins, and two of the three act at the same site, it is obvious that enzymes that inactivate peptides are not very specific.

Although there are no known membrane transporters for peptide transmitters, peptides can be accumulated by neurons. This occurs by internalization of the peptide bound to its receptor. G protein-coupled receptors undergo internalization via an endocytotic mechanism, where they are either recycled to the membrane after various steps or shipped to lysosomes for degradation (Tsao *et al.*, 2001). Receptor-bound peptides can also be internalized through this process and once inside the cell dissociate from the receptor.

### Coexistence of Neurotensin and Classical Transmitters

Neurotensin is colocalized with dopamine in certain hypothalamic and midbrain neurons. The colocalization of NT and DA has provided a useful system in which to explore the interrelationships between two colocalized transmitters. In the prefrontal cortex of the rat, NT is found only in DA axons. Neurotensin release in the prefrontal cortex is increased when neuronal firing is increased or when DA neurons enter into a burst-like firing pattern (Bean and Roth, 1992). In addition, the release-modulating dopamine autoreceptor on DA axons regulates NT release, but in a very different manner than it regulates DA release. Dopamine agonists (which decrease DA release) enhance NT release from colocalized DA-NT axons; conversely, antagonists at the DA autoreceptor decrease NT release but enhance DA release. Thus, the release of NT and DA are regulated reciprocally by actions at a DA autoreceptor.

## UNCONVENTIONAL TRANSMITTERS

The differences between peptide and classical transmitters originally were viewed as inconsistent with a transmitter role of the peptides, and the common acceptance of peptides as transmitters met with considerable resistance. However, once this battle was won, the gate was opened for the consideration of radically different molecules as transmitters.

Remarkable technical advances have allowed us to measure substances in the brain that are present in minute quantities or are very unstable. This has forced

**FIGURE 7.4** Schematic illustration of the synthesis, release, and termination of action of the peptide transmitter neurotensin (NT). The illustrative panels of the bottom show processing of NT from the prohormone (left) and enzymatic inactivation of NT (right).

us to consider the possibility that substances that do not meet the established requirements for neurotransmitters may indeed be transmitters. What then should be the key attribute of a neurotransmitter? One simple approach would be to designate as a neurotransmitter any compound that permits information flow from one neuron to another. This definition circumvents the matter of glial contribution to the ionic milieu of the neuron, which certainly imparts information concerning the function of the glia. However, this definition is similar to that of a hormone and does not address the temporal characteristics of transmitter action and the distance of the target cell from the transmitter release

site. Finally, this definition does not accommodate unconventional roles for transmitters, such as the regulation of neuronal development or intracellular trafficking of proteins. We will now discuss what we call, for lack of a better term, “unconventional” transmitters.

### Gases as Unconventional Transmitters

Nitrates such as nitroglycerine have been long been used to treat angina pectoris, in which chest pain arises because of insufficient blood delivery to the heart muscle. Nitrates dilate cardiac blood vessels, thereby

increasing blood flow and relieving the pain. However, the mechanism by which nitrates dilate coronary arteries was not known until relatively recently. In 1980, an endothelial-derived relaxing factor contained in the cells lining blood vessels was found to potently and rapidly dilate blood vessels. This factor was soon shown to be the gas nitric oxide (NO). In addition, glutamate acting at one type of glutamate receptor was noted to release a factor that caused blood vessels in the brain to dilate. It became apparent that the endothelial-derived relaxing factor and the glutamate-induced factor that caused cerebrovascular vasodilation were the same compound, NO. Thus, NO was present in neurons as well as vasculature. These data

led to the proposal that NO may take part in intercellular communication (see Box 7.2).

Nitric oxide is a well-known air pollutant. The idea that an unstable toxic gas could serve as a transmitter led to several incredulous questions, including "how can a gas be stored for release in an impulse-dependent manner?" The answer is simple: it is not stored. If one accepts the argument that NO is a transmitter, the classical definition of a neurotransmitter becomes untenable. Many theories can accommodate one exception. However, NO is not the only gas neurotransmitter; carbon monoxide and hydrogen sulfide play similar transmitter-like roles (Baranano *et al.*, 2001).

### BOX 7.2

#### GOING FOR GASES AS NEUROTRANSMITTER

One of the most rewarding experiences for a scientist is to find that long-held prejudices are altogether wrong and that a new, correct insight reveals a novel scientific principle. In the late 1950s, only acetylcholine and the biogenic amines were known to be neurotransmitters. The next decade saw amino acids acknowledged as neurotransmitters. The discovery of enkephalins and endorphins in the mid-1970s reinforced gradually accumulating evidence that peptides are transmitters, and now we find that there are over 100 different bioactive brain peptides.

In the 1970s and early 1980s, nitric oxide (NO) was found to mediate the ability of macrophages to kill tumor cells and bacteria and to regulate blood vessel relaxation. A short report suggested that NO can be formed in brain tissue. Progress in the NO field at that time was slow because assaying NO synthase (NOS), the enzyme that oxidizes the amino acid arginine to NO, was quite tedious, based on the accumulation of nitrite formed from the NO. A much simpler approach was to monitor the conversion of [<sup>3</sup>H]arginine into [<sup>3</sup>H]citrulline, which is formed simultaneously with NO; this assay could process 100 or more samples in an hour. Research on blood vessels revealed that NO acts by stimulating cyclic GMP formation. In the brain, the excitatory neurotransmitter glutamate was known to augment cyclic GMP levels. Glutamate, acting through its NMDA receptor, triples NO synthase activity in a matter of seconds, and arginine derivatives that inhibit NOS activity block the elevation of cyclic GMP. This finding causally linked the actions of so prominent a neurotransmitter as glutamate to NO.

To determine if NO was a neurotransmitter, it was necessary to ascertain whether NOS was localized in neurons. The most straightforward approach would be to generate an antibody to use in anatomical studies. However, purifying NOS protein to generate an antibody proved very difficult because the enzyme lost its activity in attempts to purify it. The addition of calmodulin was found to stabilize the enzyme. Because calmodulin is a calcium-binding protein, this finding immediately explained how NO formation can be triggered rapidly by synaptic activation through glutamate. When glutamate activates its NMDA receptor, Ca<sup>2+</sup> rushes into the cell, binds to calmodulin, and activates NOS.

The ability of purified NOS led to antibodies being developed and NOS being localized by immunohistochemistry. The neuronal form of NOS (nNOS) is present in only about 1% of the neurons in the brain. However, these cells give rise to processes that ramify so extensively that probably every neuron in the brain is exposed to NO. The purified NOS protein also allowed an amino acid sequence to be obtained and the gene for the enzyme cloned. The structure of NOS revealed that it is regulated by many more factors than virtually any other enzyme in biology, including at least five oxidative-reductive cofactors, four phosphorylating enzymes, and three binding proteins. This makes sense because of the unique properties of NO as a gaseous neurotransmitter. Most neurotransmitters are stored in vesicles with large storage pools so that only a small amount of the transmitter is released with each nerve impulse. In contrast, every time a neuron wishes to release a molecule of NO, it must

(Continues)

**BOX 7.2** (*cont'd*)
 

---

activate NOS—hence, a requirement for exquisitely subtle regulation of the enzyme.

Neurotransmitters come in chemical classes such as biogenic amines, amino acids, and peptides. Might there be at least one other gaseous neurotransmitter? Carbon monoxide (CO) is normally formed in the body by the enzyme heme oxygenase, which is primarily responsible for degrading heme in aging red blood cells. It cleaves the heme ring to form biliverdin, which is reduced rapidly to bilirubin, the pigment that accounts for jaundice in patients with a degradation of red blood cells. When the enzyme cleaves the heme ring, CO is released as a single carbon fragment.

The biosynthetic enzyme for a transmitter should be localized to selected neuronal populations. Heme oxygenase-2, the neuronal form of the enzyme, was shown to be localized to discrete neuronal populations throughout the brain. To seek a neurotransmitter function, the peripheral nervous system (in which synaptic transmission is characterized more readily than in the brain) was used. The myenteric plexus of nerves regulates intestinal peristalsis. A previously unidentified neurotransmitter of myenteric

plexus neurons accounts for the relaxation phase of peristalsis. nNOS had already been localized to neurons of the myenteric plexus, and some functional evidence showed that NO might be a neurotransmitter of this pathway. Heme oxygenase-2 was found to be localized to the same myenteric plexus neurons as NOS. Mice with targeted deletions of the genes for nNOS or heme oxygenase-2 were used to elucidate function. In both types of gene knockout mice, intestinal relaxation evoked by neuronal depolarization was reduced about 50%, implying that NO and CO each contribute half of the relaxation. This finding, along with other evidence, established transmitter functions for both NO and CO and suggested that they are functioning as cotransmitters, although exactly how they interact remains a mystery. Such a cotransmitter role reminds us of the fact that most neurons in the brain contain at least two and sometimes more neurotransmitters. Thus, in addition to overturning a number of dogmas about neurotransmission, NO and CO may help resolve the riddle of cotransmission.

*Solomon H. Snyder*

The list of exceptions posed by NO to the dogma of traditional neurotransmitters is long. NO is not stored in cells, is not released in an exocytotic manner, lacks an active process that terminates its action, does not interact with specific membrane receptors on target cells, and often acts as a retrograde transmitter to regulate axon terminals presynaptic to the neuron in which NO is synthesized. It is therefore not difficult to understand the skepticism that first met the hypothesis that NO is a neurotransmitter, or to have some sympathy for those who expressed the view that NO is not a transmitter but an alien event, benign or otherwise, intent on making neuroscientists question their most cherished beliefs (Fig. 7.5).

### Endocannabinoids

The psychoactive properties of marijuana have been known for thousands of years. However, how marijuana exerts these actions was not uncovered until 1990, when the receptor at which  $\Delta$ -9-tetrahydrocannabinol, the major active component of marijuana, was cloned. Two years later an endogenous ligand that binds to the cannabinoid receptor was identified. Over

the past decade the identification of multiple endocannabinoids (ECs), the enzymes involved in synthesizing and degrading endocannabinoids, and the characterization of cannabinoid receptors have led to the realization that ECs serve as chemical messengers between neurons.

Endocannabinoids are highly hydrophobic, which allows them to pass easily through plasma membranes, but prevents them from being stored in vesicles. Instead, they are synthesized and released when needed from lipid precursors present in neuronal membranes. There are two major ECs in brain, anandamide and 2-arachidonoylglycerol (2-AG). Anandamide is a fatty acid amide and is the best characterized of the ECs. It is “stored” in the cell membrane in the form of a lipid precursor, from which it is cleaved by the enzyme phospholipase D. 2-AG is more abundant in brain than anandamide, and also is produced from membrane lipids, but via the action of two other enzymes.

Three proteins are involved in EC inactivation. Two are enzymes (fatty acid amide hydrolyase [FAAH] and monoacylglycerol lipase [MGL]), with the third protein an anandamide transporter. FAAH is found mainly in

**FIGURE 7.5** Schematic representation of a nitric oxide (NO)-containing neuron. NO is formed from arginine by the actions of different nitric oxide synthases (NOS). NO diffuses freely across cell membranes and can thereby influence both presynaptic neurons (such as the glutamatergic presynaptic neuron in the figure) or other cells that are not apposed directly to the NOS-containing neuron; these other cells can be neurons or glia.

the soma and dendrites of neurons, whereas MGL is more prominent in synaptic terminals. The anandamide transporter is a sodium- and energy-dependent carrier protein, acting by a process with the characteristics of facilitated diffusion.

Recent studies have demonstrated that ECs act as retrograde messengers at synapses. Thus, ECs are produced on demand in an activity-dependent manner by a neuron through the cleavage of membrane lipids. The resultant ECs travel backward (retrogradely) across the synapse to activate presynaptic cannabinoid receptors on axon terminals, resulting in a suppression of transmitter release. Because the presynaptic CB1 cannabinoid receptor is found on both GABAergic and glutamatergic nerve endings, EC signaling can modulate both excitatory and inhibitory transmission. EC-mediated retrograde signaling appears to be crucial for certain types of short- and long-term synaptic plasticity that underlie learning and memory.

Although still early, studies of ECs already have inspired the development of novel treatment strategies for neuropsychiatric disorders. Consistent with subjective reports that marijuana increases eating (the “munchies”), early clinical trials have reported some success of CB1 receptor antagonists in the treatment of obesity. Similarly, CB1 antagonists have been advanced as an aide to smoking cessation.

## Summary

We have discussed but two “unconventional” transmitters, one a gas, the other a lipid. This growing category of transmitters contains many other similarly unconventional molecules, including growth factors, neuroactive steroids, and others still to be uncovered. All offer a significant challenge to our definitions of what constitutes a neurotransmitter, but with the advantage of expanding our knowledge of how the nervous system works in health and disease.

## SYNAPTIC TRANSMISSION IN PERSPECTIVE

Several of the key proteins involved in regulating chemical neurotransmission in mammals have been identified on the basis of homologies to proteins found in invertebrates such as the worm *C. elegans* and the fly *Drosophila melanogaster*. It now appears that some of the molecules used as neurotransmitters even are found in plants, as are their receptors! As nervous systems have evolved, many transmitter-related proteins have maintained roles that are not directly related to transmitter function or, alternatively, are involved in less discrete and more spatially elaborate signaling.

An example is acetylcholine, the synthesis of which depends on the cytosolic enzyme choline acetyltransferase. ChAT mRNA is also found in the testes, leading to the appearance of ACh in spermatozoa. There is even one form of ChAT that is targeted to the nucleus of cells. ChAT mRNA has also been reported to be present in lymphocytes, as have certain muscarinic cholinergic receptors. Also found in these white blood cells are AChE mRNAs, and decreases in both acetylcholinesterase and butyrylcholinesterase enzyme activity have been reported in Alzheimer's disease. Still another example is the presence of AChE in bone marrow cells and peripheral blood cells in certain leukemias; recent data indicate that inhibition of AChE gene expression in bone marrow suppresses apoptosis, or programmed cell death (see Chapter 19). These examples clearly indicate that although a neurotransmitter may have one role in the brain, a totally different role may emerge in other tissues—thus encouraging us to attend to developments in diverse fields.

We have discussed chemically-coded synaptic transmission. However, one cannot discuss the biochemistry and pharmacology of synaptic transmission without referring to and appreciating critical information about the structure (anatomy) and function (physiology and behavior) of neurons. Neuroscience is multidisciplinary, requiring an understanding of different aspects of cellular function to come to grips with the basic principles of synaptic communication.

Our concepts of synaptic transmission are in flux, requiring frequent reevaluation and revision. This can be seen most clearly in the evolving definition of a neurotransmitter. Classical transmitters are but one part of the family of transmitters, with other relatives being peptides, gases, growth factors, and lipid-derived transmitters such as endocannabinoids. The use of the terms "conventional" and "unconventional" in discussing transmitters is indicative of our current

unease with the expanding definition of transmitters. This dynamic state of affairs is seen in all areas of neuroscience and helps make neuroscience such an exciting discipline.

## Release of Neurotransmitters

The synapse is the primary place at which information is transmitted from neuron to neuron or from neuron to peripheral target, be it a gland or a muscle. Most synapses rely on a chemical intermediary, or transmitter, secreted in response to an action potential in the presynaptic cell in order to influence the activity of the postsynaptic cell. In chemical transmission, a single action potential in a small presynaptic terminal can generate a large *postsynaptic potential* (PSP) (as large as tens of millivolts). This is accomplished by the release of thousands to hundreds of thousands of molecules of transmitter that can bind to postsynaptic receptor molecules and open (or close) thousands of ion channels in about 1 ms. The effect can be either excitatory or inhibitory, depending on the ions that permeate the channels operated by the receptor. The resulting responses are either *excitatory postsynaptic potentials* (EPSPs) or *inhibitory postsynaptic potentials* (IPSPs), depending on whether they drive the cell toward a point above or below its firing threshold, as discussed in Chapter 11.

Why are most synapses chemical? The simpler alternative might appear to be the electrical synapse (see Chapter 11) in which the electrical signal from one cell can cross directly into the next through the electrically conducting pathway of the gap junction. Even when pre- and postsynaptic elements are coupled in this manner, however, a presynaptic spike of 100 mV would likely cause only a 1-mV change in the postsynaptic cell because relatively little charge can flow through these junctions to charge the large membrane capacitance of the postsynaptic cell. More efficient electrical transfer requires that the presynaptic terminal be as large as or larger than the postsynaptic element and therefore only a few presynaptic cells could converge on a given postsynaptic cell. Such synapses would

further limit the computational capacity of the brain because they could only induce excitation, not inhibition, in response to a presynaptic action potential. Chemical synapses are characterized by great flexibility. Different afferents can have different effects, with different strengths and time courses, on each other as well as on postsynaptic cells. These differences depend on the identity of the transmitter(s) released and the receptors present (see Chapters 7 and 9). Chemical synapses often are modified by prior activity in the presynaptic neuron. Chemical synapses are also particularly subject to the modulation of presynaptic ion channels by substances released by the postsynaptic or neighboring neurons. This flexibility is essential for the complex processing of information that neural circuits must accomplish, and it provides an important locus for modifying neural circuits in adaptive processes such as learning (Chapters 49 and 50).

### TRANSMITTER RELEASE IS QUANTAL

In order to secrete thousands of transmitter molecules rapidly and simultaneously, nerve terminals, like other secretory cells, package the transmitter into membrane-enclosed organelles. When one of these *synaptic vesicles* fuses with the plasma membrane, the contents of the vesicle (approximately 5000 molecules) can diffuse into the extracellular space and encounter receptors on the postsynaptic cell within hundreds of microseconds. A consequence of releasing transmitter by the fusion of vesicles with the plasma membrane (called *exocytosis*) is that synaptic transmission is *quantal*—responses are built from signals with a discrete amplitude corresponding to a single vesicle. In

◀ **FIGURE 8.1** Ultrastructural images of exocytosis and active zones. (A–C) Synapses from frog sartorius neuromuscular junctions were quick-frozen milliseconds after stimulation in conditions that enhance transmission. (A) A thin section showing vesicles clustered in the active zone (arrows) some docked at the membrane. (B) Shortly (5 ms) after stimulation, vesicles were seen to fuse with the plasma membrane. (C) After freezing, presynaptic membranes were freeze-fractured and a platinum replica was made of the external face of the cytoplasmic membrane leaflet. Vesicles fuse about 50 nm from rows of intramembranous particles thought to include  $\text{Ca}^{2+}$  channels. (D–F) The fine structure of the active zone at a frog neuromuscular junction as seen with electron tomography. (D) In a cross-sectional image from tomographic data, two vesicles are docked at the plasma membrane and additional electron-dense elements are seen. When these structures are traced and reconstructed through the volume of the EM section (E), proteins of the active zone (gold) appear to form a regular structure adjacent to the membrane that connects the synaptic vesicles (silver) and plasma membrane (white). Viewed from the cytoplasmic side (E, lower image), proteins are seen to extend from the vesicles and connect in the center. (F) Schematic rendering of an active zone based on tomographic analysis. An ordered structure aligns the vesicles and connects them to the plasma membrane and to one another. Parts A and B from Heuser (1977); part C from Heuser *et al.* (1979). Part B reproduced from the *Journal of Cell Biology* 88, 564–580 (1981). (D–F) After Harlow *et al.* (2001).

the absence of presynaptic electrical activity, transmitter is released spontaneously as individual quanta. Each packet generates a small postsynaptic signal—either a *miniature excitatory* or a *miniature inhibitory postsynaptic potential* (MEPSP or MIPSP, respectively, or just “mini”)—that can be detected by microelectrode recording (Katz, 1969). An action potential accelerates tremendously, but very briefly, the rate of secretion of quanta and synchronizes them to evoke a PSP. At a synapse between two neurons, this might represent the release of 1 to 10 vesicles. At the vertebrate neuromuscular junction, a remarkably large and specialized synapse, hundreds of vesicles can be released, and the response is, to a first approximation, the sum of the individual quanta.

The anatomical specializations of the synapse and the properties of the presynaptic ion channels and postsynaptic receptors unite to achieve fast, quantal transmission (Figs. 8.1 and 8.2). The chief anatomical feature of the terminal is the profusion of synaptic

**FIGURE 8.2** The life cycle of synaptic vesicles. Transmitter-filled vesicles can be observed in clusters in the vicinity of the active zone. Some vesicles are recruited to sites within the active zone in a process called docking. These vesicles subsequently are primed for release. The rise in cytosolic  $\text{Ca}^{2+}$  that occurs during an action potential triggers the opening of a fusion pore between some of the primed, docked vesicles and the plasma membrane. Transmitter exits through this fusion pore. Three pathways are proposed by which the now empty vesicle can be recovered and returned to the releasable pool: (1) by a direct reclosing of the fusion pore and reformation of the vesicle, often called “kiss and run”; (2) by complete fusion (i.e., the flattening of the vesicle onto the membrane surface) followed by clathrin-mediated endocytosis, removal of the clathrin coat, and return of the vesicle to the releasable pool; and (3) by complete fusion and recycling as in the second pathway, but the endocytosed vesicle fuses first with an endosome and mature vesicles are subsequently formed by budding from the endosome. After or during this recycling process, the vesicle must be refilled with transmitter.

vesicles, typically 50 nm in diameter, that cluster near the synapse and dock at specialized sites called *active zones* along the presynaptic membrane (Fig. 8.1). The vesicles may differ in their appearance depending on the transmitter they enclose: thus glutamate and acetylcholine are stored in small clear vesicles, whereas peptide neurotransmitters occupy large dense-cored vesicles. Although it may appear as indistinct fuzz on electron micrographs, the active zone is likely to be a highly structured specialization of the membrane and cytoskeleton (Fig. 8.1; also, see discussion later). Action potentials release transmitter by triggering the exocytosis of vesicles with the plasma membrane (Figs. 8.1B and 8.1C) and the release of their contents into the narrow *synaptic cleft* (about 100 nm wide) separating the presynaptic terminal from high concentrations of postsynaptic receptors. At neuromuscular junctions, one of the best studied synapses, transmitter from one vesicle diffuses across the synaptic cleft in 2 ms and reaches a concentration of about 1 mM at the postsynaptic receptors. A large number of these receptors (up to 2000) will bind transmitter rapidly and thereby open an ion channel (see Chapter 9). Each channel has a 25 pS conductance and remains open for about 1.5 ms, admitting a net inflow of 35,000 positive ions. Thus, a single vesicle can cause 70 million ions to cross the membrane and give rise to a mini of a few millivolts. The neuromuscular junction also is specialized for efficiency; a single nerve ending will have about 1000 active zones and a single action potential will cause a vesicle to fuse at about a third of those. The consequence is the release of about 300 quanta within 1.5 ms. The resulting postsynaptic depolarization begins after a synaptic delay of about 0.5 ms, reaches a peak of tens of millivolts, and is typically sufficient to generate an action potential in the muscle fiber.

The anatomy and physiology are somewhat different at fast central synapses. Postsynaptic cells make contact with presynaptic axon swellings that are called *varicosities* when they occur along fine axons and are called *boutons* when they are located at the tips of axons. The postsynaptic cell can be contacted on the cell body, but often the synapse is made onto a fine dendritic branch or tiny spine with a length of a few micrometers. A typical varicosity or bouton contains one to four active zones. At any single active zone, an action potential may release zero, one, or perhaps two vesicles. However, with multiple active zones between two cells, the action of each zone will be additive in determining the response of the postsynaptic cell. At a representative excitatory glutamatergic synapse, each action potential releases from 5 to 10 quanta. Each quantum that is released elevates transmitter concentration in the cleft to about 1 mM, as at the neuromus-

cular junction, but because there are fewer receptors clustered beneath these synapses, each quantum activates only 30 or so ion channels as compared with the 1000–2000 channels activated at the neuromuscular junction. At excitatory synapses, the release of a quantum may be sufficient to generate EPSPs of 1 mV or less in amplitude, clearly subthreshold for generating action potentials. However, central neurons often receive thousands of inputs, each of which has a “vote” on how the cell should respond.

A comparison of these excitatory synapses at small neurons and the vertebrate neuromuscular junction at the much larger skeletal muscle fiber illustrates two important points: (1) the fundamental quantal nature of the chemical synapse is universal and (2) the different physiological requirements of particular synapses, such as synapses onto small or large cells, can be met by differences in any of several parameters, including the number of receptors activated per quantum, the number of active zones connecting two cells, the probability of a given active zone releasing a vesicle, and the conductance of the postsynaptic receptor channel. In describing synaptic transmission, two parameters are particularly important. *Quantal size* or quantal amplitude describes the unitary response to release of a single quantum (vesicle), whereas *quantal content* refers to the average number of quanta released by a single impulse. These parameters are discussed further later.

## EXCITATION–SECRETION COUPLING

The action potential is an electrical event—a change in the voltage gradient across the plasma membrane. How is this electrical change converted to the fusion of synaptic vesicles and the release of neurotransmitter? The classic studies of Bernard Katz and colleagues (Katz, 1969) established that this coupling is achieved by the use of  $\text{Ca}^{2+}$  as an intracellular messenger.  $\text{Ca}^{2+}$  inside the cell normally is buffered to very low levels (~100 nM), and both concentration and electrical gradients provide a strong driving force for  $\text{Ca}^{2+}$  entry. Thus, when a voltage-dependent  $\text{Ca}^{2+}$  channel opens in response to the depolarization of the membrane during an action potential, there is the potential for the intracellular  $\text{Ca}^{2+}$  concentration to increase 1000-fold. In this manner, the electrical signal is converted to a large chemical signal, and  $\text{Ca}^{2+}$  sensors in the fusion machinery can trigger vesicle fusion. The mechanism of fusion itself is discussed later, but the nature of the  $\text{Ca}^{2+}$  signal and the evidence for its centrality must be understood first.

It has been known for over 100 years that  $\text{Ca}^{2+}$  must be present in the extracellular saline for transmission to occur. Subsequently (Katz, 1969), it was shown that  $\text{Ca}^{2+}$  need be present only at the moment of invasion of the nerve terminal by the action potential. Changing the timing of the influx of  $\text{Ca}^{2+}$  or the amount of influx (by changing the extracellular  $\text{Ca}^{2+}$  concentration or blocking  $\text{Ca}^{2+}$  channels with divalent cations such as  $\text{Co}^{2+}$  and  $\text{Mn}^{2+}$ ) will change the timing and amplitude of the synaptic response. Similarly, an ionophore that lets  $\text{Ca}^{2+}$  ions flow across the membrane will cause a sustained increase in intracellular  $\text{Ca}^{2+}$  and the sustained outpouring of quanta of transmitter. It has also become possible to fill a terminal with a caged form of the  $\text{Ca}^{2+}$  ion; that is, with  $\text{Ca}^{2+}$  ions bound up within a chemical carrier. A flash of light can rearrange this carrier, uncaging the  $\text{Ca}^{2+}$ , and thereby cause an abrupt increase in cytosolic  $\text{Ca}^{2+}$  and a sudden increase in secretion as well. Finally, loading the terminal with  $\text{Ca}^{2+}$  chelators to prevent increases in cytosolic  $\text{Ca}^{2+}$  can prevent release. Thus a rise in intracellular  $\text{Ca}^{2+}$  is the essential trigger for vesicle fusion.

### Vesicles Are Released by Calcium Microdomains

The opening of  $\text{Ca}^{2+}$  channels during a single action potential allows in enough  $\text{Ca}^{2+}$  to raise the concentration in the bouton from approximately 100 to 110 nM. How can a mere 10% change in the concentration cause a 1000-fold shift in the activity of the fusion machinery? Furthermore, because  $\text{Ca}^{2+}$  pumps and exchangers on the plasma membrane work relatively slowly, this small rise in  $\text{Ca}^{2+}$ , which can be detected with fluorescent  $\text{Ca}^{2+}$  indicator dyes, persists for hundreds of milliseconds after the action potential. Why then does transmitter secretion occur only for a millisecond or so? The answer to both of these questions lies in the fact that the release mechanism is *not* responding to the general concentration of  $\text{Ca}^{2+}$  in the bouton, but rather to the concentration in a *microdomain* in the immediate vicinity of the  $\text{Ca}^{2+}$  channels (Fig. 8.3). In these microdomains, very high concentrations of  $\text{Ca}^{2+}$  are reached very quickly and drop rapidly to near resting levels within microseconds of the closing of the channels. Presently, there are no  $\text{Ca}^{2+}$  dyes that are sufficiently local, sensitive, and fast that one can measure the concentration changes in these microdomains directly. Instead, our understanding of these signals comes from diffusion modeling, from modifying the buffering capacity of the cytosol, and from using indirect indicators of the local  $\text{Ca}^{2+}$  concentration, such as the gating of  $\text{Ca}^{2+}$ -activated  $\text{K}^+$

channels or transmitter release itself (Roberts, 1994; Schneggenburger and Neher, 2000).

In the brief period for which the  $\text{Ca}^{2+}$  channels are open, the cytosol that lies within 100 nm of the mouth of each channel is flooded with  $\text{Ca}^{2+}$ , and the local  $\text{Ca}^{2+}$  concentration is likely to reach 100  $\mu\text{M}$  or higher; the closer to the channel, the higher the concentration (Figs. 8.3A and 8.3B). The further from the channel, the more dilute the  $\text{Ca}^{2+}$  becomes and the greater the chance that it has been bound up by the high  $\text{Ca}^{2+}$ -buffering capacity of the cytosol. After the channels close, diffusion and buffering bring the  $\text{Ca}^{2+}$  concentration of the microdomains to near resting levels within a few milliseconds: the concentration gradient that existed around the mouth of the channel completely dissipates, and only the small net rise of total  $\text{Ca}^{2+}$  in the terminal remains (Fig. 8.3C). This signal, sometimes called residual  $\text{Ca}^{2+}$ , is what is detected by fluorescent indicator dyes. The effect may be compared to dumping a bucket of water into a swimming pool—a dramatic rise in water level occurs at one spot but it is very transient and gives rise to just a small net rise in the level of the entire pool.

A single active zone may have more than 100 channels in its membrane and a single vesicle may therefore be within 50-nm of as many as 10  $\text{Ca}^{2+}$  channels. Though not all these channels will open during each action potential, more than one channel is likely to open, and therefore  $\text{Ca}^{2+}$  entering through several nearby channels can sum in overlapping microdomains to influence a vesicle (Fig. 8.3). Of the subtypes of  $\text{Ca}^{2+}$  channels that have been described, N and P/Q types of  $\text{Ca}^{2+}$  channels appear to be the most prevalent at CNS synapses, although R and L types are also reported at certain synapses.

### The Exocytosis Trigger Must Have Fast, Low-Affinity, Cooperative $\text{Ca}^{2+}$ Binding

The sensor that detects the  $\text{Ca}^{2+}$  so as to trigger release must also have special properties to achieve fast and transient exocytosis. Estimates at several synapses suggest that the  $\text{Ca}^{2+}$ -sensor has an affinity in the range of 10–100  $\mu\text{M}$ , as appropriate for the relatively high concentrations of  $\text{Ca}^{2+}$  in the microdomains near channels. The on rate must be particularly fast. This is confirmed by the finding that presynaptic injection of relatively slow  $\text{Ca}^{2+}$  chelators such as ethylene glycol bis( $\beta$ -aminoethyl ether)- $N,N'$ -tetraacetic acid (EGTA) have almost no effect on transmitter release to single action potentials. Only fast  $\text{Ca}^{2+}$  chelators, such as 1,2-bis(2-aminophenoxy)ethane- $N,N,N',N'$ -tetraacetic acid (BAPTA), with on rates of about  $5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ , can capture  $\text{Ca}^{2+}$  ions before they bind to the secretory

◀ **FIGURE 8.3** Microdomains with high  $\text{Ca}^{2+}$  concentrations form in the cytosol near open  $\text{Ca}^{2+}$  channels and trigger the exocytosis of synaptic vesicles. (A) In this adaptation of a model of  $\text{Ca}^{2+}$  dynamics in the terminal, a set of  $\text{Ca}^{2+}$  channels is spaced along the x axis, as if in a cross-section of a terminal. The channels have opened and, while they are open, the cytosolic  $\text{Ca}^{2+}$  concentration (y axis) is spatially inhomogeneous. Near the mouth of the channel, the influx of  $\text{Ca}^{2+}$  drives the local concentration to as high as  $800\ \mu\text{M}$ , but within just  $50\ \text{nm}$  of the channel, the concentration drops off to  $100\ \mu\text{M}$ . Channels are spaced irregularly but are often sufficiently close to one another that their clouds of  $\text{Ca}^{2+}$  can overlap and sum. (B) In the active zone (gray), an action potential has opened a fraction of the  $\text{Ca}^{2+}$  channels, and microdomains of high cytosolic  $\text{Ca}^{2+}$  (pink) arise around these open channels as  $\text{Ca}^{2+}$  flows into the cell. In the rest of the cytoplasm, the  $\text{Ca}^{2+}$  concentration is at resting levels ( $0.10\ \mu\text{M}$ ), but within these microdomains, particularly near the channel mouth,  $\text{Ca}^{2+}$  concentrations are much higher, as in (A). Synaptic vesicles docked and primed at the active zone may come under the influence of one or more of these microdomains and thereby be triggered to fuse with the membrane. (C) A few milliseconds after the action potential, the channels have closed and the microdomains have dispersed. The overall  $\text{Ca}^{2+}$  concentration in the terminal is now slightly higher ( $0.11\ \mu\text{M}$ ) than before the action potential. If no other action potentials occur, the cell will pump the extra  $\text{Ca}^{2+}$  out across the plasma membrane and restore the initial condition after several  $100\ \text{ms}$ .

trigger, indicating that the on-rate of  $\text{Ca}^{2+}$  binding to this trigger is similarly fast. At a rate of  $5 \times 10^8\ \text{M}^{-1}\ \text{s}^{-1}$ ,  $100\ \mu\text{M}$   $\text{Ca}^{2+}$  reaches equilibrium with its target in about  $50\ \mu\text{s}$ . The off rate of  $\text{Ca}^{2+}$  dissociation from these sites must also be fast, at least  $10^3\ \text{s}^{-1}$ , to account for the rapid termination of transmitter release ( $0.25\ \text{ms}$  time constant) after  $\text{Ca}^{2+}$  channels close and  $\text{Ca}^{2+}$  microdomains collapse.

Importantly, the relationship of  $\text{Ca}^{2+}$  influx or cytosolic  $\text{Ca}^{2+}$  in microdomains to the amount of release is not linear at most synapses. By plotting this relationship on a log-log plot, a Hill coefficient can be determined, and values as high as 3 or 4 commonly are obtained. This value implies a high cooperativity in the action of  $\text{Ca}^{2+}$  inside the terminal, perhaps because multiple  $\text{Ca}^{2+}$ -binding sites must be occupied in order to trigger release efficiently (Schneggenburger and Neher, 2000). The interesting physiological consequence of this steep relationship is that small modulations of  $\text{Ca}^{2+}$  channels that increase or decrease  $\text{Ca}^{2+}$  influx can have a large effect on the strength of a synapse. For example, at a synapse from a parallel fiber onto a Purkinje cell in the cerebellum, when the activation of modulatory presynaptic GABA receptors inhibits  $\text{Ca}^{2+}$  channels sufficiently to reduce  $\text{Ca}^{2+}$  influx by 25%, the amplitude of transmission decreases by 70%.

## Summary

Chemical synapses permit one neuron to rapidly and effectively excite or inhibit the activity of another cell. A diversity of transmitters and receptors allows varied postsynaptic responses. The packaging of transmitter into vesicles and its release in quanta enable a single action potential to secrete hundreds of thousands of molecules of transmitter almost instantaneously onto another cell.  $\text{Ca}^{2+}$  acts as an intracellular messenger tying the electrical signal of presynaptic depolarization to neurosecretion. At fast synapses,  $\text{Ca}^{2+}$  enters through clusters of channels near docked synaptic vesicles in active zones. This  $\text{Ca}^{2+}$  acts at extremely short distances (tens of nanometers) in remarkably little time ( $200\ \mu\text{s}$ ) and at very high local concentrations ( $\sim 100\ \mu\text{M}$ ), in calcium microdomains, by binding cooperatively to a low-affinity receptor with fast kinetics to trigger exocytosis. When  $\text{Ca}^{2+}$  channels close, these microdomains of high  $\text{Ca}^{2+}$  return to near resting concentrations quickly and the evoked response is terminated. Speed, efficiency, and flexibility are the hallmarks of this process.

## MOLECULAR MECHANISMS OF THE NERVE TERMINAL

To release neurotransmitter in response to an action potential, a synaptic vesicle must fuse with the plasma membrane with great rapidity and fidelity, and thus the synapse requires an effective and well-regulated molecular machine. This machine must include the means to load the vesicle with transmitter, to dock the vesicle near the membrane so that it can fuse with a short latency, to define a release site on the plasma membrane, and to cause the release itself. Additionally, a reserve of synaptic vesicles must be held near the active zone (e.g., Fig. 8.1A) and those vesicles must be recruited to the plasma membrane as needed. The number of vesicles that are ready to fuse must be strictly determined, and the protein and lipid components of the vesicle must be recycled to form a new vesicle after fusion has occurred. For each of these processes, a molecular understanding remains incomplete, but rapid progress in this field has resulted in considerable headway.

### Most Neurons Require a Cycle of Membrane Trafficking

Active neurons are in constant need of transmitter-filled vesicles ready to release their contents. A bouton

in the CNS, for example, may contain a store of 200 vesicles, but if it releases even one of these with each action potential and if the cell is firing at an unexceptional rate such as 5 Hz, the store of vesicles would be consumed within less than a minute. Transport of newly synthesized vesicles from the cell body would be far too slow to support such a demand and the axonal traffic needed to supply an entire arbor of nerve terminals would be staggering.

In short, active neurons need an efficient mechanism to recycle and reload vesicles within the terminal. The exception is peptidergic neurons because peptides must be synthesized in the endoplasmic reticulum (ER), chiefly in the cell body. Not surprisingly, therefore, peptide vesicles are released at very low rates. For most neurotransmitters, however, the exocytosis of a synaptic vesicle is followed rapidly by endocytosis and within approximately 30 s the vesicle is again available for release. This pathway is sometimes referred to as the exo-endocytic cycle (Fig. 8.2). If we start with a transmitter-filled vesicle in the cytosol, we can outline its progression through this cycle. The vesicle will be mobilized from the reserve pool in the cytosol to the readily releasable pool by translocating to the active zone and becoming “docked” at the plasma membrane. Biochemical priming steps may occur at this point that will enable the vesicle to fuse within microseconds once the  $\text{Ca}^{2+}$  signal is given. Exocytosis often involves a complete merging of the vesicle membrane with the plasma membrane, though some research supports the coexistence of a second pathway involving only a transient connection of the two. In the latter case (see later), the vesicle, having emptied its contents, may return directly to the vesicle pool and be refilled with transmitter. If fusion is complete, however, the vesicle needs to be reformed with a clathrin cage and pinched off the plasma membrane. In some cases, these endocytosed vesicles seem to fuse with endosomes or large membranous sacs called cisternae, and mature synaptic vesicles then bud from this compartment. In other cases, the mature vesicle may be formed directly from the plasma membrane. In either case, the vesicle must be reloaded with transmitter prior to its reuse. The pathways for neurotransmitters are discussed in Chapter 7.

Histological tracers have provided a means to follow the vesicle cycle. One such tracer is the enzyme horseradish peroxidase (HRP), which could be placed in the extracellular solution and which would be internalized into intracellular compartments, including synaptic vesicles, when the synapse was stimulated. Another set of useful tracers are lipophilic dyes, including FM1-43, which partition into the surface membrane of the cell and are similarly internalized as membrane vesicles

endocytosis. When the dye is washed from the extracellular space, the surface destains, but dye remains trapped in internal compartments. Loading of this dye upon stimulation and subsequent release of the dye with further stimulation has been an important method for examining the kinetics of the cycle.

A defect in any single step in the exo-endocytic cycle will halt transmitter release. Moreover, each step in this cycle represents a potential control point for modulating the efficacy of the synapse. For example, regulation by  $\text{Ca}^{2+}$  and other second messenger systems is known to affect the docking, fusing, and recycling of vesicles at some synapses and is also likely to regulate the balance between reserve stores and those vesicles actively engaged in the exo-endocytic cycle. Understanding the mechanisms of this modulation is an important goal and will certainly require the detailed understanding of the fundamental machinery itself.

### The Fusion Mechanism Is Rapid

As discussed earlier in this chapter, the delay between the arrival of an action potential at a terminal and the secretion of the transmitter can be less than  $200\ \mu\text{s}$ . This places severe constraints on the fusion mechanism. Vesicles must already be present at the release sites, as there is no time to mobilize them from a distance. A catalytic cascade during fusion, such as that involved in phototransduction or in excitation-contraction coupling in smooth muscle, would also be far too slow for excitation-secretion coupling at the nerve terminal. Models therefore favor the idea that a fusion-ready complex of the vesicle and plasma membrane is preassembled at release sites and that  $\text{Ca}^{2+}$  binding need only trigger a simple conformation change in this complex to open a pathway for the transmitter to exit the vesicle.

Because the volume of the synaptic vesicle is small, the diffusion of transmitter from the vesicle proceeds almost instantaneously as soon as a pore has opened up between the vesicle lumen and the extracellular space. This structure is referred to as the fusion pore, but its biochemical nature is unknown. Thus, the time-critical steps come between the influx of  $\text{Ca}^{2+}$  and the formation of the fusion pore, and these steps establish the latency between arrival of the action potential and transmitter diffusion into the cleft. Any further step, such as the complete merging of the vesicle and plasma membrane, can occur on a slower time course, after the transmitter has left the vesicle. The tethering of the vesicle at the release site (often called docking) and any biochemical events that need to occur in order for the vesicle to reach the fusion-ready state (often called

priming) can also be slower. Docking and priming a vesicle cannot be *too* slow, however; a central nervous system (CNS) synapse is estimated to have 2 to 20 vesicles in this fusion-ready state; therefore, if a synapse is to respond faithfully to a sustained train of action potentials, it must be able to replace the fusion-ready vesicles with a time course of seconds. The rate at which this occurs may determine some of the dynamic properties of the synapse.

The short latency of transmission would seem to preclude the involvement of ATP hydrolysis at the fusion step because such a reaction would be too slow. Indeed, fusion can proceed without ATP present and thus, if energy is needed to fuse the membranes, it must be stored in the fusion-ready state of the vesicle-membrane complex and released upon addition of  $\text{Ca}^{2+}$ .

### Transmitter Release Is a General Cell Biological Question

Exocytosis and endocytosis are not unique to neurons; these processes go on in every eukaryotic cell. Moreover, exocytosis itself is only one representative of a general class of membrane-trafficking steps in which one membrane-bound compartment fuses with another. Other examples would include transport from the ER to the Golgi, or transport from endosomal compartments to lysosomes. In each case, the same biophysical problem must be overcome to bring the membranes close together and drive fusion.

At present, it appears that all the membrane-trafficking steps within the cell use a similar set of proteins to accomplish this task (Fig. 8.6). Indeed, it appears that representatives of this core set of proteins are present on every trafficking vesicle or target membrane and are required for every fusion step, whether it be in yeast, an epithelial cell, or a neuron. This discovery, which grew from the conjunction of independent studies of different model systems (Bennett and Scheller, 1993), has led to the exciting hypothesis that all intracellular membrane fusions will be united by a single and universal mechanism. To the extent that this proves true, it will be a great boon to cell biology: experiments in one model system, for example, the highly developed genetic analysis of membrane fusion in yeast, can be absorbed into neuroscience. Similarly, the abundance of synaptic vesicles for biochemical analysis and the unparalleled precision of electrophysiological assays of single vesicle fusions can deepen the understanding of other cellular events. Are these disparate membrane fusion events truly identical in their mechanisms? Most likely, different membrane fusions will present variations on a common theme;

the fundamental processes will be adapted to the specific requirements of each physiological step. The need for extremely tight control of fusion in the nerve terminal—for rapid rates of fusion with very short latencies to occur in brief bursts at precise points on the plasma membrane—may require some important differences in how the synaptic isoforms of these proteins function compared to the isoforms involved in general cellular traffic.

### Synaptic Proteins Have Been Identified from Purified Vesicles

Synaptic vesicles are abundant in nervous tissue and, due to their unique physical properties (uniform small diameter and low buoyant density), they can be purified to homogeneity by subcellular fractionation techniques. As a result, at a biochemical level, synaptic vesicles are among the most thoroughly characterized organelles. The protein compositions of synaptic vesicles from different sources are remarkably similar, demonstrating that many of the proteins present on the synaptic vesicle membrane perform general functions that are not restricted to a single class of transmitter.

Our knowledge of many of the important proteins in vesicle fusion commenced with the characterization of purified synaptic vesicles from which individual proteins could be isolated and subsequently cloned. The major constituents of the synaptic vesicle are shown in Figure 8.4. For some of these proteins there are well-established functions, but for others, the functions remain uncertain (Table 8.1). The proton transporter, for example, is an ATPase that acidifies the lumen of the vesicle. The resulting proton gradient provides the energy by which transmitter is moved into the vesicle. This task is carried out by another vesicular protein, a vesicular transporter that allows protons to move down their electrochemical gradient and out of the vesicle in exchange for transmitter that moves into the lumen. Several vesicular transporters are known, all structurally related, and by their substrate selectivity they help specialize a terminal for release of the appropriate transmitter (see later). Two other large proteins with multiple transmembrane domains are abundant in vesicles: synaptic vesicle protein 2 (SV2) and synaptophysin. The mechanism of action of these proteins remains elusive despite extensive biochemical and genetic characterization. Other vesicular proteins are discussed later in this chapter.

Transmitter release depends on more than just vesicular proteins, however; proteins of the plasma membrane and cytoplasm are also important. In many cases, the identification of these additional

FIGURE 8.4 Schematic representation of the structure and topology of major synaptic vesicle membrane proteins (see also Table 8.1).

components or an appreciation of their importance to the synapse derived from investigations of vesicular proteins. Two examples will serve to illustrate this point. The first example begins with synaptotagmin, an integral membrane protein of the synaptic vesicle that was purified from synaptic vesicles and cloned. The portion of synaptotagmin that extends into the cytoplasm (the majority of the protein, see Fig. 8.4) was subsequently used for affinity column chromatography. In this manner, a protein called syntaxin was identified as a synaptotagmin-binding protein. This protein resides in the plasma membrane and is now appreciated as one of the critical players in vesicle fusion (see later). More recently, yeast two-hybrid

screens have been conducted and used to identify proteins that bind to syntaxin. One such protein, synaptaphilin, may serve as a regulator or modulator of syntaxin function. Thus, subsequent to the isolation of an abundant vesicular protein, biochemical assays have led to a fuller picture.

A second and similar example (Gonzalez and Scheller, 1999) began with the realization that an abundant small GTP-binding protein, rab3, was present on the vesicle surface. This protein, discussed further later, may regulate vesicle availability or docking to release sites. Subsequently, rabphilin was identified on the basis of its affinity for the GTP-bound form of rab3. Rabphilin lacks a transmembrane domain but is

TABLE 8.1 Function of Synaptic Vesicle Proteins

Protein	Function
Proton pump	Generation of electrochemical gradient of protons
Vesicular transmitter transporter	Transmitter uptake into vesicle
VAMP/synaptobrevin	Component of SNARE complex; acts in a late, essential step in vesicle fusion
Synaptotagmin	Ca <sup>2+</sup> binding; possible trigger for fusion and component of vesicle docking at release sites via interactions with SNARE complex and lipid; promotes clathrin-mediated endocytosis by binding AP-2 complex
Rab3	Possible role in regulating vesicle targeting and availability
Synapsin	Likely to tether vesicle to actin cytoskeleton
Cysteine string protein	Promotes reliable coupling of action potential to exocytosis
SV2	Unknown
Synaptophysin	Unknown

recruited to the surface of the synaptic vesicle by binding to rab3. Rabphilin may have a role in modulating transmission, particularly in mossy fiber terminals of the hippocampus. Still later, many additional rab3-binding proteins were identified, including RIM, a component of the active zone. Rab3 can exist in either GTP- or GDP-bound states, and additional factors that regulate these states were also identified: a GDP dissociation inhibitor (GDI), a GDP/GTP exchange protein (GEP), and a GTPase activating protein (GAP). Thus, from the identification of a synaptic vesicle protein, an array of additional factors has come to light, all of which are likely to figure in the exo-endocytic cycle.

### Genetic Screens Have Led to the Identification of Synaptic Proteins

Genetic screens have provided an independent method for identifying the machinery of transmitter release. One of the most fertile screens was carried out not in the nervous system, but in yeast. Because membrane trafficking in yeast is closely parallel to vesicle fusion at the terminal, mutations that alter the secretion of enzymes from yeast can be a springboard for the identification of synaptic proteins. In the early 1980s, a series of such screens was carried out, and a collection of over 50 mutants was obtained. Many of these were shown to accumulate in post-Golgi vesicles

in the cytoplasm and thus appeared to block a late stage of transport, such as the targeting or fusion of these vesicles at the plasma membrane. Screens for suppressors and enhancers of these secretion mutations uncovered further components. Subsequently, excellent *in vitro* assays have been established in which to study the fusion of vesicles derived from yeast with their target organelles. Among the secretion mutants and their interacting genes were homologues of some of the proteins discussed earlier: *sec4* encodes a small GTP-binding protein like rab3, and *Sso1* and *Sso2* encode plasma membrane proteins that are homologues of syntaxin. The *sec1* gene encodes a soluble protein with a very high affinity for *Sso1*, and the mammalian homologue of this protein, *n-sec1*, is bound tightly to syntaxin in nerve terminals and has an essential function in transmission. The convergence of neuronal biochemistry with yeast genetics has built a strong case for a common mechanism of vesicle fusion.

Yeast is not the only organism in which a genetic screen uncovered an important protein for the synapse: the *unc-13* mutation of *Caenorhabditis elegans*, e.g., identified a component of the active zone membrane that is important in priming vesicles for fusion and in modulation of the synapse.

Genetics has further contributed to our understanding of synaptic proteins by allowing tests of the significance of an identified protein for synaptic transmission. Such studies have been carried out in *C. elegans*, *Drosophila*, and mice, and can reveal either an absolute requirement for the protein (as in the case of syntaxin mutants in *Drosophila*) or relatively subtle effects (as in the case of rab3 mutations in mice).

From biochemical purifications, *in vitro* assays, genetic screens, and fortuitous discoveries, a list of nerve terminal proteins has been assembled (Tables 8.1 and 8.2). The manner in which these proteins coordinate the release of transmitter, as well as all the other cell biological functions of the exo-endocytic cycle, remains uncertain, but a consensus has emerged in recent years that puts one set of proteins at the core of the vesicle fusion.

### SNAREs and the Core Complex Are Key to Membrane Fusions

Three synaptic proteins, vesicle-associated membrane protein (VAMP)/synaptobrevin, syntaxin, and the synaptosomal associated protein of 25 kDa (SNAP-25), are capable of forming an exceptionally tight complex with one another that generally is referred to as either the *core complex* or the *SNAP receptor (SNARE) complex* (Sollner *et al.*, 1993; Sutton *et al.*, 1998). The

**TABLE 8.2** Additional Proteins Implicated in Transmitter Release

Protein	Function
Syntaxin	SNARE protein present on plasma membrane (and on synaptic vesicles to a lesser extent); forms core complex with SNAP-25 and VAMP/synaptobrevin; essential for late step in fusion
SNAP-25	SNARE protein present on plasma membrane (and on synaptic vesicles to a lesser extent); forms core complex with syntaxin and VAMP/synaptobrevin; essential for late step in fusion
Nsec-1/munc-18	Syntaxin-binding protein required for all membrane traffic to the cell surface; likely bound to syntaxin when syntaxin is not in a SNARE complex
Synaphin/complexin	Syntaxin-binding protein; may oligomerize core complexes
Syntaphilin	Binds syntaxin; prevents formation of SNARE complex (?)
Snapiin	Binds SNAP-25; associated with synaptic vesicles; unknown function
NSF	ATPase that can disassemble SNARE complex; likely to disrupt complexes after exocytosis
$\alpha$ -SNAP	Cofactor for NSF in SNARE complex disassembly
unc-13/munc-13	Active zone protein; vesicle priming for release; modulation of transmission by diacyl glycerol
Rabphilin	C2 domain protein; Ca <sup>2+</sup> -binding protein; binds rab3 and associates with synaptic vesicle; modulation of transmission (?)
DOC2	C2 domain protein; Ca <sup>2+</sup> -binding protein; binds Munc-18; unknown function
RIM1 and related proteins	Active zone proteins; bind rab3; modulation of transmission (?)
Piccolo	Likely scaffolding protein to tether vesicles near active zone
Bassoon	Likely scaffolding protein to tether vesicles near active zone
Exocyst (sec6/8 complex)	Marks plasma membrane sites of vesicle fusion in yeast; synaptic role uncertain
Complexin	Binds to SNARE complex and arrests membrane fusion

interaction of these three proteins is essential for synaptic transmission and is likely to lie very close to or indeed at the final fusion step of exocytosis (Figs. 8.5 and 8.6). What are these proteins?

VAMP (also called synaptobrevin) was among the first synaptic vesicle proteins to be cloned. It is

anchored to the synaptic vesicle by a single transmembrane domain and has a cytoplasmic domain that contributes a coiled-coil strand to the core complex. Syntaxin has a very similar structure but is located primarily in the plasma membrane (although some is present on vesicles as well). SNAP-25 is also a protein primarily of the plasma membrane but, unlike the others, lacks a transmembrane domain and instead is anchored in its central region by acylations. SNAP-25 contributes two strands to the SNARE coiled coil. The interactions of these proteins can be envisioned as closely juxtaposing the two membranes meant to fuse. The proteins of this complex are archetypes of a class of membrane-trafficking protein collectively called *SNAREs*. Vesicle-associated proteins, such as VAMP, are referred to as *v-SNAREs*, and those of the target membrane, such as SNAP-25 and syntaxin, are referred to as *t-SNAREs*.

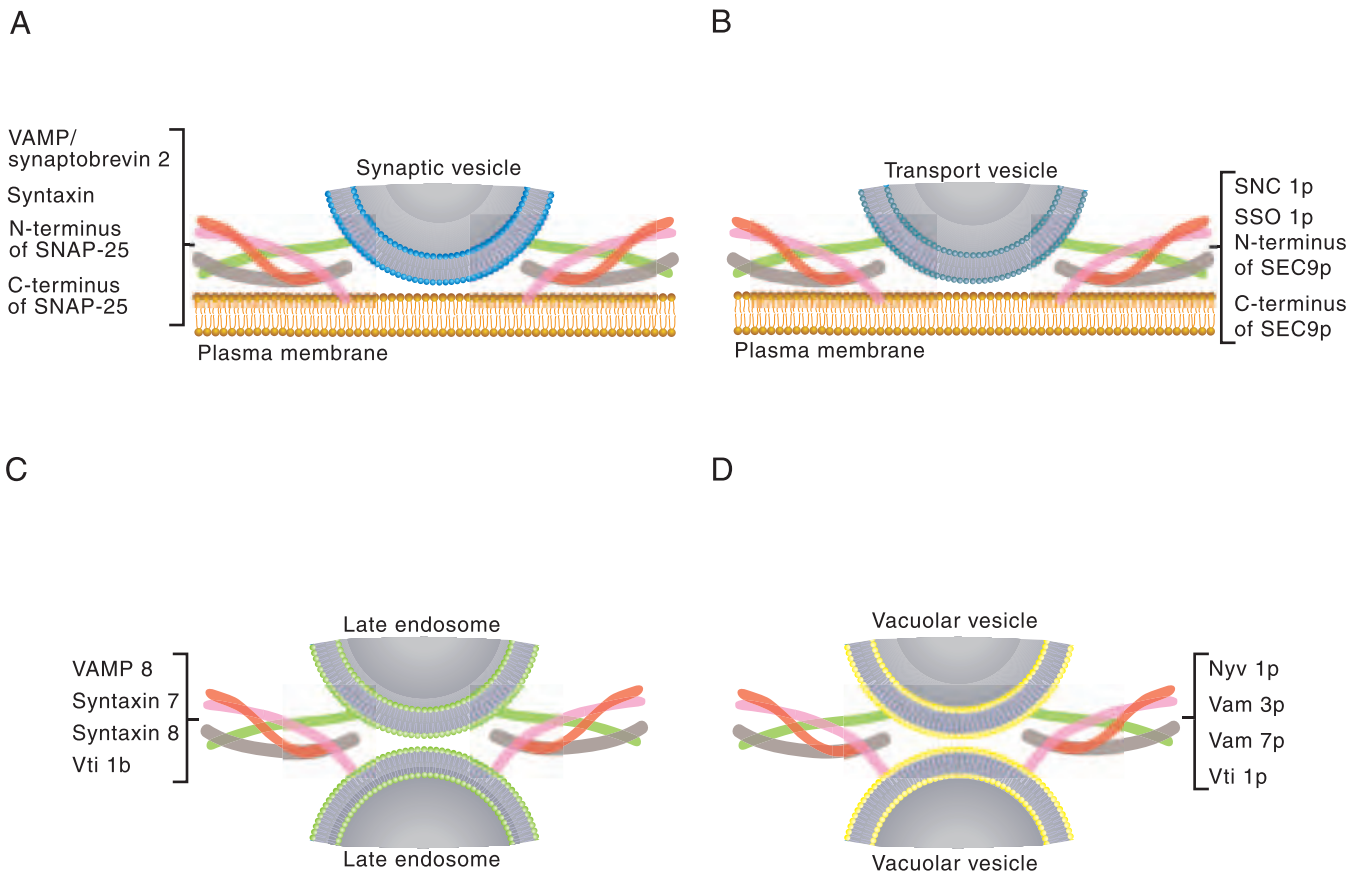

A SNARE complex is found at each membrane-trafficking step within a eukaryotic cell (Fig. 8.6). Through a combination of SNARE proteins on the opposing membranes, a four-stranded coiled-coil is formed. Alongside the example of the synapse in Figure 8.6A, three analogous cases are shown from exocytosis in yeast (Fig. 8.6B), the fusion of late endosomes with one another (Fig. 8.6C), and the fusion of vesicles that form the yeast vacuole (Fig. 8.6D).

Abundant genetic and biochemical data argue for an essential role of SNAREs, and the combination of yeast genetics, *in vitro* assays, biochemical analyses, and synaptic physiology has had a synergistic effect in advancing the field. For example, the discovery that secretory mutations in yeast were homologues of synaptic SNAREs provided some of the first functional data on these proteins (Bennett and Scheller, 1993), whereas data from synapses first placed the proteins on vesicles and the plasma membrane. In addition, the crystal structure was solved first for synaptic proteins (Sutton *et al.*, 1998). Because transmembrane domains and of course the membranes themselves, were absent from the crystallized samples, it was not possible to conclude from the structure alone that SNAREs form a bridge between the membranes rather than forming complexes within the same membrane. Instead, an *in vitro* assay with purified yeast vesicles established this point.

Some of the strongest evidence for an essential role of SNAREs at the synapse has come from the study of a potent set of eight neurotoxins produced by clostridial bacteria. These toxins (tetanus toxin and the family of related botulinum toxins) have long been known to block the release of neurotransmitter from the terminal. The discovery that they do so by proteolytically cleaving individual members of the SNARE

**FIGURE 8.5** SNARE proteins and the action of clostridial neurotoxins. The SNARE complex shown at the left brings the vesicle and plasma membranes into close proximity and likely represents one of the last steps in vesicle fusion. Vesicular VAMP, also called synaptobrevin, binds with syntaxin and SNAP-25 that are anchored to the plasma membrane. Tetanus toxin and the botulinum toxins, proteases that cleave specific SNARE proteins as shown, can block transmitter release.

**FIGURE 8.6** Neurotransmitter release shares a core mechanism with many membrane fusion events within eukaryotic cells. The fusion of synaptic vesicles (A) is driven by a particular complex of four coiled-coil domains contributed by three different proteins. Exocytosis in yeast (B), the fusion of late endosomes in mammalian cells (C), and the fusion of vacuolar vesicles in yeast (D) exemplify the closely related four-stranded coiled-coil complexes required to drive fusion in other membrane-trafficking steps.

complex provided neurobiologists with a set of tools with which to probe SNARE function (Fig. 8.5).

Each of the toxins comprises a heavy and a light chain that are linked by disulfide bonds. The heavy chain binds the toxin to surface receptors on neurons, thereby enabling the toxin to be endocytosed. Once inside the cell, the disulfide bond is reduced and the free light chain enters the cytoplasm of the cell. This light chain is the active portion of the toxin and is a member of the  $Zn^{2+}$ -dependent family of proteases. The catalytic nature of the toxin accounts for its astonishing potency; a few tetanus toxin light chains at a synapse can suffice to proteolyse all the VAMP/synaptobrevin, thereby shutting down transmitter release. The toxins are highly specific, recognizing unique sequences within an individual SNARE protein, as summarized in Fig. 8.5. VAMP/synaptobrevin can be cleaved not only by tetanus toxin but by the botulinum toxins of types B, D, F, and G, and each toxin cleaves at a different peptide bond within the structure. SNAP-25 is cleaved by botulinum toxins A and E, but again at different sites from one another. Botulinum toxin C1 cleaves both syntaxin and, less efficiently, SNAP-25.

What precisely is the function of SNARE proteins in promoting transmitter release? How does the assembly of this complex relate to membrane fusion? Studies with botulinum toxins, yeast mutants, mutants of *Drosophila* and *C. elegans*, and permeabilized mammalian cells all place SNAREs late in the process. Synapses that lack an individual SNARE, e.g., synapses whose VAMP has been mutated or cleaved by toxin, have the expected population of synaptic vesicles, and these vesicles accumulate at active zones in the expected manner. Indeed, as judged by electron microscopy, there may even be an excess of vesicles in close proximity to the plasma membrane at the active zone. Yet these synapses are incapable of secreting transmitter. Thus, SNAREs appear to be essential for a step that comes after the arrival of the vesicle to the release site, but before the fusion pore opens and transmitter can diffuse into the cleft. The details of how the complex functions, however, are less certain.

One attractive model is that the energy released by the formation of this very high-affinity complex is used to drive together the two membranes. A loose complex of the SNAREs would form and then “zipper up” and pull the membranes together. This may correspond to the actual fusion of the membranes or, alternatively, to a priming step that requires a subsequent rearrangement of the lipids in order to open the pore that will connect the vesicle lumen to the extracellular space. Evidence from the fusion of yeast vacuolar vesicles implicates a distinct downstream step, regu-

lated by  $Ca^{2+}$ /calmodulin and involving subunits of the proton pump, but whether this is true of neurons as well remains unknown. Vesicles consisting of only lipid bilayers and SNAREs can fuse *in vitro*, suggesting that no other proteins will be essential for the fusion step.

One additional function may reside with SNARE proteins: identification of an appropriate target membrane. Within a cell, there are myriad membrane compartments with which a transport vesicle can fuse: how then is specificity achieved? The great diversity of SNAREs (Fig. 8.6) may account for some of this specificity because not all combinations of vesicle-associated and target-associated SNAREs (v- and t-SNAREs) will form functional complexes. This potential mechanism, however, is likely to be only a part of the story. Particularly in the nerve terminal, it appears that synaptic vesicles can find the active zone even in the absence of the relevant SNAREs; for example, when a SNARE has been cleaved by a clostridial toxin or in a mutant lacking a SNARE. In addition, the t-SNAREs syntaxin and SNAP-25 can be present along the entire axon and thus are inadequate to explain the selective release of transmitter at synapses and active zones.

### NSF—An ATPase for Membrane Trafficking

At some point as vesicles move through their exocytotic cycle, energy must be added to the system. N-Ethylmaleimide sensitive factor (NSF), an ATPase involved in membrane trafficking, is one likely source. NSF was first identified as a required cytosolic factor in an *in vitro* trafficking assay (Block *et al.*, 1988). The importance of NSF was confirmed when it was found to correspond to the yeast *sec18* gene, an essential gene for secretion. NSF hexamers bind a cofactor called  $\alpha$ -SNAP (Soluble NSF Attachment Protein), or *sec17*, and this complex in turn can bind to the SNARE complex. When Mg-ATP is hydrolyzed, the SNARE complex is disrupted into its component proteins (Sollner *et al.*, 1993). If SNARE complexes form between VAMP, syntaxin, and SNAP-25 all in the same membrane, these futile complexes can be split apart by NSF so that productive complexes bridging the membrane compartments can be formed. After fusion, the tight SNARE complex needs to be disrupted so that the VAMP can be recycled to synaptic vesicles while the other SNAREs remain on the plasma membrane. If, indeed, the energy of forming a tight SNARE complex is part of the energy that drives fusion, NSF, by restoring the SNAREs to their dissociated, high-energy state, will be an important part of the energetics of membrane fusion.

## Docking and Priming Vesicles Prepares Them for Fusion

As discussed earlier and outlined in Figure 8.2, many preparatory and regulatory steps may precede the action of SNAREs and the membrane fusion step at which SNAREs appear to act. These preparatory steps must tether the vesicle at an appropriate release site in the active zone and hold the vesicle in a fusion-ready state. These mechanisms remain among the most obscure of the processes involved in exocytosis, but there is a growing list of proteins that may participate (Table 8.2). One example is the syntaxin-binding protein n-sec1 (also called munc18), the neuronal homologue of the product of the yeast *sec1* gene. Mutations of this protein prevent trafficking in both yeast and higher organisms. It appears likely that n-sec1 serves two functions: it may promote membrane fusion by priming syntaxin so that, once it has dissociated, it can participate correctly in fusion, but it may also be a negative regulator, keeping syntaxin inert until an appropriate vesicle or signal displaces n-sec1 and allows a SNARE complex to form.

Rab3, a small GTP-binding protein mentioned earlier, is another protein for which a priming or regulatory role often is invoked at the synapse. In yeast, and at other membrane-trafficking steps within mammalian cells, rab proteins have essential roles. They appear to help a vesicle to recognize its appropriate target and begin the process of SNARE complex formation. At the synapse, however, the significance of rab3 is still uncertain. Although it is clearly associated with synaptic vesicles, genetic disruption of rab3 has a surprisingly slight phenotype and causes only subtle alterations in synaptic properties. Whether this is due to additional, redundant rab proteins or whether the rab family has been relegated to a more minor role at the synapse remains to be determined.

Because synaptic vesicles dock and fuse specifically at the active zone, this region of the nerve terminal membrane must have unique properties that promote docking and priming. The special nature of this domain is easily discernible in electron micrographs: an area of electron-dense material can be observed opposite the postsynaptic density (Fig. 8.1). In some synapses, such as photoreceptors, hair cells, and many insect synapses, the structures are more elaborate and include ribbons, dense bodies, and T bars that extend into the cytoplasm and appear to have a special relationship with the nearby pool of vesicles.

Advances in electron microscopy have allowed a more detailed look at the association of vesicles and plasma membrane at the active zone (Harlow *et al.*, 2001). At the neuromuscular junction of the frog (Fig.

8.1), the electron-dense material adjacent to the presynaptic plasma membrane is actually a highly ordered structure—a lattice of proteins that connect the vesicles to a cytoskeleton, to one another, and to the plasma membrane. The molecules that correspond to these structures are not yet known. A few proteins, however, are known to be concentrated in the active zone or in the cloud of vesicles near the active zone. These proteins, piccolo, bassoon, RIM1, and unc-13, may be a part of the machinery that defines the active zone as the appropriate target for synaptic vesicle fusion.

In addition to the specializations of the active zone, additional machinery must be present to preserve a dense cluster of synaptic vesicles extending approximately 200 nm back from the active zone (Fig. 8.1). The vesicles in this domain are not likely to be releasable within microseconds of the arrival of an action potential but are instead likely to represent a reserve pool from which vesicles can be mobilized to release sites on the plasma membrane. The equilibrium between this pool and vesicles actually at the membrane may be an important determinant of the number of vesicles released per impulse, but remains poorly understood.

One protein family likely to play a role in the maintenance of the reserve pool is the synapsins, a set of peripheral membrane proteins on synaptic vesicles. Synapsins can also bind actin filaments and thus may provide a linker that tethers the vesicles in the cluster to the synaptic cytoskeleton. Disruption of this link can cause the vesicle cluster to be diminished and reduce the number of vesicles in the releasable pool of the terminal. Synapsin has attracted considerable interest because it is the substrate for phosphorylation by both cAMP and Ca<sup>2+</sup>-dependent protein kinases. These phosphorylations may influence the availability of reserve vesicles for recruitment to release sites.

## Ca<sup>2+</sup>-Binding Proteins Are Candidates for Coupling the Action Potential to Exocytosis

The most striking difference between synaptic transmission and traffic between other cellular compartments is the rapid triggering of fusion by action potentials. As discussed previously, the opening of Ca<sup>2+</sup> channels and the focal rise of intracellular Ca<sup>2+</sup> activate the fusion machinery. How does the terminal sense the rise in Ca<sup>2+</sup>? What is the Ca<sup>2+</sup> trigger and how does it open the fusion pore? Is it a single Ca<sup>2+</sup>-binding protein or do several components respond to the altered Ca<sup>2+</sup> concentration? Does Ca<sup>2+</sup> remove a brake that normally prevents a docked, primed vesicle from fusing or does Ca<sup>2+</sup> induce a conformational change

that is actively required to promote fusion? How does the steep, exponential relationship of release to intracellular  $\text{Ca}^{2+}$  arise? These questions are an active area of investigation and debate.

The leading candidate for being the synaptic  $\text{Ca}^{2+}$  sensor is synaptotagmin, an integral membrane protein of the synaptic vesicle (Fig. 8.4). Synaptotagmin has a large cytoplasmic portion that comprises two  $\text{Ca}^{2+}$ -binding C2 domains, called C2A and C2B. These domains can also interact with the SNARE complex proteins and with phospholipids in a  $\text{Ca}^{2+}$ -dependent manner. It has been hypothesized that one or more of these interactions is the molecular correlate of the triggering event for fusion. Consistent with this hypothesis, mutations that remove synaptotagmin profoundly reduce synaptic transmission in flies, worms, and mice, while having little effect on or enhancing the rate of spontaneous release of transmitter. Whether this reduction in evoked release is due specifically to the loss of the  $\text{Ca}^{2+}$  trigger, however, is harder to demonstrate. Synaptotagmin is likely to be involved in endocytosis and potentially in vesicle docking as well, which has complicated the analysis. These processes, as mentioned earlier, are also likely to be regulated by  $\text{Ca}^{2+}$ , and the  $\text{Ca}^{2+}$ -binding sites on synaptotagmin may be relevant for this regulation as well.

Recently, an intriguing model has emerged in which the fusion of membranes is arrested at an intermediate state by the binding of a small protein called complexin to the assembled SNARE complex. Synaptotagmin, in the presence of  $\text{Ca}^{++}$ , can bind to the SNARE complex and displace complexin, thereby allowing the fusion reaction to proceed. Evidence, both from *in vitro* studies of the biochemical interaction of complexin and synaptotagmin with the SNARE complex and from assays of membrane fusion suggests that complexin serves as a brake and that the primary function of synaptotagmin in exocytosis is to release that brake.

### Transmitter Must Be Packaged into the Vesicle

To achieve the synchronous release of thousands of molecules of transmitter from the presynaptic nerve terminal, synaptic vesicles accumulate and store high concentrations of transmitter. In cholinergic neurons, for example, the concentration of acetylcholine within the synaptic vesicle can reach  $0.6M$ , more than 1000-fold greater than that in the cytoplasm. Two synaptic vesicle proteins mediate the uptake of transmitter: the vacuolar proton pump and a family of transmitter transporters. The vacuolar proton pump is

a multisubunit ATPase that catalyzes the translocation of protons from the cytoplasm into the lumen of a variety of intracellular organelles, including synaptic vesicles. The resulting transmembrane electrochemical proton gradient is utilized as the energy source for the active uptake of transmitter by transmitter transporters.

Transmitter uptake has been characterized in isolated synaptic vesicle preparations in which at least four types of distinct transporters have been identified: one for acetylcholine, another for catecholamines and serotonin, a third for the excitatory amino acid glutamate, and the fourth for the inhibitory amino acids GABA and glycine. At least one gene for each of these classes of transmitter transporter has now been cloned. As expected, these distinct transporters are expressed differentially by neurons. The type of transporter in a cell dictates the type of transmitter stored in the synaptic vesicles of a particular neuron, and when investigators drive the expression of a glutamate transporter, e.g., in a GABA-releasing neuron, they can trick the cell into releasing glutamate.

Vesicular transporters are integral membrane proteins with 12 membrane-spanning domains that display sequence similarity with bacterial drug-resistance transporters. Synaptic vesicle transporters are clearly distinct from the plasma membrane transmitter transporters that remove transmitter from the synaptic cleft and thereby contribute to the termination of synaptic signaling. The distinguishing characteristics include their transport topology, energy source, pharmacology, and structure. The sequestration of transmitter into vesicles, in addition to its obviously essential role for transmitter exocytosis, has some further benefits to the cell. Sequestration can prevent high cytosolic concentrations of the transmitter from inhibiting the biosynthetic enzymes for transmitter synthesis and can protect the transmitter from catabolic enzymes. In addition, in some cell types, sequestration may protect the cell from damage caused by the oxidation of labile transmitters, particularly dopamine.

In contrast to small chemical transmitters, proteinaceous signaling molecules, including neuropeptides and hormones, typically are stored in granules that are larger and have a higher electron density than synaptic vesicles. The contents of these granules are not recycled at the release sites; as a result, their replenishment requires new protein synthesis followed by packaging into secretory vesicles in the cell body. Because of the slow kinetics of their release, the slow responsiveness of their postsynaptic receptors, and their inability to be recycled locally, proteinaceous signaling molecules typically mediate regulatory functions.

## Endocytosis Recovers Synaptic Vesicle Components

After exocytosis, the components of the synaptic vesicle membrane must be recovered from the presynaptic plasma membrane, as discussed previously. Vesicle recycling theoretically could be accomplished by either of two mechanisms (Fig. 8.2). The first is simply a reversal of the fusion process. In this case, a fusion pore opens to allow transmitter release and then closes rapidly to reform a vesicle. Often nicknamed “kiss and run,” it has the theoretical advantage that it would allow all the vesicular components to remain together on a single vesicle that would be available immediately for reloading with transmitter. The mechanism is potentially quick and energetically efficient. This mechanism is employed in some nonneuronal cells, but its relevance for the synapse is an unresolved, and highly controversial, issue.

The predominant pathway for synaptic vesicle recycling is more likely to be a second mechanism, endocytosis. Endocytosis of synaptic vesicle components, like receptor-mediated endocytosis in other cell types, is mediated by vesicles coated with the protein clathrin. Accessory proteins select the cargo incorporated into these vesicles as they assemble. The final pinching off of clathrin-coated vesicle requires the protein dynamin, which can form a ring-like collar around the neck of an endocytosing vesicle. The importance of dynamin is demonstrated most clearly in *Drosophila* via a temperature-sensitive dynamin mutant known as *shibire*: at the nonpermissive temperature, *shibire* flies become paralyzed rapidly due to a nearly complete depletion of synaptic vesicles from their nerve terminals. Once the components of the synaptic vesicle membrane have been recovered in clathrin-coated vesicles, recycling is completed by vesicle uncoating and, perhaps, passage through an endosomal compartment in the nerve terminal (Fig. 8.2).

### Summary

The life of the synaptic vesicle involves much more than just the  $\text{Ca}^{2+}$ -dependent fusion of a vesicle with the plasma membrane. It is a cyclical progression that must include endocytosis, transmitter loading, docking, and priming steps as well. In many regards, this cell biological process shares mechanistic similarities with membrane trafficking in other parts of the cell and with simpler organisms such as yeast. Interaction of vesicular and plasma membrane proteins of the SNARE complex—VAMP/synaptobrevin, syntaxin, and SNAP-25—is an essential late step in fusion. Many other proteins have been identified that are likely to

precede the action of the SNAREs, regulate the SNAREs, and recycle them. Components of the synaptic vesicle membrane, the presynaptic plasma membrane, and the cytoplasm all contribute to the regulation of synaptic vesicle function. Together, these proteins build on the fundamental core apparatus to create an astonishingly accurate, fast, and reliable means of delivering transmitter to the synaptic cleft.

## QUANTAL ANALYSIS: PROBING SYNAPTIC PHYSIOLOGY

A quantitative description of the signal passing across a synapse can be a source of insight into the biophysics of transmission and its regulation. As discussed earlier, the response to an action potential in the presynaptic cell reflects the release of discrete packets of transmitter, called quanta, that are a direct consequence of the vesicular release of transmitter. A given synapse, however, will not secrete exactly the same number of vesicles in response to each stimulus. Instead, the probabilistic nature of the presynaptic apparatus typically causes the amount released to fluctuate from trial to trial in a quantal manner; that is, the postsynaptic response adopts preferred levels, which arise from the summation of various numbers of vesicle fusions (Katz, 1969). Thus, although a particular synapse may release an average of two vesicles per action potential, it may release one vesicle in response to one stimulation and three vesicles in response to the next. To the third stimulus, the synapse may fail to release any transmitter at all. From a full description of the properties of the synapse, the size of the individual quantum response can be estimated, as well as the average number of quanta released for a given presynaptic action potential. This approach, called quantal analysis, is also a source of insight into the probabilistic processes underlying transmitter release from the presynaptic terminal and into the mechanisms by which transmission can be modified by physiological, pharmacological, and pathological phenomena.

### A Standard Model of Quantal Transmission Can Describe Many Synapses

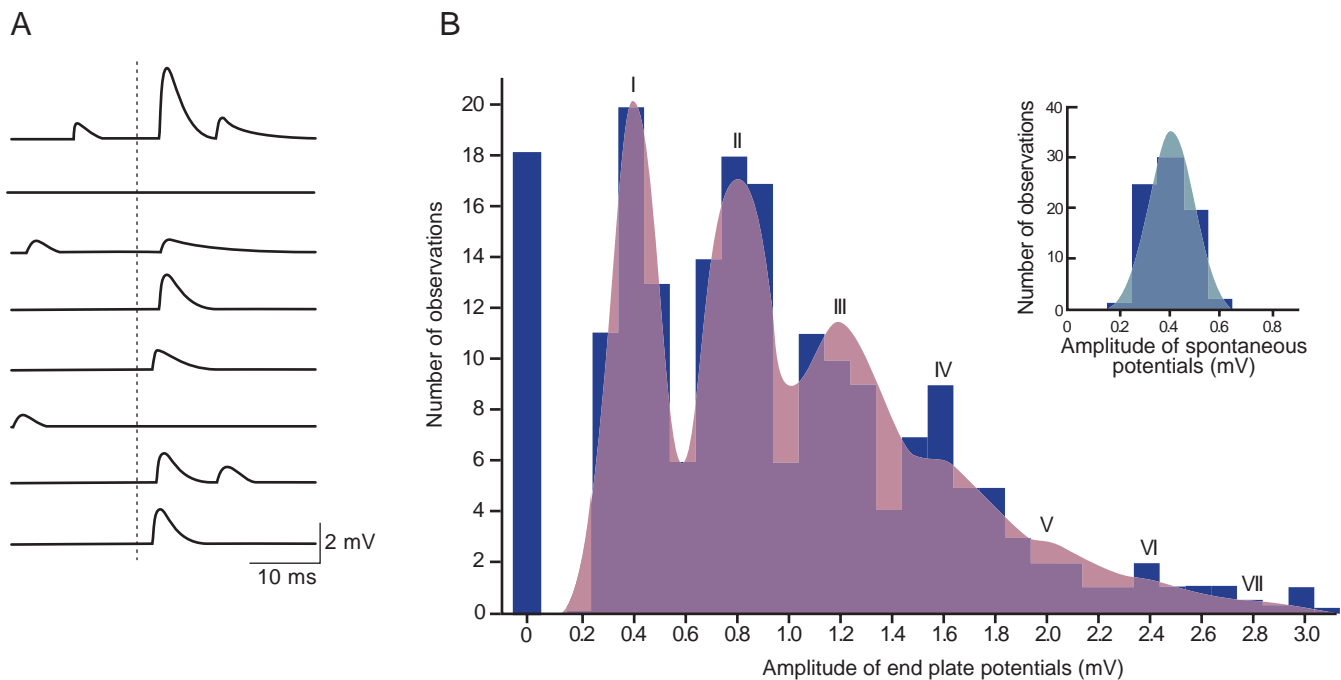

The quantal nature of transmission was first demonstrated in the early 1950s by Bernard Katz and colleagues, who recorded from the frog neuromuscular junction. Spontaneous signals that were approximately 1/100 of the signal evoked by stimulating the presynaptic axon were observed to occur at random intervals.

These spontaneous minis were of roughly constant amplitude, with a coefficient of variation of 30%. As discussed previously, a neuromuscular junction normally releases hundreds of quanta per impulse, but when extracellular  $\text{Ca}^{2+}$  was lowered to reduce transmitter release to very low levels, the evoked response fluctuated from trial to trial between preferred amplitudes, which coincided with integral multiples of the mini amplitude (Fig. 8.7).

We now understand this to arise from the fact that minis are the fusion of a single vesicle and that evoked responses can represent one or more of these same vesicles. Before the vesicle hypothesis was established, however, Katz and colleagues inferred that the mini is the quantal building block, variable numbers of which are released to make up the evoked signal. The relative numbers of trials resulting in 0, 1, 2, . . . quanta were well described by a Poisson distribution—a statistical distribution that arises in many instances where a random process operates. On the basis of this evidence, Katz and colleagues proposed the following model of

transmission, which has gained wide acceptance and will be referred to as the standard Katz model.

- Arrival of an action potential at the presynaptic terminal briefly raises the probability of release of quanta of transmitter (i.e., the fusion of synaptic vesicles).
- Several quanta (synaptic vesicles) are available to be released, and every quantum gives roughly the same electrical signal in the postsynaptic cell. This is the quantal size or amplitude,  $Q$ , which sums linearly with all other quanta released.
- The average number of quanta released,  $m$ , is given by the product of  $n$ , the number of available quanta, and  $p$ , the average release probability:  $m = np$ . The average response to a stimulus is the product of the quantal size and the average number of quanta per stimulus,  $Qm$  or  $Qnp$ .
- The relative probability of observing 0, 1, 2, . . . ,  $n$  quanta released is then given by a binomial distribution, with parameters  $n$  and  $p$ .

**FIGURE 8.7** Quantal transmission at the neuromuscular junction. (A) Intracellular recordings from a rat muscle fiber in response to repeated presynaptic stimulation of the motor axon. Low extracellular  $[\text{Ca}^{2+}]$  and high  $[\text{Mg}^{2+}]$  restricted  $\text{Ca}^{2+}$  entry and so kept transmission to a very low level. The stimulus was given at the time marked by the dotted line. The size of the postsynaptic response fluctuated from trial to trial, with some trials giving failures of transmission. Spontaneous minis occurring in the background (e.g., those events that occur before the dotted line) had approximately the same amplitude as the smallest evoked responses, implying that they arose from the release of single quanta of acetylcholine. From Liley (1956). (B) Peak amplitudes of 200 evoked responses [end plate potentials (EPPs)] from a similar experiment, plotted as an amplitude histogram. Eighteen trials resulted in failures of transmission (indicated by the bar at 0 mV), and the rest gave EPPs whose amplitude tended to cluster at integral multiples of 0.4 mV. This coincides with the mean amplitude of the spontaneous minis, whose amplitude distribution is shown in the insert together with a Gaussian fit. Shading through the EPP histogram is a fit obtained by assuming a Poisson model of quantal release. Roman numerals indicate the number of quanta corresponding to each component in the distribution. From Boyd and Martin (1956).

The value of  $Q$  has a clear underlying basis: the efficacy of an individual synaptic vesicle fusion in altering the conductance of the postsynaptic membrane. The binomial parameters,  $n$  and  $p$ , however, are formalisms whose underlying meanings are harder to pin down.  $n$  may correspond to the number of vesicles in a primed, fusion-ready state at the active zone or to discrete release sites competent for release, or even to the number of active zones. Correspondingly,  $p$  may represent the probability of fusion of any individual vesicle or the probability of fusion at a given release site or active zone. For some mechanisms, therefore, it is difficult to say whether  $n$  or  $p$  is altered. For example, if additional vesicles are recruited to release sites, that change may be manifest as a change in  $n$  because there are more releasable quanta or as a change in  $p$  because the probability of fusion at a given release site has increased because it is more likely to be charged with a vesicle.

These quantal parameters remain a useful description of the synapse, however, despite their obscurity on a mechanistic level. For example, it is often useful to classify synapses as having a high or low probability of release ( $p$ ) to explain their behavior during trains of stimuli (see later). In a synapse with few releasable vesicles and a high  $p$ , a train is predicted to deplete the releasable pool rapidly and the strength of transmission declines, a phenomenon known as synaptic depression. Another synapse might have the same average quantal content, but accomplish this with a large releasable pool and a low probability of fusion for any individual vesicle in the pool. Such a synapse would be less prone to depression and indeed both types of synapse are encountered.

A major impetus for the accurate measurement of quantal parameters is that it may help determine the locus of modulatory effects on synaptic transmission, or the site of action of a drug. A blocker of postsynaptic receptors, for example, will not alter the mini frequency or the number of quanta released, but will decrease the amplitudes of both spontaneous minis and the quantal components of evoked responses. A change in the loading of transmitter into a vesicle could cause a similar change. In contrast, a synaptic modulator that decreased  $\text{Ca}^{2+}$  channel opening or a blocker of those channels would decrease the probability of presynaptic release and be recognized as a decrease in quantal content,  $m$ . Many modulators of presynaptic transmission cause a parallel change in quantal content and in the frequency of spontaneous minis. This sort of analysis has been instrumental in understanding synaptic plasticity and in determining whether a given alteration occurs at the presynaptic terminal or the postsynaptic membrane.

## The Standard Katz Model Does Not Always Apply

Incorrectly applying the Katz model and quantal analysis to synapses at which its assumptions do not hold has been a frequent source of error. Although a superb description of transmission at the neuromuscular junction, it is not uniformly applicable to central nervous system synapses, and the technical difficulties of isolating and accurately sampling the physiology of an individual synapse in the CNS can make the determination of quantal parameters exceptionally difficult.

In particular, five issues arise at CNS synapses with which the standard Katz model cannot deal adequately. These are *nonuniformity of quanta*, *nonuniformity of release sites*, *postsynaptic membranes that distort responses*, *saturation of receptors*, and *silent synapses*.

For quantal analysis to work, individual quanta should be roughly equivalent in size, that is, with the same amount of transmitter in each vesicle and with similar populations of receptors facing their release sites, as is true at the frog neuromuscular junction. But in the CNS, both vesicle content and receptor populations may differ widely, particularly where more than one synapse connects two cells. The resulting *nonuniformity of quanta* means that mini amplitudes will not have a normal distribution and will not sum to tidy peaks like those shown in Figure 8.7. Mini amplitude in the CNS can also be very hard to measure: the smallest events may be lost in the noise and the large variety of inputs converging on a postsynaptic cell makes it difficult to determine which responses derive from an individual presynaptic input. *Nonuniformity of release sites* can similarly prevent responses from falling in a simple binomial distribution. For example, the Ca channels at a nerve terminal may be of different isoforms or differentially phosphorylated and vesicles will therefore vary in their release probability depending on the channels closest to them.

*Postsynaptic membranes that distort responses* introduce another problem: the voltage-dependent properties of the postsynaptic cell and the particular electrical properties of dendritic spines can prevent vesicles from summing in a simple linear fashion. Equally problematic is the *saturation of receptors* on the postsynaptic membranes of many CNS synapses. A glutamatergic CNS synapse may have fewer than 100 receptors present, and if a single quantum activates most of these, it is impossible for quanta to sum linearly. Indeed, a major difference between some vertebrate CNS synapses and the neuromuscular junction is that the quantal amplitude often is determined not by the vesicle contents, but by the number of available

receptors. In the extreme case of a developing synapse, the variation from impulse to impulse might depend as much on whether one, two, or three receptors were activated per vesicle fusion as whether one, two, or three vesicles fused.

*Silent synapses* represent an extreme form of the variability of postsynaptic responses and may be an important consideration for AMPA receptors at glutamatergic synapses (see Chapter 9). At these synapses, active zones may be secreting transmitter without producing a physiological response because no receptors are present in the postsynaptic membrane. These so-called silent synapses can spring to life when a set of receptors is inserted into the postsynaptic membrane in a concerted fashion. Because more active zones now are contributing to the detected physiological response, mini frequency will be higher and evoked release increased, although the quantal size will not have changed. Whereas the Katz model from the neuromuscular junction would consider these changes to be the hallmarks of a presynaptic change in release, the “unsilencing” of these CNS synapses is a postsynaptic event.

Thus, many of the requirements for the standard Katz model cannot realistically be expected to hold in all cases and the evidence that these simple probabilistic models are correct is far from compelling. However, despite the technical difficulties and theoretical caveats, the analysis of mini frequency, quantal size, quantal content, and synaptic probability has been the foundation of our description of synaptic transmission and the source of great insight into synaptic modulation.

It has been possible to augment this understanding with independent methods, including the ability to monitor vesicle fusion optically from the unloading of the lipophilic dyes discussed earlier, and thereby to describe presynaptic activity without depending on the postsynaptic membrane to report the event. Another method of indirectly estimating release probability at glutamatergic synapses makes use of a blocker of NMDA receptors, MK-801, that will act only in the open state. From the rate of blockade during a train of stimuli, the probability of the channel having been opened by a given impulse can be inferred.

## Summary

Quantal analysis has improved our understanding of biophysical and pharmacological mechanisms of transmission by describing normal transmission and by offering a tool to distinguish and characterize presynaptic and postsynaptic actions of drugs or endogenous agents that modify the strength of a synapse.

Although these methods must be applied with caution, they yield a unique insight into the mechanisms of synaptic plasticity. The nature of transmission at CNS synapses can be quite different from what is encountered at the classical synapse of the neuromuscular junction.

## SHORT-TERM SYNAPTIC PLASTICITY

Chemical synapses are not static transmitters of information. Their effectiveness waxes and wanes, depending on the frequency of stimulation and the history of prior activity. Because information processing in the nervous system is not conducted by individual action potentials at widely spaced intervals, this plasticity is of the utmost importance to the function of the synapse within its physiological circuit. At most synapses, repetitive high-frequency stimulation (called a *tetanus*) initially is dominated by a growth in successive PSP amplitudes, called *synaptic facilitation* (Fig. 8.8). This process builds to a steady state within about 1 s and decays equally rapidly when stimulation stops. Decay is measured by single test stimuli given at various intervals after a conditioning train. Facilitation does not require a train to be observed; at many synapses it can be seen after a single action potential. Thus, when two stimuli are given with very close spacing, the second one can be as much as twice the amplitude of the first. This is called *paired-pulse facilitation* (Fig. 8.8). At most synapses, a slower phase of increase in efficacy, which has a characteristic time constant of several seconds (called *augmentation*), succeeds facilitation. Finally, with prolonged stimulation, some synapses display a third phase of growth in PSP amplitude that lasts minutes (called *potentiation*). Potentiation often is visible in isolation only long after a tetanus and is thus called *posttetanic potentiation* (PTP).

**FIGURE 8.8** Short-term synaptic plasticity. (A) An idealized synapse in which facilitation predominates. Two stimuli (paired pulses) are given to the presynaptic nerve in each line and postsynaptic voltage responses are shown. Closely spaced stimuli (top line) facilitate strongly but as the interval between stimuli increases, the degree of facilitation diminishes. The fifth line illustrates how facilitation can accumulate during a train of stimuli. (B) An idealized synapse in which synaptic depression predominates. (C) At most synapses, both depression and facilitation occur and, depending on the nature of the individual synapse and the time course of facilitation, depression, augmentation, and potentiation, any of these phenomena may predominate at a given moment. Thus, in a realistic pattern of activity, with unevenly spaced action potentials arriving at a terminal, the strength of transmission can depend greatly on the previous history of the synapse.

A Facilitation

B Depression

C

Often, a phase of decreasing transmission, called synaptic *depression*, is superimposed on these processes (Fig. 8.8). Synaptic depression leads to a dip in transmission during repetitive stimulation, which often tends to overlap and obscure the augmentation and potentiation phases. At some synapses, it is manifest after only a single action potential and gives rise to *paired-pulse depression*.

Additional forms of use-dependent plasticity, called long-term potentiation and long-term depression (LTP and LTD), have received considerable attention as likely correlates of some forms of learning and are discussed elsewhere (Chapter 49). Most frequently, at synapses in which a quantal analysis has been done, all these forms of synaptic plasticity (except some forms of cortical LTP) are due to changes in the number of quanta released by action potentials.

The propensity to facilitation or depression can be quite different at different types of synapse and thus contributes to the diversity of synaptic communication and the flexibility of information processing by synapses. At a given synapse, the frequency and duration of a train can alter whether facilitation or depression is most in evidence. In a physiologically realistic setting of irregularly spaced stimuli, all these phenomena may be simultaneously at play and one or another may predominate for any given response, depending on the preceding history of stimulation. Thus, responses in the postsynaptic cell will be anything but a constant response to each action potential in the train.

### Synaptic Depression May Arise from Depletion of Readily Releasable Vesicles, Autoinhibition, or Receptor Desensitization

The rate at which synaptic depression develops usually depends on stimulation frequency. At many synapses, depression is relieved when transmission is reduced by lowering  $\text{Ca}^{2+}$  or raising  $\text{Mg}^{2+}$  in the medium—when little or no release occurs, there is little depression of the subsequent response. These characteristics are consistent with depression being due to the depletion of a readily releasable store of docked or nearly docked vesicles and recovery being due to their replenishment from a nearby supply (Fig. 8.9) (Zucker, 1989). The parameters of such a depletion model can be estimated from the rate of recovery from depression, which gives the rate of refilling the releasable store, and the fractional drop in PSPs given at short intervals, which gives the fraction of the releasable store liberated by each action potential.

As mentioned previously, synapses with a high probability of release from a relatively small pool of vesicles will be the most prone to this form of depres-

sion. Recovery from this form of depression appears to be influenced by cytosolic  $\text{Ca}^{2+}$  as well, consistent with a hypothetical ability of elevated  $\text{Ca}^{2+}$  in the cytosol to enhance the recruitment of reserve vesicles to release sites.

Vesicle depletion cannot account for all forms of synaptic depression. At some synapses, depression is due to an inhibitory action of released transmitter on presynaptic receptors called autoreceptors. For example, in rat hippocampal cortex, the depression of GABA responses is blocked by antagonists of presynaptic GABAB receptors. Presumably, GABA acts to hyperpolarize nerve terminals and block transmitter release. At other synapses, desensitization of postsynaptic receptors contributes heavily to the observed depression.

### Facilitation, Augmentation, and Potentiation Are Due to Effects of Residual $\text{Ca}^{2+}$

With few exceptions, all the phases of increased short-term plasticity are  $\text{Ca}^{2+}$ -dependent in the sense that little or no facilitation, augmentation, or potentiation is generated by stimulation in  $\text{Ca}^{2+}$ -free medium. Originally, these phases of increased transmission were thought to be due to the effect of residual  $\text{Ca}^{2+}$  remaining in active zones after presynaptic activity and summing with  $\text{Ca}^{2+}$  influx during subsequent action potentials to generate slightly higher peaks of  $\text{Ca}^{2+}$  (Katz and Miledi, 1968; Zucker, 1989). Due to the highly nonlinear dependence of transmitter release on  $\text{Ca}^{2+}$ , a small residual amount could activate a substantial increase in phasic transmitter release during an action potential, while having only a small effect on mini frequency itself. However, as this relationship was examined more closely and with  $\text{Ca}^{2+}$  indicators to actually measure the residual intracellular  $\text{Ca}^{2+}$ , this hypothesis became unlikely. These findings led to the proposal that, in addition to summing with peak  $\text{Ca}^{2+}$  transients to drive fusion,  $\text{Ca}^{2+}$  acts to increase transmission at one or more targets distinct from the sites triggering exocytosis. Unlike the triggering site, the facilitation site for  $\text{Ca}^{2+}$  binding should be a high-affinity site that can be influenced by the relatively low levels of residual  $\text{Ca}^{2+}$ . Other second messenger systems and kinases may also be involved.

Potentiation lasts for a long period after a strong tetanus because residual  $\text{Ca}^{2+}$  is present for the duration of PTP, presumably due to overloading of the processes responsible for removing excess  $\text{Ca}^{2+}$  from neurons. These processes include  $\text{Ca}^{2+}$  extrusion pumps, such as plasma membrane ATPase and  $\text{Na}^+$ - $\text{Ca}^{2+}$  exchange, and  $\text{Ca}^{2+}$  uptake into organelles such as endoplasmic reticulum and mitochondria.

**FIGURE 8.9** Depletion model of synaptic depression depicting the action of two stimuli ( $t_1$  and  $t_2$ ) that arrive so closely spaced that no vesicles have been recruited to the releasable pool to replace those that fused in response to the first stimulus. (A) A synapse in which the releasable pool ( $n$ ) is large and the probability of fusion for a given vesicle ( $p$ ) is low shows little or no depression. Because only a small fraction of the docked, releasable vesicles fused in response to the first stimulus, the second response is comparable in amplitude. (B) A synapse in which the releasable pool ( $n$ ) is small but the probability of fusion ( $p$ ) is high is likely to be strongly depressing. Vesicles released by the first impulse deplete half the fusion-competent pool, leaving  $n$  at  $t_2$  equal to half its value at  $t_1$ . If  $p$  has not changed at  $t_2$ , the second stimulus will release half as many quanta.

## Summary

Short-term synaptic plasticity allows synaptic strength to be modulated as a function of prior activity and can cause large changes in responses during physiologically relevant patterns of stimulation. Synapses may show a decline in transmission (depression) or an increase in synaptic efficacy with time constants ranging from seconds (facilitation and augmentation) to minutes (potentiation or PTP) to hours (LTP); many

synapses show a mixture of several of these phases. Synaptic depression may be due to depletion of a readily releasable supply of vesicles, to the inhibitory action of transmitter on presynaptic autoreceptors, or to the desensitization of postsynaptic receptors. Depression makes synapses selectively responsive to brief stimuli or to changes in level of activity. Frequency-dependent increases in synaptic efficacy are due to the effects of residual presynaptic  $\text{Ca}^{2+}$  acting to modulate the release process, probably

through a high-affinity binding site. These frequency-dependent increases in synaptic efficacy allow synapses to distinguish significant signals from noise and to respond to selected patterns of activity.

# Neurotransmitter Receptors

Chemical synaptic transmission plays a fundamental role in neuron-to-neuron and neuron-to-muscle communication and is mediated by receptors embedded in the plasma membrane. These receptors can either mediate the direct opening of an ion channel (ionotropic receptors) or alter the concentration of intracellular metabolites (metabotropic receptor). The sign of a given response can be inhibitory or excitatory, and the response magnitude is determined by receptor number, the “state” of the receptors, and the amount of transmitter released. Finally, the temporal and spatial summation of information conveyed by the activation of multiple receptors ultimately determines whether that neuron will fire an action potential or the muscle will contract. As one can see, there is remarkable flexibility and diversity in molding the response to neurotransmitter by constructing a synapse with the desired receptor types.

Two broad classifications exist for receptors. An *ionotropic receptor* is a relatively large, multisubunit complex typically composed of four or five individual proteins that combine to form an ion channel through the membrane (Fig. 9.1A). In the absence of neurotransmitter, these ion channels exist in a closed state and are largely impermeable to ions. Neurotransmitter binding induces rapid conformational changes that open the channel, permitting ions to flow down their electrochemical gradients. Changes in membrane current resulting from ligand binding to ionotropic receptors generally are measured on a millisecond time scale. The ion flow ceases when transmitter dissociates from the receptor or when the receptor becomes desensitized, a process discussed in more detail later in this chapter.

In contrast, a *metabotropic receptor* is composed of a single polypeptide (Fig. 9.1B) and exerts its effects not

through the direct opening of an ion channel, but through binding to and activating GTP-binding proteins (often referred to as G-proteins). Transmitters that activate metabotropic receptors typically produce responses of slower onset and longer duration (from tenths of seconds to potentially hours) due to the series of enzymatic steps necessary to produce a response. The metabotropic receptors have more recently been named G-protein-coupled receptors, or GPCRs for short, to more accurately capture their properties; the latter nomenclature is adopted in this chapter.

## IONOTROPIC RECEPTORS

All ionotropic receptors are membrane-bound protein complexes that form an ion-permeable pore in the membrane. By comparing the amino acid sequence of cloned ionotropic receptors, one can deduce that they are similar in overall structure, although two independent ancestral genes have given rise to two distinct families. One family includes one of the receptors for acetylcholine (ACh), the nicotinic ACh receptor (nAChR), a receptor for  $\gamma$ -aminobutyric acid (GABA), the GABA<sub>A</sub> receptor, the glycine receptor, and one subclass of serotonin (5-HT) receptors, the 5HT<sub>3</sub> receptor. The other family comprises the set of ionotropic glutamate receptors (Hollmann and Heinemann, 1994).

### The nAChR Is a Heteromeric Protein Complex with a Distinct Architecture

The nAChR is so named because the plant alkaloid nicotine can bind to the ACh-binding site and activate

**FIGURE 9.1** Structural comparison of ionotropic and metabotropic receptors. (A) *Ionotropic receptors* bind transmitter, and this binding translates directly into the opening of the ion channel through a series of conformational changes. Ionotropic receptors are composed of multiple subunits. The five subunits that together form the functional nAChR are shown. Note that each of the nAChR subunits wraps back and forth through the membrane four times and that the mature receptor is composed of five subunits. (B) *Metabotropic receptors* bind transmitter and, through a series of conformational changes, bind to G-proteins and activate them. G-proteins then activate enzymes such as adenylyl cyclase to produce cAMP. Through the activation of cAMP-dependent protein kinase, ion channels become phosphorylated, which affects their gating properties. Metabotropic receptors are single subunits. They contain seven transmembrane-spanning segments, with the cytoplasmic loops formed between the segments providing the points of interactions for coupling to G-proteins. Adapted from Kandel (1991).

the receptor. The nAChR purified as described from the electric organ of *Torpedo* ray is composed of five subunits (see Fig. 9.1A) and has a native molecular mass of approximately 290 kDa. The subunits are designated  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ , and each receptor complex contains two copies of the  $\alpha$  subunit. The subunits are homologous membrane-bound proteins that assemble in the bilayer to form a ring enclosing a central pore. The extracellular domain of each subunit together forms a funnel-shaped opening that extends approximately 100 Å outward from the outer leaflet of the plasma membrane. The funnel at the outer portion of the receptor has an inside diameter of 20–25 Å. The funnel shape is thought to concentrate and force ions and transmitter to interact with amino acids in the limited space of the pore without producing a major barrier to diffusion. This funnel narrows near the center of the lipid bilayer to form the domain of the receptor that determines the opened or closed state of the ion pore (Fig. 9.1). The intracellular domain of the receptor forms short exits for ions traveling into the

cell and an entrance for ions traveling out of the cell. The intracellular domain also establishes the association of the receptor with other intracellular proteins that determine the subcellular localization of the nAChR.

### Each nAChR Subunit Has Multiple Membrane-Spanning Segments

The primary structure of each nAChR subunit was obtained by the efforts of Shosaka Numa and colleagues. The deduced amino acid sequence from cloned mRNAs indicates that nAChR subunits range in size from 40 to 65 kDa. Each subunit consists of four transmembrane (TM)-spanning segments referred to as TM1–TM4 (Fig. 9.2A). Each segment is composed mainly of hydrophobic amino acids that stabilize the domain within the hydrophobic environment of the lipid membrane. The four transmembrane domains are arranged in an antiparallel fashion, wrapping back and forth through the membrane. The N terminus of

**FIGURE 9.2** (A) Diagram highlighting the orientation of membrane-spanning segments of one subunit of the nAChR. The amino and carboxy termini extend in the extracellular space. The four membrane-spanning segments are designated TM1–TM4. Each forms an  $\alpha$  helix as it traverses the membrane. (B) Side view of the five subunits in their approximate positions within the receptor complex. There are two  $\alpha$  subunits present in each nAChR. (C) Top view of all five subunits highlighting the relative positions of their membrane-spanning segments, TM1–TM4, and the position of TM2 that lines the channel pore. Adapted from Kandel (1991).

each subunit extends into the extracellular space, as does the loop connecting TM2 and TM3, as well as the C terminus. Amino acids linking TM1 and TM2 and those linking TM3 and TM4 form short loops that extend into the cytoplasm.

### Structure of the Channel Pore Determines Ion Selectivity and Current Flow

In the model shown in Figure 9.2C, each subunit of the nAChR can be seen to contribute one cylindrical component (representing a membrane-spanning segment) that presents itself to a central cavity that forms the ion channel through the center of the complex. The membrane-spanning segments that line the pore are the five TM2 regions, one contributed by each subunit. The amino acids that compose the TM2 segment are arranged in such a way that three rings of negatively charged amino acids are oriented toward the central pore of the channel (Fig. 9.3A). These rings of negative charge appear to provide much of the selectivity filter of the channel, ensuring that only cations can pass through the pore. The nAChR is permeable to most cations, such as Na<sup>+</sup>, K<sup>+</sup>, and Ca<sup>2+</sup>, although monovalent cations are preferred. The restricted physical dimensions of the pore—9–10 Å in the open state—contribute greatly to the selectivity for particular ions (Unwin, 1995). A coarse filtering that also influences selectivity appears to be a shielding effect produced by other negatively charged amino acids surrounding the outer channel region of the receptor. Collectively, these physical characteristics of the pore—together with the electrochemical gradient across the plasma membrane—determine the possibility of ion movements. Thus, when the pore of the nAChR opens, anions remain restricted from movement across the membrane while positively charged cations move down their respective electrochemical gradients, resulting in an influx of Na<sup>+</sup> and Ca<sup>2+</sup> and a small efflux of K<sup>+</sup>.

### Opening of the nAChR Occurs through Concerted Conformational Changes Induced by Binding of Two ACh Molecules

Each receptor complex has two ACh-binding sites that reside in the extracellular domain and are formed for the most part by six amino acids in  $\alpha$  subunits; however, amino acids in both  $\gamma$  and  $\delta$  subunits also contribute to binding. The two binding sites are not equivalent because of the asymmetry of the receptor due to the different neighboring subunits (either  $\gamma$  or  $\delta$ ) adjacent to the two  $\alpha$  subunits. Significant cooperativity also exists within the receptor molecule, and so binding of the first molecule of ACh enhances binding of the second. When nAChR binds two molecules of ACh, the channel opens almost instantaneously (time constants for opening are approximately 20  $\mu$ s), thus permitting the passage of ions. A model developed from electron micrographic reconstructions of the nicotine-bound form of the nAChR indicates that the closed-to-open transition is associated with a rotation of the TM2 segments (Fig. 9.3; Unwin, 1995). The TM2 segments are helical and exhibit a kink in their structure that forces a Leu residue from each segment into a tight ring that effectively blocks the flow of ions through the central pore of the receptor. When the TM2 segments rotate because of ACh binding, the

kinks also rotate; relaxing the constriction formed by the Leu ring, and ions can then permeate through the pore. The rotation also orients a series of Ser and Thr residues (amino acids with a polar character) into the central area of the pore (compare Figs. 9.3B to 9.3C), which facilitates the permeation of water-solvated cations. The well-established architecture of the nAChR provides a structural framework to which all other ionotropic receptors can be compared.

### The Muscle Form of the nAChR Is Very Similar to the nAChR from *Torpedo*

nAChRs at the neuromuscular junction are a concentrated collection of homogeneous receptors having a structure similar to that of the *Torpedo* electric organ. This similarity is not surprising because the electric organ is a specialized form of muscle tissue. The adult form of the muscle receptor has the pentameric structure  $\alpha_2\beta\epsilon\delta$ . An embryonic form of the receptor has an analogous structure, except that the  $\epsilon$  subunit is replaced by a unique  $\gamma$  subunit. The embryonic and adult subunits of both mouse and bovine muscle receptors have been cloned and expressed and the receptors differ in both channel kinetics and channel conductance. These differences in channel properties appear to be necessary for the proper function of the nAChRs

**FIGURE 9.3** (A) Relative positions of amino acids in the TM2 segment of one of the nAChR  $\alpha$  subunits modeled as an  $\alpha$  helix. Glutamate residues (E) that form parts of the negatively charged rings for ion selectivity are shown at the top and bottom of the helix. (B) Arrangement of three of the TM2 segments of the nAChR modeled with the receptor in the closed (ACh-free) configuration. In the closed configuration, leucine (L) residues form a tight ring in the center of the pore that blocks ion permeation. (C) Arrangement of the three TM2 segments after ACh binds to the receptor. In the open configuration, constriction formed by the ring of leucine (L) residues opens as the helices twist about their axes. Note that polar serine (S) and threonine (T) residues align when ACh binds, which apparently helps the water-solvated ions travel through the pore. Adapted from Unwin (1995).

as they undergo the transition from developing to mature neuromuscular junction synapses.

### The nAChR Has Well-Ordered Assembly and Is Posttranslationally Modified

The pathway of nAChR assembly in muscle is a tightly regulated process. For example, the five subunits of nAChR have the potential to assemble randomly into 208 different combinations. Nevertheless, in vertebrate muscle, only one of these configurations ( $\alpha_2\beta\epsilon\delta$ ) typically is found in mature tissue, indicating a very high degree of coordinated assembly and, ultimately, little structural variability. The well-ordered assembly takes place within the endoplasmic reticulum and during intracellular maturation, each subunit is glycosylated. Two highly conserved disulfide bonds in the N-terminal extracellular domain are essential for efficient assembly of the mature receptor. The first is between two adjacent Cys residues and resides very close to the ACh-binding site on the receptor. The second bond is between two Cys residues 15 amino acids apart, forming a loop in the extracellular domain.

Many ionotropic receptors, such as the nAChR, are phosphorylated, although the functional significance of the phosphorylation is not always evident. The nAChR is phosphorylated by at least three protein kinases. cAMP-dependent protein kinase (PKA) phosphorylates the  $\gamma$  and  $\delta$  subunits,  $\text{Ca}^{2+}$ /phospholipid-dependent protein kinase (PKC) phosphorylates the  $\delta$  subunit, and an unidentified tyrosine kinase phosphorylates the  $\beta$ ,  $\gamma$ , and  $\delta$  subunits. The phosphorylation sites are all found in the intracellular loop between TM3 and TM4 membrane-spanning segments. Phosphorylation by these three protein kinases increases the rate of desensitization of the receptor. Desensitization of receptors is a common observation, and this process limits the amount of ion flux through a receptor by producing transitions into a closed state (one that does not permit ion flow) in the continued presence of neurotransmitter. For the nAChR, the rate of desensitization has a time constant of approximately 50–100 ms.

### Neuronal nAChRs Contain Two Types of Subunits and Their Assembly Leads to Functional Diversity

Neuronal nAChRs are similar, yet distinct in structure to the *Torpedo* isoform of the receptor. For example, the neuronal nAChR is composed of only two types of subunits,  $\alpha$  and  $\beta$ , which combine to produce the functional receptor, and the majority of these receptors do

not bind to  $\alpha$ -bungarotoxin. At least nine different  $\alpha$  subtypes ( $\alpha 1$  being the muscle  $\alpha$  subunit) have been identified, and some are species-specific ( $\alpha 8$  is found only in chicken and  $\alpha 9$  is found only in rat). Four different  $\beta$  subtypes ( $\beta 1$  being the muscle  $\beta$  subunit) have been identified. The neuronal  $\beta$  subunits are distantly related to the muscle  $\beta 1$  subunit and sometimes are referred to simply as non- $\alpha$  subunits. All the  $\alpha$  and  $\beta$  genes encode proteins with four transmembrane-spanning segments and, although the physical structure of this receptor family has not been well characterized, it appears that each functional receptor is a pentameric assembly.

Neuronal nAChRs have diverse functions and are the receptors presumed to be responsible for the psychophysical effects of nicotine addiction. One major function of nAChRs in the brain is to modulate excitatory synaptic transmission through a presynaptic action. The diversity in function of nAChRs can be related to the heterogeneous structure contributed by the thousands of possible combinations between the different  $\alpha$  and  $\beta$  subunits. Functional neuronal nAChRs can be assembled from a single subunit (e.g.,  $\alpha 7$ ,  $\alpha 8$ , or  $\alpha 9$ ), and a single type of  $\alpha$  subunit can also be assembled with multiple types of  $\beta$  subunits (e.g.,  $\alpha 3$  with  $\beta 2$  or  $\beta 4$  or both) and vice versa. These additional possibilities produce a staggering array of potential receptor molecules, each with distinct properties, including differences in single-channel kinetics and rates of desensitization. It is also now established that subunit composition plays important roles in targeting the receptors to different intracellular locations.

Neuronal nAChRs exhibit a range of single-channel conductances between 5 and 50 pS, depending on the tissue or the specific subunits expressed. All the neuronal nAChRs are cation-permeable channels that, in addition to permitting the influx of  $\text{Na}^+$  and the efflux of  $\text{K}^+$ , permit an influx of  $\text{Ca}^{2+}$ . The  $\text{Ca}^{2+}$  permeability for neuronal nAChR is greater than that for the muscle nAChR and is variable among the different neuronal receptor subtypes. Indeed, some receptors have very high  $\text{Ca}^{2+}/\text{Na}^+$  permeability ratios; for example,  $\alpha 7$  nAChRs exhibit a  $\text{Ca}^{2+}/\text{Na}^+$  permeability ratio of nearly 20, whereas other neuronal isoforms exhibit  $\text{Ca}^{2+}/\text{Na}^+$  permeability ratios of about 1.0–1.5. The  $\text{Ca}^{2+}$  permeability of the  $\alpha 7$  nAChR can be eliminated by the mutation of a single amino acid residue in TM2 (Glu-237 for A1a) without significantly affecting other aspects of the receptor. This key Glu residue presumably lies within the pore of the receptor and enhances the passage of  $\text{Ca}^{2+}$  ions through an interaction with its negatively charged side chain. Activation of  $\alpha 7$  receptors through the binding of ACh therefore could produce a significant increase in the level of

intracellular  $\text{Ca}^{2+}$  without the opening of voltage-gated  $\text{Ca}^{2+}$  channels. Subunits  $\alpha 7$ ,  $\alpha 8$ , and  $\alpha 9$  are also the  $\alpha$ -bungarotoxin-binding subtypes of neuronal nAChRs.

For the nAChR from muscle, desensitization is minor and probably is not of physiological significance in determining the shape of the synaptic response at the neuromuscular junction. However, for some neuronal nAChRs, desensitization likely plays a major role in determining the effects of the actions of ACh. Receptors composed of  $\alpha 7$ ,  $\alpha 8$ , and certain  $\alpha/\beta$  combinations exhibit desensitization time constants of between 100 and 500 ms, whereas others exhibit desensitization constants between 2 and 20 s. Given the diverse functions of neuronal nAChRs, the variable rates of desensitization likely play important roles whereby this inherent property of the receptor shapes the physiological response generated from binding ACh.

### One Serotonin Receptor Subtype, 5-HT<sub>3</sub>, Is Iontropic and Is a Close Relative of the nAChR

5-HT historically is thought of as a metabotropic transmitter that binds to and activates only GPCRs (described in more detail later). The 5-HT<sub>3</sub> subclass is an exception forming an ionotropic receptor activated by binding 5-HT. The 5-HT<sub>3</sub> receptor is permeable to  $\text{Na}^+$  and  $\text{K}^+$  ions and is similar in many ways to nAChR in that both desensitize rapidly and are blocked by tubocurarine. From expression studies of the cloned cDNA, it appears that the 5-HT<sub>3</sub> receptor is a homomeric complex composed of five copies of the same subunit. The deduced amino acid sequence of the cDNA indicates that the protein is 487 amino acids long (56 kDa) and has a structure most analogous to the  $\alpha 7$  subtype of neuronal nAChRs, which also forms a homooligomeric receptor.

The 5-HT<sub>3</sub> receptor is mostly impermeable to divalent cations. For example,  $\text{Ca}^{2+}$  is largely excluded from permeation and in fact effectively blocks current flow through the pore, even though the predicted pore size of the channel (7.6 Å) is approximately the same as that for the nAChR (8.4 Å). Apparently, other physical or electrochemical barriers limit the capacity of divalent ions to permeate the 5-HT<sub>3</sub> pore. Dose-response studies indicate that at least two ligand-binding sites must be occupied for the channel to open; however, the binding of agonist and/or opening of the channel appears to be approximately 10 times slower than for most other ligand-gated ion channels. The functional significance or physical explanation of this slow opening is not known. The native 5-HT<sub>3</sub> receptor also exhibits desensitization (time constant 1–5 s), although the reported desensitization rate varies widely,

depending on the methodology used for analysis and the source of receptor. Interestingly, this desensitization can be significantly slowed or enhanced by single amino acid substitutions at a Leu residue in the TM2 segment of the subunit.

5-HT<sub>3</sub> receptors are distributed sparsely on primary sensory nerve endings in the periphery and are distributed widely at low concentrations in the mammalian CNS. The 5-HT<sub>3</sub> receptor is clinically significant because antagonists of 5-HT<sub>3</sub> receptors have important applications as antiemetics, anxiolytics, and antipsychotics.

### GABA<sub>A</sub> Receptors Are Related in Structure to nAChRs, but Exhibit an Inhibitory Function

Synaptic inhibition in the mammalian brain is mediated principally by GABA receptors. The most widespread ionotropic receptor activated by GABA is designated GABA<sub>A</sub>. The subunits composing the GABA<sub>A</sub> receptor have sequence homology with the nAChR subunit family, and the two families have presumably diverged from a common ancestral gene. The GABA<sub>A</sub> receptor is composed of multiple subunits, probably forming a heteropentameric complex of approximately 275 kDa. Five different types of subunits are associated with GABA<sub>A</sub> receptors and are designated  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$ . An additional subunit,  $\rho$ , is found predominantly in the retina, whereas the other subunits are distributed widely in the brain. Each subunit group also has different subtypes; for example, six different  $\alpha$ , four  $\beta$ , four  $\gamma$ , and two  $\rho$  subunits have been identified. The predicted amino acid sequences indicate that each of these subunits has a molecular mass ranging between 48 and 64 kDa. Like neuronal nAChR, these subunits mix in a heterogeneous fashion to produce a wide array of GABA<sub>A</sub> receptors with different pharmacological and electrophysiological properties. The predominant GABA<sub>A</sub> receptor in brain and spinal cord is  $\alpha 1$ ,  $\beta 2$ , and  $\gamma 2$  with a likely stoichiometry of two  $\alpha 1$ s, two  $\beta 2$ s, and one  $\gamma 2$ . Expression of subunit cDNAs in oocytes indicates that the  $\alpha$  subunit is essential for producing a functional channel. The  $\alpha$  subunit also appears to contain the high-affinity binding site for GABA.

The ion channel associated with the GABA<sub>A</sub> receptor is selective for anions (in particular,  $\text{Cl}^-$ ), and the selectivity is provided by strategically placed positively charged amino acids near the ends of the ion channel. When GABA binds to and activates this receptor,  $\text{Cl}^-$  flows into the cell, producing a hyperpolarization by moving the membrane potential away from the threshold for firing an action potential. The neuronal

GABA<sub>A</sub> receptor exhibits multiple conductance levels, with the predominant conductance being 27–30 pS. Measurements and modeling of single-channel kinetics suggest that two sequential binding sites exist for anions within the pore.

### The GABA<sub>A</sub> Receptor Binds Several Compounds That Affect Its Properties

The GABA<sub>A</sub> receptor is an allosteric protein, its properties are modulated by the binding of a number of compounds. Two well-studied examples are barbiturates and benzodiazepines, both of which bind to the GABA<sub>A</sub> receptor and potentiate GABA binding. The net result is that in the presence of barbiturates, benzodiazepines, or both, the same concentration of GABA will cause increased inhibition. Benzodiazepine binding is conferred on the receptor by the  $\gamma$  subunit, but the presence of  $\alpha$  and  $\beta$  subunits is necessary for the qualitative and quantitative aspects of benzodiazepine binding. The benzodiazepine-binding site appears to lie along the interface between  $\alpha$  and  $\gamma$  subunits and only certain subtypes are sensitive to benzodiazepines. Benzodiazepine binding to GABA<sub>A</sub> receptors requires  $\alpha$ , 2, or 5 and  $\gamma$ 2 or 3; other subunit combinations are insensitive to benzodiazepines.

Picrotoxin, a potent convulsant compound, appears to bind within the channel pore of the GABA<sub>A</sub> receptor and prevent ion flow. Single-channel experiments indicate that picrotoxin either slowly blocks an open channel or prevents the GABA receptor from undergoing a transition into a long-duration open state. Apparently, barbiturates produce similar changes in channel properties, but they potentiate rather than inhibit GABA<sub>A</sub> receptor function. Bicuculline, another potent convulsant, appears to inhibit GABA<sub>A</sub> receptor channel activity by decreasing the binding of GABA to the receptor. Steroid metabolites of progesterone, corticosterone, and testosterone also appear to have potentiating effects on GABA currents that are similar in many ways to the action of barbiturates; however, the binding sites for these steroids and the barbiturates are distinct. Finally, penicillin directly inhibits GABA receptor function, apparently by binding within the pore and thus is designated an open channel blocker.

The physiological effects of compounds such as picrotoxin, bicuculline, and penicillin are striking. Each of these compounds at a sufficiently high concentration can produce widespread and sustained seizure activity. Conversely, many, but not all, of the sedative properties associated with barbiturates and benzodiazepines can be attributed to their ability to augment inhibition in the brain through enhancing the inhibitory potency of GABA.

Interestingly,  $\rho$ -subunit-containing GABA receptors, found in abundance in the retina, are pharmacologically unique. They are resistant to the inhibitory action of bicuculline, although they remain sensitive to blockage by picrotoxin. In addition, these retinal receptors are not sensitive to modulation by barbiturates or benzodiazepines. Thus,  $\rho$ -containing receptors are distinct from GABA<sub>A</sub> receptors and are similar to receptors earlier designated GABA<sub>C</sub>.

### The Glycine Receptor Is Closely Related to the GABA<sub>A</sub> Receptor

Glycine receptors are the major inhibitory receptors in the spinal cord and the brain stem. Glycine receptors are similar to GABA<sub>A</sub> receptors in that both are ion channels selectively permeable to the anion Cl<sup>-</sup>. The structure of the glycine receptor is indicative of this similarity in properties. The native complex is approximately 250 kDa and is composed of two main subunits:  $\alpha$  (48 kDa) and  $\beta$  (58 kDa). The receptor appears to be pentameric, most likely composed of three  $\alpha$  and two  $\beta$  subunits. The glycine receptor has an open channel conductance of approximately 35–50 pS, similar to that of the GABA<sub>A</sub> receptor. Strychnine is a potent antagonist of the glycine.

Four distinct  $\alpha$  subunits and one  $\beta$  subunit of the glycine receptor have been cloned. Each exhibits the typical predicted four transmembrane segments and are approximately 50% identical with one another at the amino acid level. Expression of a single  $\alpha$  subunit in oocytes is sufficient to produce functional glycine receptors, indicating that the  $\alpha$  subunit is the pore-forming unit of the native receptor.  $\beta$  subunits play exclusively modulatory roles, affecting, for example, sensitivity to the inhibitory actions of picrotoxin, and they are widespread in the brain. Because their distribution does not specifically colocalize with glycine receptor  $\alpha$  subunit mRNA,  $\beta$  subunits may serve other functions independent of their association with glycine receptor.

### Certain Purinergic Receptors Are Also Ionotropic

Purinergic chemical transmission is distributed throughout the body and is considered in greater detail in a later section on GPCRs. Purinergic receptors bind to ATP (or other nucleotide analogs) or its breakdown product adenosine. ATP is released from certain synaptic terminals in a quantal manner and often is packaged within synaptic vesicles containing another neurotransmitter, the best described being ACh and catecholamines.

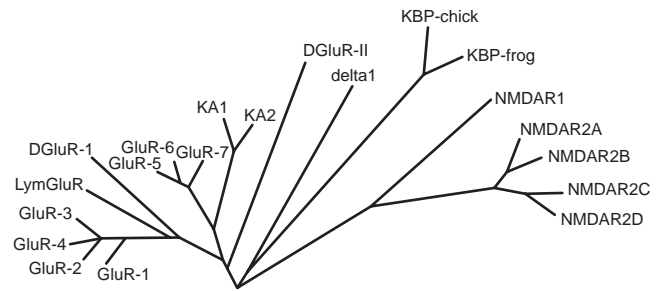

Two subtypes of ATP-binding purinergic receptors (P2x and P2z) have been discovered to be ionotropic receptors, but data on their functions and properties are sparse. P2x receptors appear to mediate a fast depolarizing response in neurons and muscle cells to ATP by the direct opening of a nonselective cation channel. cDNAs encoding the P2x receptor indicate that its structure comprises only two transmembrane domains, with some homology in its pore forming region with K<sup>+</sup> channels. The P2z receptor is also a ligand-gated channel that permits permeation of either anions or cations and even molecules as large as 900Da.

### Glutamate Receptors Are Derived from a Different Ancestral Gene and Are Structurally Distinct from Other Ionotropic Receptors

Glutamate receptors are widespread in the nervous system where they are responsible for mediating the vast majority of excitatory synaptic transmission in the brain and spinal cord. In the 1970s, Jeffrey Watkins and colleagues advanced this field significantly by developing agonists that could pharmacologically distinguish between different glutamate receptor subtypes. Four of these agonists—*N*-methyl-*D*-aspartate (NMDA), amino-3-hydroxy-5-methylisoxazolepropionic acid (AMPA), kainate, and quisqualate—are distinct in the type of receptors to which they bind and have been used extensively to characterize the glutamate receptor family (Watkins *et al.*, 1990; Hollmann and Heinemann, 1994). A convenient distinction for describing ionotropic glutamate receptors has been to classify them as either NMDA or non-NMDA subtypes, depending on whether they bind the agonist NMDA. Non-NMDA receptors also bind the agonist kainate or AMPA. Both NMDA and non-NMDA receptors are ionotropic. Quisqualate is unique within this group of agonists in having the capacity to activate both ionotropic and GPCR glutamate receptor subtypes (Hollmann and Heinemann, 1994). A family tree highlighting the evolutionary relationship of the glutamate receptors is shown in Figure 9.4.

### Non-NMDA Receptors Are a Diverse Family

In 1989, the isolation of a cDNA that produced a functional glutamate-activated channel when expressed in *Xenopus* oocytes was reported (Hollmann *et al.*, 1989). The initial glutamate receptor was termed GluR-K1, and the cDNA encoded a protein with an estimated molecular mass of 99.8kDa. Not long after this original report, several groups (Boulter *et al.*, 1990; Keinänen *et al.*, 1990; Nakanishi *et al.*, 1990) indepen-

**FIGURE 9.4** Evolutionary relationships of the ionotropic glutamate receptor family. Adapted from Hollmann and Heinemann (1994).

dently reported the isolation of families of glutamate receptor subunits, termed either GluR1–GluR4 or GluRA–GluRD. Each GluR subunit consists of approximately 900 amino acids and has four predicted membrane-spanning segments (TM1–TM4); however, there is an important distinction in the TM2 domain making the GluRs distinct from the nAChR family (Figs. 9.5A and 9.5B). The native form of GluR subunits appears to be a tetrameric complex with an approximate molecular mass of 600kDa. Thus, the size of the glutamate receptor is almost twice that of the nAChR, mostly because of the large extracellular domain where glutamate binds to the receptor.

### Unique Properties of Non-NMDA Receptors Are Determined by Assembly of Different Subunits

When cDNAs encoding these receptors were expressed in either oocytes or HeK-293 cells, application of the non-NMDA receptor agonist AMPA produced substantial inward currents. A striking observation from these expression studies was that when the GluR2 subunit alone was expressed in the oocytes, little current was obtained when the preparation was exposed to agonist, unlike the large currents found when either GluR1 or GluR3 was expressed (Verdoorn *et al.*, 1991; Nakanishi *et al.*, 1990). GluR2 subunits by themselves appear to form poorly conducting receptors. However, when GluR2 is expressed with either GluR1 or GluR3, the behavior of the heteromeric receptor is distinctly different.

Examination of *I/V* plots indicates that when GluR1 and GluR3 are expressed alone or together, they produce channels with strong inward rectification. Coexpression of GluR2 with either GluR1 or GluR3 produces a channel with little rectification and a near linear *I/V* plot. Further analyses indicated that GluR1 and GluR3, either independently or when coexpressed, exhibited channels permeable to Ca<sup>2+</sup> (Hollmann and

**FIGURE 9.5** (A) Model of one of the subunits of the ionotropic glutamate receptor. Ionotropic glutamate receptors have four membrane-associated segments; however, unlike nAChR, only three of them completely traverse the lipid bilayer. TM2 forms a loop and reexits into the cytoplasm. Thus, the large N-terminal region extends into the extracellular space, whereas the C terminus extends into the cytoplasm. Two domains in the extracellular segments associate with each other to form the binding site for transmitter, in this example kainate, a naturally occurring agonist of glutamate. (B) Enlarged area of the predicted structure and amino acid sequence of the TM2 region of the glutamate receptor, GluR3. TM1 and TM3 are drawn as cylinders in the membrane flanking TM2. The residue that determines  $\text{Ca}^{2+}$  permeability of the non-NMDA receptor is the glutamine residue (Q) highlighted in gray. In NMDA receptors, an asparagine residue at this same position is the proposed site of interaction with  $\text{Mg}^{2+}$  ions that produce the voltage-dependent channel block. Serine (S) and phenylalanine (F), also shaded in gray, are highly conserved in the non-NMDA receptor family. The aspartate (D) residue is also conserved and is thought to form part of the internal cation-binding site. The break in the loop between TM1 and TM2 indicates a domain that varies in length among ionotropic glutamate receptors. Adapted from Wo and Oswald (1995).

non- $\text{Ca}^{2+}$ -permeable to a  $\text{Ca}^{2+}$ -permeable channel (Burnashev *et al.*, 1992). Apparently, an Arg at this position blocks  $\text{Ca}^{2+}$  from traversing the pore formed in the center of the GluR channel.

### Functional Diversity in GluRs Is Produced by mRNA Splicing and RNA Editing

Analysis of mRNAs encoding GluR subunits indicated that each could be expressed in one of two splice variants, termed flip and flop. These flip and flop modules are small segments (38 amino acids) just preceding the TM4 domain in all four GluR subunits. The receptor channel expressed from these splice variants has distinct properties, depending on which of the two modules is present. Specifically, flop-containing receptors desensitize more during glutamate application. Therefore, GluRs with flop modules express smaller steady-state currents than GluRs with flip modules. Both flip- and flop-containing GluRs are widely expressed in the brain with a few exceptions. One unique cell type appears to be pyramidal CA3 cells in the rat hippocampus, where the GluRs are deficient in flop modules. In neighboring CA1 pyramidal cells and dentate granule cells, flop-containing GluRs appear to dominate. The significance of these splice variations for information processing in the brain is not known, but the physiological prediction would be that CA3 neurons exhibit larger steady-state glutamate-activated currents due to decreased desensitization from the absence of flop modules.

Heinemann, 1994). In contrast, any combination of receptor that included the GluR2 subunit produced channels impermeable to  $\text{Ca}^{2+}$ . The replacement of a single amino acid (Arg for Gln) in TM2 of the GluR2 subunit (see Fig. 9.5 for identification of this amino acid) was shown to switch its behavior from a

Typically, one believes that there is absolute fidelity in the process of transcribing DNA into mRNA and then into protein; that is, that nucleotides present in the DNA are accurate predictors of the ultimate amino acid sequence of the protein. However, a novel mechanism in the neuronal nucleus was discovered that edits mRNAs post transcriptionally, and at least three of the four GluR subunits are subjected to this process (Sommer *et al.*, 1991). In fact, one of the sites edited is the critical Arg residue regulating  $\text{Ca}^{2+}$  permeability in the GluR2 subunit. At another edited site, Gly replaces Arg-764 in the GluR2 subunit, and this editing also takes place in GluR3 and GluR4. The Arg-to-Gly conversion at amino acid 764 produces receptors that exhibit significantly faster rates of recovery from the desensitized state. The extent to which other receptors or other protein molecules undergo this form of editing is an area rich for investigation. At a minimum, this editing mechanism produces dramatic differences in the function of GluRs.

### Glutamate Receptors Do Not Conform to the Typical Four Transmembrane-Spanning Segment Structures Described for nAChR

Although the field of glutamate receptors is advancing at a rapid pace, we have limited structural data on the native molecule or on the topology of any single GluR subunit as it exists in the membrane. One exception is the recent report of the 3D structure of the native AMPA receptor determined by electron microscopy reconstructions (Nakagawa *et al.*, 2005). The study reveals the overall architecture of the tetrameric AMPA receptor complex and provides some global insights into how glutamate binding leads to channel opening. This low resolution structure compliments a significant amount of work analyzing crystal structures of the isolated glutamate receptor ligand binding domain with and without the presence of agonists and antagonists.

The glutamate receptor has a large extracellular domain that serves as the binding site for kainate and glutamate (Fig. 9.5A). Superficially, the remainder of the receptor originally was thought to resemble the nAChR in having four transmembrane segments that wrap back and forth through the membrane in an antiparallel fashion. However, that model now has been proven incorrect by a number of elegant molecular and biochemical studies. The most recent information indicates that the TM2 segment does not traverse the membrane completely (Fig. 9.5). Instead, it forms a kink within the membrane and enters back into the

cytoplasm, similar in some ways to the pore-forming domain (P segment) of voltage-activated  $\text{K}^+$  channels. An enlargement of this P segment (Fig. 9.5B) highlights the amino acids conserved in all the GluRs and further identifies the critical Gln residues responsible for  $\text{Ca}^{2+}$  permeability of the receptor. It also appears that glutamate receptors do not conform to the five-subunit structure of the nAChR. Both biochemical (Armstrong and Gouaux, 2000) and electrophysiological (Rosenmund *et al.*, 1998) evidence indicates that functional glutamate receptors are composed of four, not five subunits. Thus, it appears that glutamate receptors are a rather highly divergent form of the nAChR receptor family. In fact, their general structural features conform more closely to the family of  $\text{K}^+$  channels in that both appear tetrameric and both have a unique P segment that forms the selectivity filter.

### Other Non-NMDA GluRs Have Poorly Characterized Functions

Three other members, GluR5–7, now form a second non-NMDA receptor subfamily (Fig. 9.4), whose contribution to producing functionally distinct receptors is less well understood. Their overall structure is similar to that of GluR1–4, and they exhibit about 40% sequence homology; however, their agonist-binding profile and their electrophysiological properties are distinct. They are expressed at lower levels in the brain than the GluR1–4 family (Hollmann and Heinemann, 1994).

Two members of the glutamate receptor family, KA-1 and KA-2, are the high-affinity kainate-binding receptors found in brain. Clearly distinct from the glutamate receptors discussed so far, KA-1 and KA-2 are more similar to the GluR5–7 subfamily than to the GluR1–4 subfamily as indicated by their evolutionary relatedness (Fig. 9.4). Neither KA-1 nor KA-2 produces a functional channel when expressed in cells or oocytes, even though high-affinity kainate-binding sites were detected. KA-1 does not appear to form functional receptors or channels with any of the other GluR subunits, and its physiological relevance remains obscure. It is expressed at high concentrations in only two cell types, hippocampal CA3 and dentate granule cells. KA-2 exhibits interesting properties when combined with other GluR subunits. For example, coexpression of GluR6 and KA-2 produces functional receptors that respond to AMPA, although neither subunit itself responds to this agonist. This information indicates that agonist-binding sites are at least partly formed at the interfaces between subunits.

## NMDA Receptors Are a Family of Ligand-Gated Ion Channels That Are Also Voltage Dependent

NMDA receptors appear to be at least partly responsible for aspects of development, learning and memory, and neuronal damage due to brain injury. The particular significance of this receptor to neuronal function comes from two of its unique properties. First, the receptor exhibits associativity. For the channel to be open the receptor must bind glutamate and the membrane must be depolarized. This behavior is due to a  $Mg^{2+}$ -dependent block of the receptor at normal membrane resting potentials. Second, the receptor permits a significant influx of  $Ca^{2+}$ , and increases in intracellular  $Ca^{2+}$  activate a variety of processes that alter the properties of the neuron. Excess  $Ca^{2+}$  is also toxic to neurons, and the hyperactivation of NMDA receptors is thought to contribute to a variety of neurodegenerative disorders.

Many pharmacological compounds produce their effects through interactions with the NMDA receptor. For example, certain hallucinogenic compounds, such as phencyclidine (PCP) and dizocilpine (MK-801), are effective blockers of the ion channel associated with

the NMDA receptor (Fig. 9.6). These potent antagonists require the receptor channel to be open to gain access to their binding sites and therefore are referred to as open-channel blockers. They also become trapped when the channel closes and therefore are difficult to wash out of the channel of the NMDA receptor. Antagonists for the glutamate-binding site also have been developed, and some of the most well known are AP-5 and AP-7. These and other antagonists specific for the glutamate-binding site also produce hallucinogenic effects in both animal models and humans. NMDA remains a specific agonist for this receptor; however, it is about one order of magnitude less potent than L-Glutamate for receptor activation. L-Glutamate is the predominant neurotransmitter that activates the NMDA receptor; however, L-aspartate can also activate the receptor, as can an endogenous dipeptide in the brain, *N*-acetylaspartylglutamate (Hollmann and Heinemann, 1994).

## NMDA Receptor Subunits Show Similarity to Non-NMDA Receptor Subunits

The primary structure of the NMDA receptor was revealed in 1990 when the first cDNA encoding

**FIGURE 9.6** Diagram of a NMDA receptor highlighting binding sites for numerous agonists, antagonists, and other regulatory molecules. The location of these sites is a crude approximation for the purpose of discussion. Adapted from Hollmann and Heinemann (1994).

a subunit of the NMDA receptor was isolated (Moriyoshi *et al.*, 1991). The first cloned subunit was aptly named NMDAR1, and the deduced amino acid sequence indicated a protein of approximately 97 kDa, similar to other members of the GluR family. Four potential transmembrane domains were identified, and the current assumption is that four individual subunits compose the macromolecular NMDA receptor complex. However, recall that the transmembrane organization of GluR subunits indicates that TM2 does not fully transverse the membrane. It seems likely that the NMDA receptor subunits will also follow this recent modification of the model. The TM2 segment of each subunit clearly lines the pore of the NMDA receptor channel, as does the TM2 segment of the GluR subunits. In fact, a single Asn residue, analogous to that in the GluR2 subunit, regulates the  $\text{Ca}^{2+}$  permeability of the NMDA receptor. Mutation of this Asn residue reduces  $\text{Ca}^{2+}$  permeability markedly.

Three of the best-characterized facets of the NMDA receptor were found when the NMDAR1 subunit initially was expressed by itself in oocytes, although currents were relatively small. These characteristics are (1) a  $\text{Mg}^{2+}$ -dependent, voltage-sensitive ion channel block, (2) a glycine requirement for effective channel opening, and (3)  $\text{Ca}^{2+}$  permeability (Moriyoshi *et al.*, 1991). As described later, other NMDAR subunits contribute to assembly of the receptors thought to exist in the nervous system.

### Functional Diversity of NMDA Receptors Occurs through RNA Splicing

At least eight splice variants now have been identified for the NMDAR1 subunit and these variants produce differences, ranging from subtle to significant, in the properties of the expressed receptor (Hollmann and Heinemann, 1994). For example, NMDAR1 receptors lacking a particular N-terminal insert due to alternative splicing exhibit enhanced blockade by protons and exhibit responses that are potentiated by  $\text{Zn}^{2+}$  in micromolar concentrations.  $\text{Zn}^{2+}$  classically has been described as an NMDA receptor antagonist that significantly blocks its activation. Clearly, the particular splice variant incorporated into the receptor complex affects the types of physiological response generated. Spermine, a polyamine found in neurons and in the extracellular space, also slightly increases the amplitude of NMDA responses, and this modulatory effect also appears to be associated with a particular splice variant. The physiologic role of spermine in regulating NMDA receptors remains unclear.

### Multiple NMDA Receptor Subunit Genes Also Contribute to Functional Diversity

Four other members of the NMDA receptor family have been cloned (NMDAR2A–2D), and their deduced primary structures are highly related. These four NMDA receptor subunits do not form channels when expressed singly or in combination unless they are coexpressed with NMDAR1. Apparently, NMDAR1 serves an essential function for the formation of a functional pore by which activation of NMDA receptors permits the flow of ions. NMDA receptors 2A–2D play important roles in modulating the receptor activity when mixed as heteromeric forms with NMDAR1. Coexpression of NMDAR1 with any of the other subunits produces much larger currents (from 5- to 60-fold greater) than when NMDAR1 is expressed in isolation, and NMDA receptors expressed in neurons are likely to be heterooligomers of NMDAR1 and NMDAR2 subunits. The C-terminal domains of NMDAR2A–2D are quite large relative to the NMDAR1 C-terminus and appear to play roles in altering channel properties and in affecting the subcellular localization of the receptors. All the NMDAR subunits have an Asn residue at the critical point in the TM2 domain essential for producing  $\text{Ca}^{2+}$  permeability. This Asn residue also appears to form at least part of the binding site for  $\text{Mg}^{2+}$ , which suggests that the sites for  $\text{Mg}^{2+}$  binding and  $\text{Ca}^{2+}$  permeation overlap.

The distribution of NMDAR2 subunits generally is more restricted than the homogeneous distribution of NMDAR1, with the exception of NMDAR2A, which is expressed throughout the nervous system. NMDAR2C is restricted mostly to cerebellar granule cells, whereas 2B and 2D exhibit broader distributions. As noted, the large size of the C terminus of the NMDAR2 subunit suggests a potential role in association with other proteins, possibly to target or restrict specific NMDA receptor types to areas of the neuron. Mechanisms related to receptor targeting now are becoming understood and will clearly play major roles in determining the efficacy of synaptic transmission.

### NMDA Receptors Exhibit Complex Channel Properties

The biophysical properties of the NMDA receptor are complex. Single-channel conductance has a main level of 50 pS; however, subconductances are evident, and different subunit combinations produce channels with distinct single-channel properties. A binding site for the  $\text{Ca}^{2+}$ -binding protein calmodulin also has been identified on the NMDAR1 subunit. Binding of  $\text{Ca}^{2+}$ -calmodulin to NMDA receptors produces a four-fold

decrease in open-channel probability.  $\text{Ca}^{2+}$  influx through the NMDA receptor could induce calmodulin binding and lead to an immediate short-term feedback inhibition, decreasing ion flow through the receptor.

### Summary

A general model for ionotropic receptors has emerged mainly from analyses of nAChR. Ionotropic receptors are large membrane-bound complexes generally composed of five subunits. The subunits each have four transmembrane domains, and the amino acids in TM2 form the lining of the pore. Transmitter binding induces rapid conformational changes that are translated into an increase in the diameter of the pore, permitting ion influx. Cation or anion selectivity is obtained through the coordination of specific negatively or positively charged amino acids at strategic locations in the receptor pore. How well the details of structural information obtained for the nAChR will generalize to other ionotropic receptors awaits structural analyses of these other members. However, it is already clear that this model does not adequately describe the orientation of the transmembrane domains or the subunit number of the glutamate receptor family. The TM2 domain of glutamate receptors forms a hairpin instead of traversing the membrane completely, causing the remainder of the receptor to adopt a different architecture than that described for the nAChR family. It also appears that glutamate receptors are composed of four, not five, subunits. These differences are perhaps not surprising given that the nAChR family and the glutamate receptor family appear to have arisen from two different ancestral genes.

## G-PROTEIN COUPLED RECEPTORS

The number of members in the G-protein coupled receptor family is enormous, with over 1000 already identified. Historically, the term *metabotropic* was used to describe the fact that intracellular metabolites are produced when these receptors bind ligand. However, there are now clearly documented cases where the activation of "metabotropic" receptors does not produce alterations in metabolites but instead produces their effects by interacting with G-proteins that alter the behavior of ion channels. Thus, these receptors are now referred to as G-protein-coupled receptors (GPCRs).

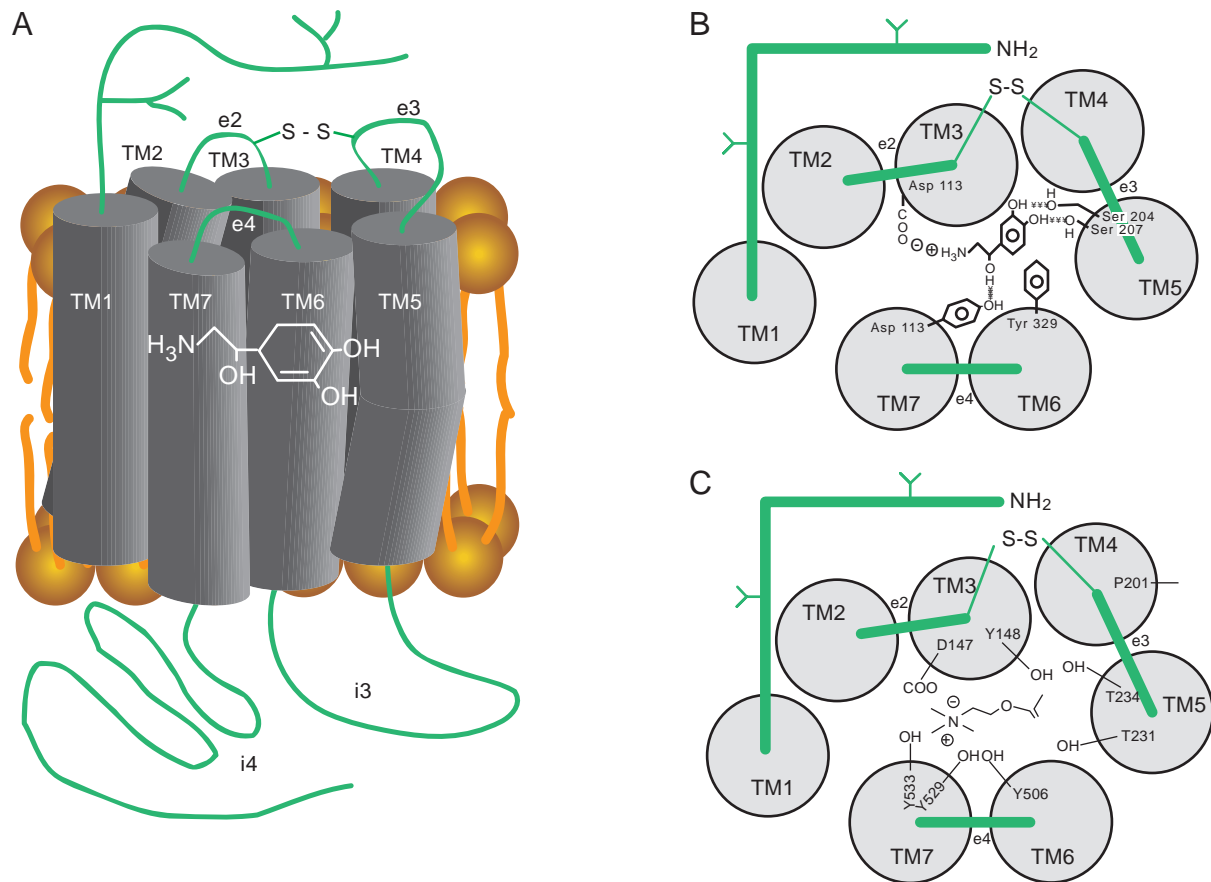

When a GPCR is activated, it couples to a G-protein initiating the exchange of GDP for GTP, activating the G-protein (Fig. 9.1B). Activated G-proteins then couple to many downstream effectors and most alter the activ-

ity of other intracellular enzymes or ion channels. Many of the G-protein target enzymes produce diffusible second messengers (metabolites) that stimulate further downstream biochemical processes, including the activation of protein kinases (see Chapter 10). Time is required for each of these coupling events, and the effects of GPCR activation are typically slower in onset than those observed following the activation of ionotropic receptors. Because there is a lifetime associated with each intermediate, the effects produced by GPCR activation are also typically longer in duration than those produced by the activation of ionotropic receptors. Most small neurotransmitters, such as ACh, glutamate, 5-HT, and GABA, can bind to and activate both ionotropic and GPCRs. Thus, each of these transmitters can induce both fast responses (milliseconds), such as typical excitatory or inhibitory postsynaptic potentials, and slow-onset and longer duration responses (from tenths of seconds to, potentially, hours). Other transmitters, like neuropeptides, produce their effects largely by binding only to GPCRs. These effects across multiple time domains provide the nervous system with a rich source for temporal information processing that is subject to constant modification. Currently, the GPCR family can be divided into three subfamilies on the basis of their structures: (1) the rhodopsin-adrenergic receptor subfamily, (2) the secretin-vasoactive intestinal peptide receptor subfamily, and (3) the metabotropic glutamate receptor subfamily.

### GPCR Structure Conforms to a General Model

A GPCR consists of a single polypeptide with a generally conserved structure. The receptor contains seven helical segments that wrap back and forth through the membrane (Fig. 9.7). G-protein-coupled receptors are homologous to rhodopsin from both mammalian and bacterial sources, and detailed structural information on rhodopsin has been used to provide a framework for developing a general model for GPCR structures. Aside from rhodopsin, two of the best structurally characterized GPCRs are the  $\beta$ -adrenergic receptor ( $\beta$ AR) and the muscarinic acetylcholine receptor (mAChR), and biochemical analyses to date support the use of rhodopsin as a structural framework for the family of GPCRs.

The most conserved feature of GPCRs is the seven membrane-spanning segments; however, other generalities can be made about their structure. The N terminus of the receptor extends into the extracellular space, whereas the C terminus resides within the cytoplasm (Fig. 9.7A). Each of the seven transmembrane domains between N and C termini consists of approximately 24

**FIGURE 9.7** (A) Diagram showing the approximate position of the catecholamine-binding site in the  $\beta$ AR. The transmitter-binding site is formed by amino acids whose side chains extend into the center of the ring produced by the seven transmembrane domains (TM1–TM7). Note that the binding site exists at a position that places it within the plane of the lipid bilayer. (B) A view looking down on a model of the  $\beta$ AR identifying residues important for ligand binding. The seven transmembrane domains are represented as gray circles labeled TM1 through TM7. Amino acids composing the extracellular domains are represented as green bars labeled e1 through e4. The disulfide bond (–S–S–) that links e2 to e3 is also shown. Each of the specific residues indicated makes stabilizing contact with the transmitter. (C) A view looking down on a model of the mAChR identifying residues important for ligand binding. Stabilizing contacts, mainly through hydroxyl groups (–OH), are made with the transmitter on four of the seven transmembrane domains. The chemical nature of the transmitter (i.e., epinephrine versus ACh) determines the type of amino acids necessary to produce stable interactions in the receptor-binding site (compare B and C). Adapted from Strosberg (1990).

mostly hydrophobic amino acids. These seven domains associate together to form an oblong ring within the plasma membrane (Fig. 9.7B). Between each transmembrane domain is a loop of amino acids of various sizes. The loops connecting TM1 and TM2, TM3 and TM4, and TM5 and TM6 are intracellular and are labeled i1, i2, and i3, respectively, whereas those between TM2 and TM3, TM4 and TM5, and TM6 and TM7 are extracellular and are labeled e1, e2, and e3, respectively (see Fig. 9.7A).

### The Neurotransmitter-Binding Site Is Buried in the Core of the Receptor

The neurotransmitter-binding site for many GPCRs (excluding the metabotropic glutamate,  $GABA_B$ , and

neuropeptide receptors) resides within a pocket formed in the center of the seven membrane-spanning segments (Fig. 9.7). In the  $\beta$ AR, this pocket resides at least 10.9 Å into the hydrophobic core of the receptor, placing the ligand-binding site within the plasma membrane lipid bilayer (Kobilka, 1992). Strategically positioned charged and polar residues in the membrane-spanning segments point inward into a central pocket that forms the binding site for the ligand. For example, Asn residues in the second and third segments, two Ser residues in the fifth segment, and a Phe residue in the sixth segment provide major contact points in the  $\beta$ AR-binding site for the transmitter (Fig. 9.7B; Kobilka, 1992). Replacing the Asp in TM3 with a Glu reduced transmitter binding by more than 100-fold, and replacement with a less conserved amino

acid, such as Ser, reduces binding by more than 10,000-fold. Two Ser residues in TM5 are also essential for efficient transmitter binding and receptor activation, as is an Asp residue in TM2 and a Phe residue in TM6. In total, the two Asp, the two Ser, and the Phe residues are highly conserved in all receptors that bind catecholamines. Variations in the amino acids at these five positions appear to provide the specificity between binding of different transmitters to the individual GPCRs.

The neurotransmitter-binding site of mAChRs, like that of the  $\beta$ 2AR, has been investigated in great detail (Fig. 9.7C). The Asp residue in TM3 is also critical for ACh binding to mAChRs. Mutagenesis studies indicate important roles for Tyr and Thr residues in TM3, TM5, TM6, and TM7 in contributing to the ligand-binding site for ACh. Interestingly, many of these mutations do not affect antagonist binding, indicating that distinct sets of amino acids participate in binding agonists and antagonists. When the transmembrane domains are examined from a side view (Fig. 9.7A), all the key amino acids implicated in agonist binding lie at about the same level within the core of the receptor structure, buried approximately 10–15 Å from the surface of the plasma membrane. An additional amino acid identified as essential for agonist binding of the mAChR is a Pro residue in TM4 (P201 in Fig. 9.7C). This residue is also highly conserved among GPCRs, and structural predictions suggest that it affects ligand binding not by interacting with agonist directly but by stabilizing a conformation essential for high-affinity binding. Structural predictions also place this Pro residue in the same plane as the Asp, Tyr, and Thr residues that form the ligand-binding site of the mAChR.

### Transmitter Binding Causes a Conformational Change in the Receptor and Activation of G-Proteins

Proposed models for GPCR activation assume that the receptor can isomerize spontaneously between inactive and active states. Only the active state interacts with G-proteins in a productive fashion. This isomerization is analogous to the spontaneous isomerization proposed for ion channels as they oscillate between open and closed states. In the absence of agonist, the inactive state of GPCRs is favored, and little G-protein activation occurs. Agonist binding stabilizes the active conformation and shifts the equilibrium toward the active form, and G-protein activation ensues. This kinetic model indicates that agonist binding is not necessary for the receptor to undergo transition into the active state; instead, it stabilizes the

activated state of the receptor. This proposed model is supported by observations of both spontaneously arising and engineered mutants of  $\beta$ AR and  $\alpha$ AR receptors. Specific amino acid replacements produced receptors that exhibit constitutive activity in the absence of agonists (Premont *et al.*, 1995). The amino acid changes apparently stabilize the active conformation of the molecule in a state more similar to the agonist-bound form of the receptor, leading to productive interactions with G proteins in the agonist-free state.

### The Third Intracellular Loop Forms a Major Determinant for G-Protein Coupling

Extensive studies using site-directed mutagenesis and the production of chimeric molecules have revealed the domains and amino acids essential for G-protein coupling to GPCRs. Receptor domains within the second (i2) and third (i3) intracellular loops (Fig. 9.7) appear largely responsible for determining the specificity and efficiency of coupling for adrenergic and muscarinic cholinergic receptors and are the likely sites for G-protein coupling of the entire GPCR family. In particular, the 12 amino acids of the N-terminal region of the third intracellular loop significantly affect the specificity of G-protein coupling. Other regions in the C terminus of the third intracellular loop and the N-terminal region of the C-terminal tail appear to be more important for determining the efficiency of G-protein coupling than for determining its specificity (Kobilka, 1992). The third intracellular loop varies enormously in size among the different G-protein-coupled receptors, ranging from 29 amino acids in the substance P receptor to 242 amino acids in the mAChR (Strader *et al.*, 1994). The intracellular loop connecting TM5 and TM6 is the main point of receptor coupling to G-proteins, and ligand binding to amino acids in TM5 and TM6 may be responsible for triggering the G-protein–receptor interaction by transmitting a conformational change to the third intracellular loop.

### Specific Amino Acids Are Involved in Transducing Transmitter Binding into G-Protein Coupling

Residues associated with transmitting the conformational change induced by ligand binding to the activation of G-proteins have been investigated with the use of mAChRs. These studies revealed that an Asp residue in TM2 is important for the receptor activation of G-proteins, and altering the Asp by site-directed mutagenesis has a major negative effect on G-protein–receptor activation. A Thr residue in TM5 (T231 in

Fig. 9.7C) and a Tyr residue in TM6 (Y506 in Fig. 9.7C) are also essential. Because these residues are connected by i3, they are assumed to play fundamental roles in transmitting the conformational change induced by ligand binding to the area of i3 essential for G-protein coupling and activation. When mutated, a Pro residue on TM7 produces a major impairment in the ability of the TM3 segment to induce the activation of phospholipase C through a G-protein and presumably is another key element in propagating the conformational changes necessary for efficient coupling to G-proteins.

As mentioned earlier, GPCRs are single polypeptides; however, they are clearly separable into distinct functional domains. For example,  $\beta$ 2AR can be physically split, with the use of molecular techniques, into two fragments: one fragment containing TM1–TM5 and the other containing TM6 and TM7. In isolation, neither of these fragments can produce a functional receptor; however, when coexpressed in the same cell, functional  $\beta$ 2ARs that can bind ligand and activate G-proteins are produced. This remarkable experiment indicates that physical contiguity in the primary sequence is not essential for producing functional  $\beta$ 2ARs and also emphasizes the contribution of domains in the separate fragments (TM1–TM5 and TM6 and TM7) to both ligand binding and G-protein coupling.

### GPCRs Also Exist as Homo- or Heterooligomers

The observation that GPCRs can be physically split through genetic engineering and produced functional channels when recombined provided the first hint that full-length GPCRs might also oligomerize with each other into functional molecules. A test of this hypothesis was accomplished by making chimeric receptors composed of the transmembrane domains 1–5 of the  $\alpha$ 2-AR and the transmembrane domains 6 and 7 of the m3 muscarinic receptors and vice versa. When either of these chimeric molecules was expressed in isolation, neither formed a functional receptor. However, when coexpressed, receptors were formed that bind both muscarinic and adrenergic ligands and ligand binding led to functional activation of downstream effectors. Through domain swapping, the ligand-binding sites for both receptor ligands were reconstituted by oligomerization of the two chimeric receptors into one bifunctional chimeric dimer. Although some debate remains, evidence now seems overwhelming that oligomerization of GPCRs is adding a new layer of complexity and diversity to the study of these receptors. Important functional consequences could relate to alterations in (1) ligand binding, (2) efficiency and

specificity of coupling to downstream effectors, (3) subcellular localization, and (4) receptor desensitization. The evolving and apparently widespread nature of direct receptor–receptor interactions leads one to believe that our current understanding of neurotransmitter receptors and their biological impact will be undergoing continual modifications for many years to come.

### G-Protein Coupling Increases Affinity of the Receptor for Neurotransmitter

The affinity of a GPCR for agonist increases when the receptor is coupled to the G-protein. This positive feedback effectively increases the lifetime of the agonist-bound form of the receptor by decreasing the dissociation rate of the agonist. An excellent demonstration of this effect comes from studies using engineered  $\beta$ AR receptors that are constitutively active in their ability to couple to G-proteins. These mutant receptors show a significantly increased affinity for agonists. When the G-protein dissociates, the agonist-binding affinity of the receptor returns to its original state. Changes induced by ligand binding apparently stabilize the receptor in a conformation with both higher affinity for ligand and higher affinity for coupling to G-proteins.

### Specificity and Potency of G-Protein Activation Are Determined by Several Factors

GPCRs associate with G-proteins to transduce ligand binding into intracellular effects. This coupling step can lead to diverse responses, depending on the type of G-protein and the type of effector enzyme present. Ligand binding to a single subtype of GPCR can activate multiple G-protein-coupled pathways. For example, activated  $\alpha$ 2ARs have been shown to couple to as many as four different G-proteins in the same cell (Strader *et al.*, 1994). Some of the specificity for G-protein activation can be determined by the specific conformations assumed by the receptor, and a single receptor can assume multiple conformations. For example,  $\alpha$ 2ARs can isomerize into at least two states. One state interacts with a G-protein that couples to phospholipase C, and a second state interacts with G-proteins that couple to both phospholipase C and phospholipase A<sub>2</sub>. Thus, a single GPCR can produce a diversity of responses, making it difficult to assign specific biological effects to individual receptor subtypes in all settings.

Activated GPCRs are free to couple to many G-protein molecules, permitting a significant amplification of the initial transmitter-binding event. This

catalytic mechanism is referred to as “collision coupling,” whereby a transient association between the activated receptor and the G-protein is sufficient to produce the exchange of GDP for GTP, activating the G-protein. For example, because adenylate cyclase appears to be tightly coupled to the G-protein, the rate-limiting step in the production of cAMP is the number of successful collisions between the receptor and the G-protein. A constant GTPase activity hydrolyzes GTP, bringing the G-protein and therefore the adenylate cyclase back to the basal state. The apparent maximal rate is achieved when all the G-protein-cyclase complexes have become activated or, more accurately, when the rate of formation is maximal with respect to the rate of GTP hydrolysis. Additionally, the important process of receptor desensitization can also regulate the number of receptors capable of productive G-protein interactions.

### Receptor Desensitization Is a Built-in Mechanism for Decreasing the Cellular Response to Transmitter

Desensitization is an important process whereby cells can decrease their sensitivity to a particular stimulus to prevent saturation of the system. Desensitization involves a complex series of events (Kobilka, 1992). For GPCRs, desensitization is defined as an increase in the concentration of agonist required to produce half-maximal stimulation of, for example, adenylate cyclase. In practical terms, desensitization of receptors produces less response for a constant amount of transmitter.

There are two known mechanisms for desensitization. One mechanism is a decrease in response brought about by the covalent modifications produced by receptor phosphorylation and is quite rapid (seconds to minutes). The other mechanism is the physical removal of receptors from the plasma membrane (likely through a mechanism of receptor-mediated endocytosis) and tends to require greater periods of time (minutes to hours). The latter process can be either reversible, sequestration, or irreversible, down-regulation (Fig. 9.8).

### The Rapid Phase of GPCR Desensitization Is Mediated by Receptor Phosphorylation

Desensitization of the  $\beta$ AR appears to involve at least three protein kinases: PKA, PKC, and  $\beta$ -adrenergic receptor kinase ( $\beta$ ARK; also referred to as a G-protein receptor kinase (GRK)). Phosphorylation of ARs by PKA does not require that the agonist be bound to the receptor and appears to be a general mechanism

**FIGURE 9.8** Intracellular pathways associated with desensitization of GPCRs. GPCRs are phosphorylated (noted with P) on their intracellular domains by PKA, GRK, and other protein kinases. The phosphorylated form of the receptor can be removed from the cell surface by a process called sequestration with the help of the adapter protein  $\beta$ -arrestin; thus fewer binding sites remain on the cell surface for transmitter interactions. In intracellular compartments, the receptor can be dephosphorylated and returned to the plasma membrane in its basal state. Alternatively, phosphorylated receptors can be degraded (downregulated) by targeting to a lysosomal organelle. Degradation requires replenishment of the receptor pool through new protein synthesis. Adapted from Kobilka (1992).

by which the cell can reduce the effectiveness of all receptors, independent of whether they are in the agonist-bound or unbound state. This process is also referred to as heterologous desensitization because the receptor does not require bound-agonist. PKA and PKC phosphorylate sites on the third intracellular loop and possibly the C-terminal cytoplasmic domain. Phosphorylation of these sites interferes with the ability of the receptor to couple to G-proteins, thus producing the desensitization.

GRKs can also phosphorylate GPCRs and lead to receptor desensitization. Six members of the GRK family of kinases have been identified: rhodopsin kinase (GRK1),  $\beta$ ARK (GRK2), and GRK3 through GRK6 (Premont *et al.*, 1995). GRK2 (originally called  $\beta$ -AR receptor kinase or  $\beta$ ARK) is a Ser- and Thr-specific protein kinase initially identified by its capacity to phosphorylate  $\beta$ AR. GRK2 phosphorylates only the agonist-bound form of the receptor, usually when agonist concentrations reach the micromolar level, as typically found in the synaptic cleft. This process is referred to as homologous desensitization because the regulation is specific for those receptor molecules that are in the agonist-bound state. Phosphorylation of  $\beta$ AR by GRK2 does not interfere substantially with coupling to G-proteins. Instead, an additional protein, arrestin, binds the GRK2-phosphorylated form of the receptor, thus blocking receptor–G-protein coupling (Fig. 9.8). This process is analogous to the desensitization of the light-sensitive receptor molecule rhodopsin produced by GRK1 phosphorylation and the binding of arrestin. Phosphorylation sites on  $\beta$ AR for GRK2 reside on the C-terminal cytoplasmic domain and are distinct from those phosphorylated by PKA.

The cycle of homologous desensitization starts with the activation of a GPCR, which induces activation of G-proteins and dissociation of the  $\beta\gamma$  subunit complex from  $\alpha$  subunits. At least one role for the  $\beta\gamma$  complex appears to be to bind to GRKs, which leads to their recruitment to the membrane in the area of the locally activated G-protein–receptor complex. The recruited GRK is then activated, leading to phosphorylation of the agonist-bound receptor and subsequent binding of arrestin. Arrestin binds to the same domains on the receptor necessary for coupling to G-proteins, thus terminating the actions of the activated receptor (Fig. 9.8). The ensuing process of sequestration follows GPCR phosphorylation and arrestin binding.

### Desensitization Can Also Be Produced by Loss of Receptors from the Cell Surface

Desensitization of GPCRs is also produced by removal of the receptor from the cell surface. This

process can be either reversible (sequestration, or internalization) or irreversible (downregulation). Sequestration is the term used to describe the rapid (within minutes) but reversible endocytosis of receptors from the cell surface after agonist application (Fig. 9.8). Neither G-protein coupling nor receptor phosphorylation appears to be essential for this process, but phosphorylation by GRKs clearly enhances the rate of sequestration. The binding of arrestins to the phosphorylated receptor also enhances sequestration (Ferguson *et al.*, 1996). Thus, arrestin binding appears to promote not only rapid desensitization by disrupting the receptor–G-protein interaction, but also receptor sequestration. Receptor cycling through intracellular organelles is a trafficking mechanism that leads to an enhanced rate of dephosphorylation of the phosphorylated receptor, returning it to the cell surface in its basal state (Fig. 9.8).

Downregulation occurs more slowly than sequestration and is irreversible (Fig. 9.8). The early phase (within 4h) may involve both a PKA-dependent and a PKA-independent process. This early phase of downregulation is apparently due to receptor degradation after endocytotic removal from the plasma membrane. The later phases (>14h) of downregulation appear to be further mediated by a reduction in receptor biosynthesis through a decrease in the stability of the receptor mRNA and a decreased transcription rate.

### Other Posttranslational Modifications Are Required for Efficient Metabotropic Receptor Function

Like many proteins expressed on the cell surface, GPCRs are glycosylated, and the N-terminal extracellular domain is the site of carbohydrate attachment. Relatively little is known about the effect of glycosylation on the function of GPCRs. Glycosylation does not appear to be essential to the production of a functional ligand-binding pocket (Strader *et al.*, 1994), although prevention of glycosylation may decrease membrane insertion and alter intracellular trafficking of the  $\beta$ 2AR.

Another important structural feature of most GPCRs is the disulfide bond formed between two Cys residues present on the extracellular loops (e2 and e3; Fig. 9.7). Apparently, the disulfide bond stabilizes a restricted conformation of the mature receptor by covalently linking the two extracellular domains, and this conformation favors ligand binding. Disruption of this disulfide bond significantly decreases agonist binding (Kobilka, 1992). A third Cys residue, in the C-terminal domain of GPCRs (in i4 Fig 9.7A), appears to serve as a point for covalent attachment of a fatty acid (often

palmitate). Presumably, fatty acid attachment stabilizes an interaction between the C-terminal domain of a GPCR and the membrane.

## GPCRs Can Physically Associate with Ionotropic Receptors

There is now good evidence that metabotropic and ionotropic receptors can interact directly with each other (Liu *et al.*, 2000). GABA<sub>A</sub> receptors (ionotropic) were shown to couple to DA (D5) receptors (metabotropic) through the second intracellular loop of the  $\gamma$  subunit of the GABA<sub>A</sub> receptor and the C-terminal domain of the D5, but not the D1, receptor. DA binding to D5 receptors produced downregulation of GABA<sub>A</sub> currents, and pharmacologically blocking the GABA<sub>A</sub> receptor produced decreases in cAMP production when cells were stimulated with DA. It further appeared that ligand binding to both receptors was necessary for their stable interaction. Whether this form of receptor regulation is unique to this pair of partners or is a widespread phenomenon remains an open question ripe for further investigation.

## GPCRs All Exhibit Similar Structures

The family of GPCRs exhibits structural similarities that permit the construction of “trees” describing the degree to which they are related evolutionarily (Fig. 9.9). Some remarkable relations become evident in such an analysis. For example, the D1 and D5 subtypes of DA receptors are related more closely to the  $\alpha$ 2AR than to the D2, D3, and D4 DA receptors. The similarities and differences among GPCR families are highlighted in the remainder of this chapter.

## Muscarinic ACh Receptors

Muscarine is a naturally occurring plant alkaloid that binds to muscarinic subtypes of the AChRs and activates them. mAChRs play a dominant role in mediating the actions of ACh in the brain, indirectly producing both excitation and inhibition through binding to a family of unique receptor subtypes. mAChRs are found both presynaptically and postsynaptically and, ultimately, their main neuronal effects appear to be mediated through alterations in the properties of ion channels. Presynaptic mAChRs take part in important feedback loops that regulate ACh release. ACh released from the presynaptic terminal can bind to mAChRs on the same nerve ending, thus activating enzymatic processes that modulate subsequent neurotransmitter release. This modulation is typically an inhibition; however, activation of m5 AChR produces an enhance-

**FIGURE 9.9** Evolutionary relationship of the GPCR family. To assemble this tree, sequence homologies in the transmembrane domains were compared for each receptor. Distance determines the degree of relatedness. r, rat; d, dog; h, human; tur, turkey; SRL, a putative serotonin receptor; and 5-HT, 5-hydroxytryptamine (serotonin). Adapted from Linden (1994). Original tree construction was by William Pearson and Kevin Lynch, University of Virginia.

ment in subsequent release. These *autoreceptors* are an important regulatory mechanism for the short-term (milliseconds to seconds) modulation of neurotransmitter release (see Chapter 7).

The family of mAChRs now includes five members (m1–m5), ranging from 55 to 70 kDa, and each of the five subtypes exhibits the typical architecture of seven transmembrane domains. Much of the diversity in this family of receptors resides in the third intracellular loop (i3) responsible for the specificity of coupling to G-proteins. The m1, m3, and m5 mAChRs couple predominantly to G-proteins that activate the enzyme phospholipase C. m2 and m4 receptors couple to G-proteins that inhibit adenylate cyclase, as well as to G-proteins that regulate K<sup>+</sup> and Ca<sup>2+</sup> channels directly. As is the case for other GPCRs, the domain near the N terminus of i3 is important for the specificity of G-protein coupling. This domain is conserved in m1, m3, and m5 AChRs, but is unique in m2 and m4. Several other important residues also have been identified for G-protein coupling. A particular Asp residue near the N-terminus of the second intracellular loop (i2) is important for G-protein coupling, as are residues residing in the C-terminal region of the i3 loop.

Major mAChRs found in the brain are m1, m3, and m4, and each is distributed diffusely. The m2 subtype is the heart isoform and is not highly expressed in other organs. Genes for m4 and m5 lack introns,

whereas those encoding m1, m2, and m3 contain introns, although little is known concerning alternatively spliced products of these receptors. Atropine is the most widely utilized antagonist for mAChR and binds to most subtypes, as does *N*-methylscopolamine. The antagonist pirenzepine appears to be relatively specific for the m1 mAChR, and other antagonists, such as AF-DX116 and hexahydrosiladifenidol, appear to be more selective for m2 and m3 subtypes.

## Adrenergic Receptors

The catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline) produce their effects by binding to and activating adrenergic receptors. Interestingly, epinephrine and norepinephrine can both bind to the same adrenergic receptor. Adrenergic receptors are currently separated into three families:  $\alpha 1$ ,  $\alpha 2$ , and  $\beta$  (Fig. 9.9). Each of the  $\alpha 1$  and  $\alpha 2$  families is further subdivided into three subclasses (Fig. 9.9). Similarly, the  $\beta$  family also contains three subclasses ( $\beta 1$ ,  $\beta 2$ , and  $\beta 3$ ; Fig. 9.9). The main adrenergic receptors in the brain are the  $\alpha 1$  and  $\beta 1$  subtypes.  $\alpha 2$ ARs have diverse roles, but the function that is best characterized (in both central and peripheral nervous tissue) is their role as autoreceptors. Different AR subtypes bind to G-proteins that can alter the activity of phospholipase C,  $\text{Ca}^{2+}$  channels, and, probably the best studied, adenylyl cyclase. For example, activation of  $\alpha 2$ ARs produces inhibition of adenylyl cyclase, whereas all  $\beta$ ARs activate the cyclase.

Only a few agonists or antagonists clearly distinguish the AR subtypes. One of them, isoproterenol, is an agonist that appears to be highly specific for  $\beta$ ARs. Propranolol is the best-known antagonist for  $\beta$  receptors, and phentolamine is a good antagonist for  $\alpha$  receptors but binds weakly at  $\beta$  receptors. The genomic organization of the different AR subtypes is unusual. Like many G-protein-coupled GPCRs,  $\beta 1$  and  $\beta 2$ ARs are encoded by genes lacking introns.  $\beta 3$ ARs, which apparently have a role in lipolysis and are poorly characterized, are encoded by an intron-containing gene, as are  $\alpha$ ARs, providing an opportunity for alternative splicing as a means of introducing functional heterogeneity into the receptor.

## Dopamine Receptors

Some 80% of the DA in the brain is localized to the corpus striatum, which receives major input from the substantia nigra and takes part in coordinating motor movements. DA is also found diffusely throughout the cortex, where its specific functions remain largely undefined. However, many neuroleptic drugs appear

to exert their effects by blocking DA binding, and imbalances in the dopaminergic system have long been associated with neuropsychiatric disorders.

DA receptors are found both pre- and postsynaptically, and their structure is homologous to that of the receptors for other catecholamines (Civelli *et al.*, 1993). Five subtypes of DA receptors can be grouped into two main classes: D1-like and D2-like receptors. D1-like receptors include D1 and D5, whereas D2-like receptors include D2, D3, and D4 (see Fig. 9.9). The main distinction between these two classes is that D1-like receptors activate adenylyl cyclase through interactions with  $G_s$ , whereas D2-like receptors inhibit adenylyl cyclase and other effector molecules by interacting with  $G_i/G_o$ . D1-like receptors are also slightly larger in molecular mass than D2-like receptors. An additional point of interest, as noted earlier, is that D5 receptors selectively associate with  $\text{GABA}_A$  receptors, impacting their function and vice versa (Liu *et al.*, 2000). The deduced amino acid sequence for the entire family ranges from 387 amino acids (D4) to 477 amino acids (D5). Main structural differences between D1-like and D2-like receptors are that the intracellular loop between the sixth and the seventh transmembrane segments is larger in D2-like receptors, and D2-like receptors have smaller C-terminal intracellular segments.

D1-like receptors, like  $\beta$ ARs, are transcribed from intronless genes. Conversely, all D2-like receptors contain introns, thus providing for possibilities of alternatively spliced products. Posttranslational modifications include glycosylation at one or more sites, disulfide bonding of the two Cys residues in e2 and e3, and acylation of the Cys residue in the C-terminal tail (analogous to the  $\beta 2$ AR). The DA-binding site includes two Ser residues in TM5 and an Asp residue in TM3, analogous to the  $\beta$ AR.

Because of the presumed role of DA in neuropsychiatric disorders, enormous effort has been put into developing pharmacological tools for manipulating this system. DA receptors bind bromocriptine, lisuride, clozapine, melperone, fluperlapine, and haloperidol. Because these drugs do not show great specificity for receptor subtypes, their usefulness for dissecting effects specifically related to binding to one or another DA receptor subtype is limited. However, their role in the treatment of human neuropsychiatric disorders is enormous (see Chapter 43).

## Purinergic Receptors

Purinergic receptors bind to ATP or other nucleotide analogs and to its breakdown product adenosine. Although ATP is a common constituent found within

synaptic vesicles, adenosine is not and is therefore not considered a "classic" neurotransmitter. However, the multitude of receptors that bind and are activated by adenosine indicates that this molecule has important modulatory effects on the nervous system. Situations of high metabolic activity that consume ATP and situations of insufficient ATP-regenerating capacity can lead to the accumulation of adenosine. Because adenosine is permeable to membranes and can diffuse into and out of cells, a feedback loop is established in which adenosine can serve as a local diffusible signal that communicates the metabolic status of the neuron to surrounding cells and vice versa (Linden, 1994).

The original nomenclature describing purinergic receptors defined adenosine as binding to P1 receptors and ATP as binding to P2 receptors. Families of both P1 and P2 receptors have since been described, and adenosine receptors are now identified as A-type purinergic receptors, consisting of A1, A2a, A2b, and A3. ATP receptors are designated as P type and consist of P2x, P2y, P2z, P2t, and P2u. Recall that P2x and P2z subtypes are ionotropic receptors (see earlier discussion).

A-type receptors exhibit the classic arrangement of seven transmembrane-spanning segments but are typically shorter than most GPCRs, ranging in size between 35 and 46 kDa. The ligand-binding site of A-type receptors is unique in that the ligand, adenosine, has no inherent charged moieties at physiological pH. A-type receptors appear to utilize His residues as their points of contact with adenosine, and, in particular, a His residue in TM7 is essential because its mutation eliminates agonist binding. Other His residues in TM6 and TM7 are conserved in all A-type receptors and may serve as other points of contact with agonists. A1 receptors are highly expressed in the brain, and their activation downregulates adenylate cyclase and increases phospholipase C activity. The A2a and A2b receptors are not as highly expressed in nervous tissue and are associated with the stimulation of adenylate cyclase and phospholipase C, respectively. The A3 subtype exhibits a unique pharmacological profile in that binding of xanthine derivatives, which blocks the action of adenosine competitively, is absent. Very low levels of the A3 receptor are found in brain and peripheral nervous tissue. The A3 receptor appears to be coupled to the activation of phospholipase C.

The P-type receptors, P2y, P2t, and P2u, are typical G-protein-linked GPCRs, mostly localized to the periphery. However, direct effects of ATP have been detected in neurons, and often the response is biphasic; an early excitatory effect followed, with its break-

down to adenosine, by a secondary inhibitory effect. Interestingly, P-type receptors exhibit a higher degree of homology to peptide-binding receptors than they do to A-type purinergic receptors. As in A-type receptors, P-type receptors have a His residue in the third transmembrane domain; however, other sites for ligand binding have not been specifically identified.

## Serotonin Receptors

Cell bodies containing serotonin (5-HT) are found in the raphe nucleus in the brain stem and in nerve endings distributed diffusely throughout the brain. 5-HT has been implicated in sleep, modulation of circadian rhythms, eating, and arousal. 5-HT also has hormone-like effects when released in the bloodstream, regulating smooth muscle contraction and affecting platelet-aggregating and immune systems.

5-HT receptors are classified into four subtypes, 5-HT1 to 5-HT4, with a further subdivision of 5-HT1 subtypes. Recall that the 5-HT3 receptor is ionotropic (see earlier discussion). The other 5-HT receptors exhibit the typical seven transmembrane-spanning segments and all couple to G-proteins to exert their effects. For example, 5-HT1a, 1b, 1d, and 4 either activate or inhibit adenylate cyclase. 5-HT1c and 5-HT2 receptors preferentially stimulate activation of phospholipase C to produce increased intracellular levels of diacylglycerol and inositol 1,4,5-trisphosphate.

5-HT receptors can also be grossly distributed into two groups on the basis of their gene structures. Both 5-HT1c and 5-HT2 are derived from genes that contain multiple introns. In contrast, similar to the  $\beta$ AR family, 5-HT1 is coded by a gene lacking introns. Interestingly, 5-HT1a is more closely related ancestrally to the  $\beta$ AR family than it is to other members of the 5-HT receptor family and originally was isolated by utilizing cDNA for the  $\beta$ 2AR as a molecular probe. This observation helps explain some pharmacological data suggesting that both 5-HT1a and 5-HT1b can bind certain adrenergic antagonists.

## Glutamate GPCRs

GPCRs that bind glutamate (metabotropic glutamate receptors (mGluRs)) are similar in general structure in having seven transmembrane-spanning segments to other GPCRs; however, they are divergent enough to be considered to have originated from a separate evolutionary-derived receptor family (Hollmann and Heinemann, 1994; Nakanishi, 1994). In fact, sequence homology between the mGluR family and other GPCRs is minimal except for the GABA<sub>B</sub> receptor. The mGluR family is heterogeneous in size, ranging

from 854 to 1179 amino acids. Both the N-terminal and the C-terminal domains are unusually large for G-protein-coupled receptors. One great difference in the structures of mGluRs is that the binding site for glutamate resides in the large N-terminal extracellular domain and is homologous to a bacterial amino acid-binding protein (Armstrong and Gouaux, 2000). In most of the other families of GPCRs, the ligand-binding pocket is formed by transmembrane segments partly buried in the membrane. Additionally, mGluRs exist as functional dimers in the membrane in contrast to the single subunit forms of most GPCRs (Kunishima *et al.*, 2000). These significant structural distinctions support the idea that mGluRs evolved separately from other GPCRs. The third intracellular loop, thought to be the major determinant responsible for G-protein coupling, of mGluRs is relatively small, whereas the C-terminal domain is quite large. The coupling between mGluRs and their respective G-proteins may be through unique determinants that exist in the large C-terminal domain.

Currently, eight different mGluRs can be subdivided into three groups on the basis of sequence homologies and their capacity to couple to specific enzyme systems. Both mGluR1 and mGluR5 activate a G-protein coupled to phospholipase C. mGluR1 activation can also lead to the production of cAMP and of arachidonic acid by coupling to G-proteins that activate adenylate cyclase and phospholipase A<sub>2</sub>. mGluR5 seems more specific, activating predominantly the G-protein-activated phospholipase C.

The other six mGluR subtypes are distinct from one another in favoring either *trans*-1-aminocyclopentane-1,3-dicarboxylate (mGluR2, 3, and 8) or 1-2-amino-4-phosphonobutyrate (mGluR4, 6, and 7) as agonists for activation. mGluR2 and mGluR4 can be further distinguished pharmacologically by using the agonist 2-(carboxycyclopropyl)glycine, which is more potent at activating mGluR2 receptors. Less is known about the mechanisms by which these receptors produce intracellular responses; however, one effect is to inhibit the production of cAMP by activating an inhibitory G-protein.

mGluRs are widespread in the nervous system and are found both pre- and postsynaptically. Presynaptically, they serve as autoreceptors and appear to participate in the inhibition of neurotransmitter release. Their postsynaptic roles appear to be quite varied and depend on the specific G-protein to which they are coupled. mGluR1 activation has been implicated in long-term synaptic plasticity at many sites in the brain, including long-term potentiation in the hippocampus and long-term depression in the cerebellum (see Chapter 49).

## GABA<sub>B</sub> Receptor

GABA<sub>B</sub> receptors are found throughout the nervous system, where they are sometimes colocalized with ionotropic GABA<sub>A</sub> receptors. GABA<sub>B</sub> receptors are present both pre- and postsynaptically. Presynaptically, they appear to mediate inhibition of neurotransmitter release through an autoreceptor-like mechanism by activating K<sup>+</sup> conductances and diminishing Ca<sup>2+</sup> conductances. In addition, GABA<sub>B</sub> receptors may affect K<sup>+</sup> channels through a direct physical coupling to the K<sup>+</sup> channel, not mediated through a G-protein intermediate. Postsynaptically, GABA<sub>B</sub> receptor activation produces a characteristic slow hyperpolarization (termed the slow inhibitory postsynaptic potential) through the activation of a K<sup>+</sup> conductance. This effect appears to be through a pertussis toxin-sensitive G-protein that inhibits adenylate cyclase.

Cloning of the GABA<sub>B</sub> receptor (GABA<sub>B</sub>R1) revealed that it has high sequence homology to the family of glutamate GPCRs, but shows little similarity to other G-protein-coupled receptors. The large N-terminal extracellular domain of the GABA<sub>B</sub> receptor is the presumed site of GABA binding. With the exception of this large extracellular domain, the GABA<sub>B</sub> receptor structure is typical of the GPCR family, exhibiting seven transmembrane domains. The initial cloning of the GABA<sub>B</sub> receptor was made possible by the development of the high-affinity, high-specificity antagonist CGP64213. This antagonist is several orders of magnitude more potent at inhibiting GABA<sub>B</sub> receptor function than the more widely known antagonist saclofen. Baclofen, an analog of saclofen, remains the best agonist for activating GABA<sub>B</sub> receptors.

Functional GABA<sub>B</sub> receptors appear to exist primarily as dimers in the membrane. Expression of the cloned GABA<sub>B</sub>R1 isoform does not produce significant functional receptors. However, when coexpressed with the GABA<sub>B</sub>R2 isoform, receptors that are indistinguishable functionally and pharmacologically from those in brain were produced. In addition, GABA<sub>B</sub> dimers exist in neuronal membranes, and all data point to the conclusion that GABA<sub>B</sub> receptors dimerize and that the dimer is the functionally important form of the receptor. As noted earlier, GPCRs can interact with themselves and other receptors. It is well to keep in mind that these types of direct receptor interactions may be more widespread than currently appreciated.

## Peptide Receptors

Neuropeptide receptors form an immense family. Because of their diversity, they cannot be covered in detail in this chapter. Despite this diversity, however,

none of the receptors that bind peptides appears to be coupled directly to the opening of ion channels. Neuropeptide receptors exert their effects either through the typical pathway of activation of G-proteins or through a more recently described pathway related to activation of an associated tyrosine kinase activity.

## Summary

GPCRs are single polypeptides composed of seven transmembrane-spanning segments. In general, the binding site for neurotransmitter is located within the core of the circular structure formed by these segments. Transmitter binding produces conformational changes in the receptor that expose parts of the i3 region, among others, for binding to G-proteins. G-protein binding increases the affinity of the receptor for transmitter. Desensitization is common among GPCRs and leads to a decreased response of the receptor to neurotransmitter by several distinct mechanisms. mGluRs are structurally distinct from other GPCRs; mGluRs have large N-terminal extracellular domains that form the binding site for glutamate. Otherwise, the basic structure of mGluRs appears to be similar to that of the rest of the GPCR family.

## Intracellular Signaling

Almost all aspects of neuronal function, from its maturation during development, to its growth and survival, cytoskeletal organization, gene expression, neurotransmission, and use-dependent modulation, are dependent on intracellular signaling initiated at the cell surface. The response of neurons and glia to neurotransmitters, growth factors, and other signaling molecules is determined by their complement of expressed receptors and pathways that transduce and transmit these signals to intracellular compartments and the enzymes, ion channels, and cytoskeletal proteins that ultimately mediate the effects of the neurotransmitters. Cellular responses are determined further by the concentration and localization of signal transduction components and are modified by the prior history of neuronal activity. Several primary classes of signaling systems, operating at different time courses, provide great flexibility for intercellular communication.

One class comprises ligand gated ion channels, such as the nicotinic receptor considered in Chapter 9. This class of signaling system provides fast transmission that is activated and deactivated within 10ms. It forms the underlying “hard wiring” of the nervous system that makes rapid multisynaptic computations possible. A second class consists of receptor tyrosine kinases, which typically respond to growth factors and to trophic factors and produce major changes in the growth, differentiation, or survival of neurons (Chapter 19). A third and largest class utilizes G-protein-linked signals in a multistep process that slows the response from 100 to 300ms to many minutes. The relatively slow speed is offset, however, by a richness in the diversity of its modulation and capacity for amplification. The initial steps in this signaling system typically generate a second messenger inside the cell, and this

second messenger then activates a number of proteins, including protein kinases that modify cellular processes. Signal transduction also modulates the level of transcription of genes, which determine the differentiated and functional state of cells.

### SIGNALING THROUGH G-PROTEIN-LINKED RECEPTORS

Signal transduction through G-protein-linked receptors requires three membrane-bound components:

1. A cell surface receptor that determines to which signal the cell can respond
2. A G protein on the intracellular side of the membrane that is stimulated by the activated receptor
3. Either an effector enzyme that changes the level of a second messenger or an effector channel that changes ionic fluxes in the cell in response to the activated G protein

The human genome encodes for more than 800 receptors for catecholamines, odorants, neuropeptides, and light that couple to one or more of the 16 identified G proteins. These, in turn, regulate one or more of more than two dozen different effector channels and enzymes. The key feature of this information flow is the ability of G proteins to detect the presence of activated receptors and to amplify the signal by altering the activity of appropriate effector enzymes and channels. A nervous system with information flow by fast transmission alone would be capable of stereotyped or reflex responses. Modulation of this transmission and changes in other cellular functions by G-protein-

linked systems and by receptor-tyrosine kinase-linked systems enables an orchestrated response. The large diversity of signaling molecules and their intracellular targets offer nearly unlimited flexibility of response over a broad time scale and with high amplification.

G proteins are GTP-binding proteins that couple the activation of seven-helix receptors by neurotransmitters at the cell surface to changes in the activity of effector enzymes and effector channels. A common effector enzyme is adenylate cyclase, which synthesizes cyclic AMP (cAMP)—an intracellular surrogate, or second messenger, for the neurotransmitter, the first messenger. Phospholipase C (PLC), another effector enzyme, generates diacylglycerol (DAG) and inositol 1, 4, 5-trisphosphate ( $IP_3$ ), the latter of which releases intracellular stores of  $Ca^{2+}$ . Information from an activated receptor flows to the second messengers that typically activate protein kinases, which modify a host of cellular functions.  $Ca^{2+}$ , cAMP, and DAG have in common the ability to activate protein kinases with broad substrate specificities. They phosphorylate key intracellular proteins, ion channels, enzymes, and transcription factors taking part in diverse cellular biological processes. The activities of protein kinases and phosphatases are in balance, constituting a highly regulated process, as revealed by the phosphorylation state of these targets of the signal transduction process.

In addition to regulating protein kinases, second messengers such as cAMP, cyclic GMP (cGMP),  $Ca^{2+}$ , and arachidonic acid can directly gate, or modulate, ion channels without the interception of second messengers or protein kinases. In these diverse ways, a neurotransmitter outside the cell can modulate essentially every aspect of cell physiology and encode the history of cell stimuli in the form of altered activity and expression of its cellular constituents. An overview of G-protein signaling to protein kinases is presented in Figure 10.1.

### Receptors Catalyze the Conversion of G Proteins into the Active GTP-Bound State

G proteins undergo a molecular switch between two interconvertible states that are used to “turn on” or “turn off” downstream signaling. G proteins taking part in signal transduction utilize a regulatory motif that is seen in other GTPases engaged in protein synthesis and in intracellular vesicular traffic. G proteins are switched on by stimulated receptors, and they switch themselves off after a time delay. G proteins are inactive when GDP is bound and are active when GTP is bound. The sole function of seven-helix receptors in activating G proteins is to catalyze an exchange of GTP

for GDP. This is a temporary switch because G proteins are designed with a GTPase activity that hydrolyzes the bound GTP and converts the G protein back into the GDP-bound, or inactive, state. Thus, a G protein must continuously sample the state of activation of the receptor, and it transmits downstream information only while the neuron is exposed to neurotransmitter. The GTPase activity of G proteins thus serves both as a regulatable timer and as an amplifier (Fig. 10.2).

### The G-Protein Cycle

G proteins are trimeric structures composed of two functional units: (1) an  $\alpha$  subunit (39–52 kDa) that catalyzes GTPase activity and (2) a  $\beta\gamma$  dimer (35 and 8 kDa,

**FIGURE 10.1** Overview of G-protein signaling to protein kinases. Norepinephrine (NE) and acetylcholine (ACh) can stimulate certain receptors that couple through distinct G proteins to different effectors, which results in increased synthesis of second messengers and activation of protein kinases (PKA and PKC). PLC, phospholipase C;  $PIP_2$ , phosphatidylinositol bisphosphate; DAG, diacylglycerol; CaM,  $Ca^{2+}$ -calmodulin dependent;  $IP_3$ , inositol 1, 4, 5-trisphosphate.

**FIGURE 10.2** GTPase activity of G proteins serves as a timer and amplifier. Receptors activated by neurotransmitters (NT) initiate the GTPase timing mechanism of G proteins by displacement of GDP by GTP. Neurotransmitters thus convert G—GDP (“turned-off state”) to GGTP (time-limited “turned-on” state).

respectively) that interacts tightly with the  $\alpha$  subunit when bound to GDP (Stryer and Bourne, 1986; Birnbaumer, 2007). The role of the three subunits in the G-protein cycle is depicted in Figures 10.3 and 10.4. In the basal state, GDP is bound tightly to the  $\alpha$  subunit, which is associated with the  $\beta\gamma$  pair to form an inactive G protein. In addition to blocking interaction of the  $\alpha$  subunit with its effector, the  $\beta\gamma$  pair increases the affinity of the  $\alpha$  subunit for activated receptors. Binding of the neurotransmitter to the receptor produces a conformational change that positions previously buried residues that promote increased affinity of the receptors for the inactive G protein. A given receptor can interact with only one or a limited number of G proteins, and the  $\alpha$  subunit produces most of this specificity. Coupling with the activated receptor reduces the affinity of the  $\alpha$  subunit for GDP, facilitating its dissociation and replacement with GTP. Thus, the receptor effectively catalyzes an exchange of GTP for GDP. GTP-GDP exchange is inherently very slow and ensures that very little of the G protein is in the on state under basal conditions. The level of G protein in the on state can increase from being 1% to being more than 50% of all G protein (Stryer and Bourne, 1986).

### Information Flow through G-Protein Subunits

One of the more tense and public debates in signal transduction has been the question whether the  $\alpha$  subunit alone conveys information that specifies which effector is activated or whether the  $\beta\gamma$  pair can also interact with effectors. One of the contestants even paid for a vanity license plate proclaiming “ $\alpha$  not  $\beta\gamma$ .” This notion was eventually changed because of the finding that  $\beta\gamma$  can directly activate certain  $K^+$  channels. It is now apparent that  $\alpha$  and  $\beta\gamma$  subunits can

**FIGURE 10.3** Interconversion, catalyzed by excited receptors, of G-protein subunits between inactive and active states. Displacement of GDP with GTP dissociates the inactive heterotrimeric G protein, generating  $\alpha$ -GTP and  $\beta\gamma$ , both of which can interact with their respective effectors and activate them. The system converts into the inactive state after GTP has been hydrolyzed and the subunits have reassociated. From Stryer (1995). Used with permission of W. H. Freeman and Company.

both modify effector enzymes, but the historic association of G-protein function with  $\alpha$  has persisted for the purpose of nomenclature, with  $G_s$  and  $\alpha_s$  referring to the G protein and its corresponding  $\alpha$  subunit, which stimulates adenylate cyclase. The  $\alpha$  subunits may act either independently or in concert with  $\beta\gamma$  (Clapham and Neer, 1993). Furthermore,  $\beta$  and  $\gamma$  subunits in a  $\beta\gamma$  pair can combine in many different ways. Other legacy terms include  $G_i$ ,  $G_p$ , and  $G_o$  used for G-protein activities that inhibited adenylate cyclase, stimulated phospholipase, or were presumed to have other effects, respectively.

### Effector Enzymes, Channels, and Transporters Decode Receptor-Mediated Cell Stimulation in the Cell Interior

The function of the trimeric G proteins is to decode information about the concentration of neurotransmitters bound to appropriate receptors on the cell surface and convert this information into a change in the activity of enzymes and channels that mediate the effects of the neurotransmitter. The known effector functions of  $\alpha$  include both stimulation and inhibition of adenylate cyclases that is sensitive to cholera toxin and pertussis toxin, respectively. In addition, it modulates activation of cGMP phosphodiesterase, PLC, and regulation of  $Na^+/K^+$  exchange, PI3K, RhoGEF, and rasGAP. The effector functions of  $\beta/\gamma$  dimers include inhibition of many adenylate cyclase and stimulation of adenylate cyclase types II and IV (with  $\alpha$ ). In addition, they regulate stimulation of phospholipase  $C\beta$ ,  $K^+$ , and  $Ca^{2+}$  channels, phospholipase  $A_2$ , phosphatidylinositol-3-kinase, PKD, and dynamin in vesicle budding.

### Response Specificity in G-Protein Signaling

Signals originating from activated receptors can either converge or diverge, depending on the receptor and on the complement of G proteins and effectors in a given neuron (Fig. 10.5). How can a neurotransmitter produce a specific response if G-protein coupling has the potential for such a diversity of effectors? A given neuron has only a subset of receptors, G proteins, and effectors, thereby limiting possible signaling pathways. Transducin, for example, is confined to the visual system, where the predominant effector is the cGMP phosphodiesterase and not adenylate cyclase. Signal specificity is further refined by selective affinities between cognate sets of receptors, G proteins, and effector(s); and by spatial compartmentalization (e.g., at nerve terminals).

Furthermore, the intrinsic GTPase activity can be modulated by GTPase-activating proteins (GAPs),

**FIGURE 10.4** (A) G proteins are held in an inactive state because of very high affinity binding of GDP to their  $\alpha$  subunits. When activated by agonist, membrane-bound seven helical receptors (right, glowing magenta) interact with heterotrimeric G proteins ( $\alpha$ , amber;  $\beta$ , teal;  $\gamma$ , burgundy) and stimulate dissociation of GDP. This permits GTP to bind to and activate  $\alpha$ , which then dissociates from the high-affinity dimer of  $\beta$  and  $\gamma$  subunits. (B) Both activated (GTP-bound)  $\alpha$  (lime) and  $\beta\gamma$  are capable of interacting with downstream effectors. This figure shows the interaction of GTP- $\alpha$  with adenylyl cyclase (catalytic domains are mustard and ash). Adenylyl cyclase then catalyzes the synthesis of the second messenger cyclic AMP (cAMP) from ATP. (C) Signaling is terminated when  $\alpha$  hydrolyzes its bound GTP to GDP. In some signaling systems, GTP hydrolysis is stimulated by GTPase-activating proteins or GAPs (cranberry) that bind to  $\alpha$  and stabilize the transition state for GTP hydrolysis. (D) Hydrolysis of GTP permits GDP- $\alpha$  to dissociate from its effector and associate again with  $\beta\gamma$ . The heterotrimeric G protein is then ready for another signaling cycle if an activated receptor is present. This figure is based on the original work of Mark Wall and John Tesmer.

which terminate its active state more quickly, and selectively affect signal output.

#### *Fine-Tuning of cAMP by Adenylyl Cyclases*

The level of cAMP is highly regulated due to a balance between synthesis by adenylyl cyclases and degradation by cAMP phosphodiesterases (PDEs). Each of these enzymes can be regulated and manipulated independently. Adenylyl cyclase was the first G-protein effector to be identified, and now a group of

related adenylyl cyclases are known to be regulated differentially by both  $\alpha$  and  $\beta\gamma$  subunits (Taussig and Gilman, 1995). G proteins can both activate and inhibit adenylyl cyclases either synergistically or antagonistically.

Adenylyl cyclases are large proteins of approximately 120 kDa. All the known classes of adenylyl cyclase consist of a tandem repeat of the same structural motif—a short cytoplasmic region followed by six putative transmembrane segments and then a

**FIGURE 10.5** Signals can converge or diverge on the basis of interactions between receptors (R) and G proteins (G) and between G proteins and effectors (E). The complement of receptors, G proteins, and effectors in a given neuron determines the degree of integration of signals, as well as whether cell stimulation will produce a focused response to a neurotransmitter or a coordination of divergent responses. Adapted from Ross (1989).

highly conserved catalytic domain of approximately 35kDa on the cytoplasmic side that bind ATP and catalyze its conversion into cAMP. Some isoforms are activated by calmodulin.

**Differential Regulation of Adenylate Cyclase Isoforms**

All adenylate cyclase isoforms are stimulated by  $G_s$  through its  $\alpha_s$  subunit. Known isoforms can be divided minimally into at least three groups on the basis of additional regulatory properties (Fig. 10.6). Group A (types I, III, and VIII) possesses a calmodulin-binding domain and is activated by  $Ca^{2+}$ -calmodulin. Group B (types II and IV) is weakly responsive to direct interaction with  $\alpha_s$  or  $\beta\gamma$  but is highly activated when both are present. As described later, this synergistic effect enables this cyclase to function as a coincidence detector. Group C is typified by types V and VI (and IX), which differ from group A cyclases in their inhibitory regulation.

**Inhibition of Adenylate Cyclases** Adenylate cyclases are also subject to several forms of inhibitory control. First, activation of all adenylate cyclases can be antagonized by  $\beta\gamma$  released from abundant G proteins, such as  $G_i$ ,  $G_o$ , and  $G_z$ , which complex with  $\alpha_s$ -GTP and shift the equilibrium toward an inactive trimer by mass

**FIGURE 10.6** Isoforms of adenylate cyclase (AC). All isoforms are stimulated by  $\alpha_s$  but differ in the degree of interaction with  $Ca^{2+}$ -calmodulin and with  $\beta\gamma$  derived from inhibitory G proteins. Not shown is the ability of excess  $\beta\gamma$  to complex with  $\alpha_s$  and inhibit group A and group C adenylate cyclases. Adapted from Taussig and Gilman (1995).

action. Second, either  $\alpha$  or  $\beta\gamma$  subunits derived from  $G_i$ ,  $G_o$ , or  $G_z$  can directly inhibit group A cyclases, and the  $\alpha$  subunit from  $G_i$  or  $G_z$  can inhibit group C cyclases. The level of  $G_s$  in particular is low; thus,  $\alpha_s$  derived from  $G_s$  is sufficient to activate adenylate cyclases, but the  $\beta\gamma$  derived from it is insufficient to directly inhibit or activate adenylate cyclases. This explains the apparent paradox that receptors that couple to  $G_s$  produce effects only through  $\alpha_s$ , whereas receptors that couple to  $G_i$  produce effects through both  $\alpha_i$  and  $\beta\gamma$  even though they can share the same  $\beta\gamma$ .

**Receptors Coupling to Adenylate Cyclase** Dozens of neurotransmitters and neuropeptides work through cAMP as a second messenger and by G-protein-linked activation or inhibition of adenylate cyclase. Among the neurotransmitters that increase cAMP are the amines norepinephrine, epinephrine, dopamine, serotonin, and histamine, and the neuropeptides vasointestinal peptide (VIP) and somatostatin. In the olfactory system, a special form of G-protein  $\alpha$  subunit, termed  $\alpha_{olf}$ , serves the same function as  $\alpha_s$  and couples several hundred seven-helix receptors to type III adenylate cyclase in the neuroepithelium.

**Adenylate Cyclases as Coincidence Detectors** Type I and type II adenylate cyclases can integrate concurrent stimulation of neurons by two or more neurotransmitters (Bourne and Nicoll, 1993). Type I adenylate cyclase is stimulated by neurotransmitters that couple to  $G_s$  and by neurotransmitters that elevate intracellular  $Ca^{2+}$ . This adenylate cyclase can convert the depolarization of neurons into an increase in cAMP. Its role in associative forms of learning may be related to its ability to link cAMP-based and  $Ca^{2+}$ -based signals. Stimulation of type II adenylate cyclase by  $\alpha_s$  is

conditional on the presence of  $\beta\gamma$  derived from an abundant G protein (i.e., other than  $G_s$ ), thus enabling the cyclase to serve as a coincidence detector. Thus, activation of a second receptor, presumably coupled to the abundant  $G_i$  and  $G_o$ , is needed to provide the  $\beta\gamma$ .

### Sources of Second Messengers: Phospholipids

Two phospholipids, phosphatidylinositol 4,5-bisphosphate ( $PIP_2$ ) and phosphatidylcholine (PC), are primary precursors for a G-protein-based second-messenger system. Three second messengers, diacylglycerol, arachidonic acid and its metabolites, and elevated  $Ca^{2+}$ , ultimately are produced. A single step converts inert phospholipid precursors into lipid messengers. DAG action is mediated by protein kinase C (PKC) (Tanaka and Nishizuka, 1994). The elevation of  $Ca^{2+}$  levels is accomplished by the regulated entry of  $Ca^{2+}$  from a concentrated pool sequestered in the endoplasmic reticulum or from outside the cell.  $Ca^{2+}$  has many direct cellular targets but mediates most of its effects through calmodulin, a  $Ca^{2+}$ -binding protein that activates many enzymes after it binds  $Ca^{2+}$ . One class of calmodulin-dependent enzymes is a family of protein kinases that enable  $Ca^{2+}$  signals to modulate a large number of cellular processes by phosphorylation (Hudmon and Schulman, 2002).

**Generation of DAG and  $IP_3$  from  $G_q$  and  $G_i$  Coupled to  $PLC\beta$**  The phosphatidylinositide-signaling pathway is just as prominent in neuronal signaling as the cAMP pathway and is similar to it in overall design. Stimulation of a large number of neurotransmitters and hormones (including acetylcholine (M1, M3), serotonin (5HT<sub>2</sub>, 5HT<sub>1C</sub>), norepinephrine ( $\alpha_{1A}$ ,  $\alpha_{1B}$ ), glutamate (metabotropic), neurotensin, neuropeptide Y, and substance P) is coupled to the activation of a phosphatidylinositide-specific PLC.

Phosphatidylinositol (PI) is composed of a diacylglycerol backbone with myoinositol attached to the *sn*-3 hydroxyl by a phosphodiester bond (Fig. 10.7). The six positions of the inositol are not equivalent: the 1 position is attached by a phosphate to the DAG moiety. PI is phosphorylated by PI kinases at the 4 position and then at the 5 position to form  $PIP_2$ . In response to the appropriate G-protein coupling, PLC hydrolyzes the bond between the *sn*-3 hydroxyl of the DAG backbone and the phosphoinositol to produce two second messengers—DAG, a hydrophobic molecule, and  $IP_3$ , which is water soluble (Fig. 10.8). Three classes of PLC that hydrolyze  $PIP_2$ ,  $PLC\beta$ ,  $PLC\gamma$ , and  $PLC\delta$  are soluble enzymes that have in common a catalytic domain structure but differ in their regulatory properties. G proteins couple to several variants of  $PLC\beta$ .  $PLC\gamma$  is regulated by growth factor tyrosine

FIGURE 10.7 Structures of phosphatidylinositol and phosphatidylcholine. The sites of hydrolytic cleavage by PLC, PLD, and PLA<sub>2</sub> are indicated by arrows. FA, fatty acid.

kinases. In contrast,  $PLC\delta$  in brain is primarily glial, and its mode of regulation is not well understood.

$PLC\beta$  is coupled to neurotransmitters by  $G_i$  and  $G_q$ . A pertussis toxin-sensitive pathway is mediated by a number of isoforms referred to as  $G_q$  and mediated by their  $\alpha_q$ .  $G_i$  is coupled to  $PLC\beta$  via its  $\beta\gamma$  rather than  $\alpha$  subunit in a pathway that is insensitive to pertussis toxin. Receptor tyrosine kinases can regulate  $PLC\gamma$  by a G-protein-independent pathway involving their recruitment to the receptor and activation via phosphorylation.

**DAG Derived from Activation of Phospholipase D** A slower but larger increase in DAG can be generated by activation phospholipase D (PLD), which cleaves phosphatidylcholine to produce phosphatidic acid and choline. Dephosphorylation of phosphatidic acid produces DAG. The PLD pathway may be used by some mitogens and growth factors and likely contains a variety of activation schemes that may include G proteins.

**Additional Lipid Messengers** DAG is itself a source of another lipid messenger, by the action of phospholipase A<sub>2</sub> (PLA<sub>2</sub>), which releases the fatty acid, typically arachidonic acid, from the *sn*-2 position of the DAG backbone (Fig. 10.7). Arachidonic acid has biological activity of its own in addition to serving as a precursor for prostaglandins and leukotrienes. Arachidonic acid and other *cis*-unsaturated fatty acids can modulate K<sup>+</sup> channels,  $PLC\gamma$ , and some forms of PKC.

A subfamily of lipid kinases that are specific for addition of a phosphate moiety on the 3 position, phosphoinositide 3-kinases (PI-3 kinases), also play a regulatory role. Depending on their preferred lipid

**FIGURE 10.8** Schematic pathway of IP<sub>3</sub> and DAG synthesis and action. Stimulation of receptors coupled to G<sub>q</sub> activates PLC $\beta$ , which leads to the release of DAG and IP<sub>3</sub>. DAG activates PKC, whereas IP<sub>3</sub> stimulates the IP<sub>3</sub> receptor in the endoplasmic reticulum (ER), leading to mobilization of intracellular Ca<sup>2+</sup> stores. Adapted from Berridge (1993).

substrate, they can produce PI-3-P, PI-3,4-P<sub>2</sub>, PI-3,5-P<sub>2</sub>, and PI-3,4,5-P<sub>3</sub>. A number of signals, including growth factors, activate PI-3 kinases to generate these lipid messengers. In turn, these lipids then bind directly to a number of proteins and enzymes to modify vesicular traffic, protein kinases involved in survival and cell death. There is also evidence that another lipid, sphingomyelin, is a precursor for intracellular signals as well.

**IP<sub>3</sub>, a Potent Second Messenger That Produces Its Effects by Mobilizing Intracellular Ca<sup>2+</sup>** The main function of IP<sub>3</sub> is to stimulate the release of Ca<sup>2+</sup> from intracellular stores. Ca<sup>2+</sup> levels are kept low in the cytosol by its sequestration in the ER where it is complexed with low-affinity-binding proteins. The ER is the major IP<sub>3</sub>-sensitive Ca<sup>2+</sup> store in cells (Fig. 10.8) and Ca<sup>2+</sup> readily flows down its concentration gradient into the cell lumen upon opening of Ca<sup>2+</sup> channels in the ER.

The IP<sub>3</sub> receptor is a macromolecular complex that functions as an IP<sub>3</sub> sensor and a Ca<sup>2+</sup> release channel. It has a broad tissue distribution but is highly concentrated in the cerebellum. The IP<sub>3</sub> receptor is a tetramer of 313-kDa subunits with a single IP<sub>3</sub>-binding site at its

N-terminal of each subunit, facing the cytoplasm. Ca<sup>2+</sup> release by IP<sub>3</sub> is highly cooperative so that a small change in IP<sub>3</sub> has a large effect on Ca<sup>2+</sup> release from the ER. The mouse mutants *pcd* and *nervous* have deficient levels of the IP<sub>3</sub> receptor and exhibit defective Ca<sup>2+</sup> signaling, and a genetic knockout of the IP<sub>3</sub> receptor leads to motor and other deficits.

**Termination of the IP<sub>3</sub> Signal** IP<sub>3</sub> is a transient signal terminated by dephosphorylation to inositol. Inactivation is initiated either by dephosphorylation to inositol 1,4-bisphosphate (Fig. 10.9) or by an initial phosphorylation to a tetrakisphosphate form that is dephosphorylated by a different pathway. Both pathways have in common an enzyme that cleaves the phosphate on the 1 position. Complete dephosphorylation yields inositol, which is recycled in the biosynthetic pathway. Recycling is important because most tissues do not contain *de novo* biosynthetic pathways for making inositol. Salvaging inositol may be particularly important when cells are actively undergoing PI turnover. It is intriguing that Li<sup>+</sup>, the simple salt used to treat bipolar disorder, selectively inhibits the salvage of inositol by inhibiting the enzyme that dephosphorylates the 1 position and is common to the two

**FIGURE 10.9** Multiple sources of  $Ca^{2+}$  converge on calmodulin and other  $Ca^{2+}$ -binding proteins. Cellular levels of  $Ca^{2+}$  can rise either by influx (e.g., through voltage-sensitive channels or ligand-gated channels) or by redistribution from intracellular stores triggered by  $IP_3$ . Calcium modulates dozens of cellular processes by the action of the  $Ca^{2+}$ -calmodulin complex on many enzymes, and calcium has some direct effects on enzymes such as PKC and calpain. CaM kinase,  $Ca^{2+}$ -calmodulin-dependent kinase.

pathways. At therapeutic doses of  $Li^+$ , the reduced salvage of inositol in cells with high phosphoinositide signaling may lead to a depletion of  $PIP_2$  and a selective inhibition of this signaling pathway in active cells.

### Calcium Ion

Calcium has a dual role as a carrier of electrical current and as a second messenger. Its effects are more diverse than those of other second messengers such as cAMP and DAG because its actions are mediated by a much larger array of proteins, including protein kinases (Carafoli and Klee, 1999). Furthermore, many signaling pathways directly or indirectly increase cytosolic  $Ca^{2+}$  concentration from 100 nM to 0.5–1.0 mM. The source of elevated  $Ca^{2+}$  can be either the ER or the extracellular space (Fig. 10.9). In addition to  $IP_3$ -mediated release,  $Ca^{2+}$  can activate its own mobilization through the ryanodine receptor on the ER. Mechanisms for  $Ca^{2+}$  influx from outside the cell include several voltage-sensitive  $Ca^{2+}$  channels and ligand-gated cation channels that are permeable to  $Ca^{2+}$  (e.g., nicotinic receptor and *N*-methyl-D-aspartate (NMDA) receptor).

**Dynamics of  $Ca^{2+}$  Signaling Revealed by Fluorescent  $Ca^{2+}$  Indicators** We know a great deal about the spatial and temporal regulation of  $Ca^{2+}$  signals because of the development of fluorescent  $Ca^{2+}$  indicators. A variety of fluorescent compounds selectively bind  $Ca^{2+}$  at physiological concentration ranges and rapidly change their fluorescent properties upon binding  $Ca^{2+}$  to a fairly accurate measurement of ionized  $Ca^{2+}$ .

### Calmodulin-Mediated Effects of $Ca^{2+}$

$Ca^{2+}$  acts as a second messenger to modulate the activity of many mediators. The predominant mediator of  $Ca^{2+}$  action is calmodulin, a ubiquitous 17-kDa calcium-binding protein.  $Ca^{2+}$  binds to calmodulin in the physiological range and converts it into an activator of many cellular targets (Cohen and Klee, 1988). Binding of  $Ca^{2+}$  to calmodulin produces a conformational change that greatly increases its affinity for more than two dozen eukaryotic enzymes that it activates, including cyclic nucleotide PDEs, adenylate cyclase, nitric oxide synthase,  $Ca^{2+}$ -ATPase, calcineurin (a phosphoprotein phosphatase), and several protein kinases (Fig. 10.9). This activation of calmodulin allows neurotransmitters that change  $Ca^{2+}$  to affect dozens of cellular proteins, presumably in an orchestrated fashion.

### Regulation of Guanylate Cyclase by Nitric Oxide

An important target of  $Ca^{2+}$ -calmodulin is the enzyme nitric oxide synthase (NOS) (Chapter 8). This enzyme synthesizes one of the simplest known messengers, the gas NO (Baranano *et al.*, 2001). In the pathway that led to its discovery, acetylcholine stimulates the PI signaling pathway in the endothelium to increase intracellular  $Ca^{2+}$ , which activates NOS so that more NO is made. NO then diffuses radially from the endothelial cells across two cell membranes to the smooth muscle cell, where it activates guanylate cyclase to make cGMP. This in turn activates a cGMP-dependent protein kinase that phosphorylates proteins, leading to a relaxation of muscle. In 1998, Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad received the Nobel Prize for their discoveries concerning nitric oxide as a signaling molecule and therapeutic mediator in the cardiovascular system.

Let us now turn to the details of the NO pathway. Nitric oxide is derived from L-arginine in a reaction catalyzed by NOS, a complex enzyme that converts L-arginine and  $O_2$  into NO and L-citrulline. NOS likely produces the neutral free radical NO as the active agent. NO lasts only a few seconds in biological fluids and thus, no specialized processes are needed to inactivate this particular signaling molecule. As a gas, NO is soluble in both aqueous and lipid media and can diffuse readily from its site of synthesis across the cytosol or cell membrane and affect targets in the same cell or in nearby neurons, glia, and vasculature (Baranano *et al.*, 2001). NO produces a variety of effects, including relaxation of smooth muscle of the vasculature, relaxation of smooth muscle of the gut in peristalsis, and killing of foreign cells by macrophages. It was first recognized as a neuronal messenger that couples glutamate receptor stimulation to increases in cGMP. NO produced by  $Ca^{2+}$ -calmodulin-dependent activa-

tion of NO synthase concentrated in cerebellar granule cells activates guanylate cyclase in nearby Purkinje cells during the induction of long-term depression in the cerebellum (Chapter 32).

**Activation of Guanylate Cyclases** Two types of guanylate cyclase, a soluble one regulated by NO and a membrane-bound enzyme regulated directly by neuropeptides, synthesize cGMP from GTP in a reaction similar to the synthesis of cAMP from ATP. NO activates the soluble enzyme by binding to the iron atom of the heme moiety. This is the basic mechanism for the regulation of soluble guanylate cyclases. A number of therapeutic muscle relaxants, such as nitroglycerin and nitroprusside, are NO donors that produce their effects by stimulating cGMP synthesis. Membrane-bound guanylate cyclases are transmembrane proteins with a binding site for neuroendocrine peptides on the extracellular side of the plasma membrane and a catalytic domain on the cytosolic side.

#### ***Cyclic GMP Phosphodiesterase, an Effector Enzyme in Vertebrate Vision***

The versatility of G-protein signaling is illustrated in vertebrate phototransduction, in which a specialized G protein called transducin ( $G_t$ ) is activated by light rather than by a hormone or neurotransmitter. Transducin stimulates cGMP phosphodiesterase, an effector enzyme that hydrolyzes cGMP and ultimately turns off the dark current (Chapter 27). Nature has evolved an elegant mechanism for using photons of light to modify a hormone-like molecule, retinal, that activates a seven-helix receptor called rhodopsin. Activated rhodopsin dissociates  $\alpha_t$  from transducin, which then activates a soluble cGMP phosphodiesterase.

Rods can detect a single photon of light because the signal-to-noise ratio of the system is very low and the amplification factor in phototransduction is quite high; one rhodopsin molecule stimulated by a single photon can activate 500 transducins. Transducin remains in the "on" state long enough to activate 500 PDEs. PDE can hydrolyze about 100 cGMP molecules in the second before it is deactivated. cGMP in rods regulates a cGMP-gated cation channel, leading to additional amplification of the signal.

#### ***Modulation of Ion Channels by G Protein***

Each type of neuron has a repertoire of ion channels that give it a distinct response signature, and it is not surprising that several types of mechanisms regulate these channels. Channel modulation occurs via G proteins, second messengers and their cognate protein kinases that phosphorylate ion channels as well as by direct effects of G proteins.

The first ion channel demonstrated to undergo regulation by G proteins was the cardiac  $K^+$  channel that mediates slowing of the heart by acetylcholine released from the vagus nerve. When this  $I_{K_{ACh}}$  channel is examined in a membrane patch delimited by the seal of a cell-attached electrode, the addition of acetylcholine within the electrode increases the frequency of channel opening dramatically, whereas the addition of acetylcholine to the cell surface outside the seal does not. The process is therefore described as membrane delimited, with a direct interaction between the G protein (either  $\alpha_i$  or  $\beta\gamma$ ) and the channel.

There is also compelling evidence for the stimulation or inhibition of  $Ca^{2+}$  channel subtypes by G proteins. The central role played by  $Ca^{2+}$  in muscle contraction, in synaptic release, and in gene expression makes  $Ca^{2+}$  influx a common target for regulation by neurotransmitters. In the heart, where L-type  $Ca^{2+}$  channels are critical for the regulation of contractile strength, the  $Ca^{2+}$  current is enhanced by  $\alpha_s$  formed by  $\beta$ -adrenergic stimulation of  $G_s$ . In contrast, N-type  $Ca^{2+}$  channels, which modulate synaptic release in nerve terminals, often are inhibited by muscarinic and  $\alpha$ -adrenergic agents and by opiates acting at receptors coupled to  $G_i$  and  $G_o$ .

#### **G-Protein Signaling Gives Special Advantages in Neural Transmission**

The G-protein-based signaling system provides several advantages over fast transmission (Hille, 1992; Birnbaumer, 2007). These advantages include amplification of the signal, modulation of cell function over a broad temporal range, diffusion of the signal to a large cellular volume, cross talk, and coordination of diverse cell functions. The sacrifice in speed relative to signaling by ligand gated ion channels is compensated by a broad range of signaling that facilitates integration of signals by the G-protein system. A slower time frame means that cellular processes that are quite distant from the receptor can be modulated. Diffusion of second messengers such as  $IP_3$ ,  $Ca^{2+}$ , and DAG can extend neurotransmission through the cell body and to the nucleus to alter gene expression and via NO to other cells. Neurotransmitters acting through G proteins can elicit a coordinated response of the cell that can modulate synaptic release, resynthesis of neurotransmitter, membrane excitability, the cytoskeleton, metabolism, and gene expression.

#### **Summary**

A major class of signaling utilizing G-protein-linked signals affords the nervous system a rich diversity of

modulation, amplification, and plasticity. Signals are mediated through second messengers activating proteins that modify cellular processes and gene transcription. A key feature is the ability of G proteins to detect the presence of activated receptors and to amplify the signal through effector enzymes and channels. Phosphorylation of key intracellular proteins, ion channels, and enzymes activates diverse, highly regulated cellular processes. The specificity of response is ensured through receptors reacting only with a limited number of G proteins. Coupling between receptor, G protein, and its effector(s), and spatial compartmentalization of the system enables specificity and localized control of signaling. Phospholipids and phosphoinositols provide substrates for second-messenger signaling for G proteins. Stimulation of release of intracellular calcium is often the mediator of the signal. Calcium itself has a dual role as a carrier of electrical current and as a second messenger. Calmodulin is a key regulator that provides complexity and enhances specificity of the signaling system. Sensitivity of the system is imparted by an extremely robust amplification system, as seen in the visual system, which can detect single photons of light.

### MODULATION OF NEURONAL FUNCTION BY PROTEIN KINASES AND PHOSPHATASES

Protein phosphorylation and dephosphorylation are key processes that regulate cellular function. They play a fundamental role in mediating signal transduction initiated by neurotransmitters, neuropeptides, growth factors, hormones, and other signaling molecules (Fig. 10.10). The functional state of many proteins is modified by phosphorylation-dephosphorylation, the most ubiquitous post-translational modification in eukaryotes. A fifth of all proteins may serve as targets for kinases and phosphatases. Phosphorylation or dephosphorylation can rapidly modify the function of enzymes, structural and regulatory proteins, receptors, and ion channels taking part in diverse processes, without a need to change the level of their expression. It can also produce long-term alterations in cellular properties by modulating transcription and translation and changing the complement of proteins expressed by cells.

Protein kinases catalyze the transfer of the terminal, or  $\gamma$ , phosphate of ATP to the hydroxyl moieties of Ser, Thr, or Tyr residues at specific sites on target proteins. Most protein kinases are either Ser/Thr kinases or Tyr kinases, with only a few designed to phosphorylate both categories of acceptor amino acids. Protein phos-

**FIGURE 10.10** Regulation by protein kinases and protein phosphatases. Enzymes and other proteins serve as substrates for protein kinases and phosphoprotein phosphatases, which modify their activity and control them in a dynamic fashion. Multiple signals can be integrated at this level of protein modification. Adapted from Svenningsson *et al.* (2004).

phatases catalyze the hydrolysis of the phosphoryl groups from phosphoserine, phosphothreonine, phosphotyrosine, or both types of phosphorylated amino acids on phosphoproteins.

The activity of protein kinases and protein phosphatases often is regulated either by a second messenger (e.g., cAMP or  $\text{Ca}^{2+}$ ) or by an extracellular ligand (e.g., nerve growth factor). In general, second-messenger-regulated kinases modify Ser and Thr, whereas receptor-linked kinases modify Tyr. Among the many protein kinases and protein phosphatases in neurons, a relatively small number serve as master regulators to orchestrate neuronal function. The cAMP-dependent protein kinase (PKA) is a prototype for the known regulated Ser/Thr kinases; they are similar in overall structure and regulatory design. PKA is the predominant mediator for signaling through cAMP, the only others being a cAMP-liganded ion channel in olfaction and exchange protein directly activate by cAMP (Epoc) which modulate GDP-GTP exchange in cell adhesion and exocytosis. In a similar fashion, the related cGMP-dependent protein kinase (PKG) mediates most of the actions of cGMP.  $\text{Ca}^{2+}$ -calmodulin-dependent protein kinase II (CaM kinase II) and several other kinases mediate many of the actions of stimuli that elevate intracellular  $\text{Ca}^{2+}$ . Finally, the PI signaling system increases both DAG and  $\text{Ca}^{2+}$ , which activate any of a family of protein kinases collectively called protein kinase C.

The activities of these second messenger-regulated protein kinases are countered by a relatively small number of phosphatases, exemplified by protein phosphatase 1 (PP-1), protein phosphatase 2A (PP-2A), and protein phosphatase 2B (PP-2B, or calcineurin). Phosphorylation and dephosphorylation are reversible processes, and the net activity of the two processes

determines the phosphorylation state of each substrate. The Nobel Prize for Physiology and Medicine was awarded to Edwin G. Krebs and Edmund H. Fischer in 1992 for their pioneering work on the regulation of cell function by protein kinases and phosphatases.

### Certain Principles Are Common in Protein Phosphorylation and Dephosphorylation

Protein kinases and protein phosphatases are described either as multifunctional if they have a broad specificity and therefore modify many protein targets, or as dedicated if they have a very narrow substrate specificity. Spatial positioning of kinases and their substrates in the cell either increases or decreases the likelihood of phosphorylation-dephosphorylation of a given substrate.

The amplification of signal transduction described earlier is continued during transmission of the signal by protein kinases and protein phosphatases. In some cases, the kinases are themselves subject to activation by phosphorylation in a cascade in which one activated kinase phosphorylates and activates a second, and so on, to provide amplification and a switch-like response termed ultrasensitivity.

Kinases and phosphatases integrate cellular stimuli and encode the stimuli as the steady-state level of phosphorylation of a large complement of proteins in the cell (Hunter, 1995). Distinct signal transduction pathways can converge on the same or different target substrates (Fig. 10.10). In some cases, these substrates can be phosphorylated by several kinases at distinct sites. Phosphorylation can alter cellular processes over broad time scales, from milliseconds to hours and much longer by altering gene expression.

Phosphorylation produces specific changes in the function of a target protein, such as increasing or decreasing the catalytic activity of an enzyme, conductance of an ion channel, or desensitization of a receptor. Kinases and phosphatases modulate proteins by regulating the presence of a highly charged and bulky phosphoryl moiety on Ser, Thr, or Tyr at a precise location on the substrate protein. The phosphate may elicit a conformational change or alter interaction with other proteins.

Finally, each of the three kinases described here is capable of functioning as a cognitive kinase—that is, a kinase capable of a molecular memory. Although each is activated by its respective second messenger, it can undergo additional modification that reduces its requirement for the second messenger. This molecular memory potentiates the activity of these kinases and may enable them to participate in aspects of neuronal plasticity.

### cAMP-Dependent Protein Kinase Was the First Well-Characterized Kinase

Neurotransmitters that stimulate the synthesis of cAMP exert their intracellular effects primarily by activating PKA. The functions (and substrates) regulated by PKA include gene expression (cAMP response element-binding protein (CREB)), catecholamine synthesis (tyrosine hydroxylase), carbohydrate metabolism (phosphorylase kinase), cell morphology (microtubule-associated protein 2 (MAP-2)), postsynaptic sensitivity (AMPA receptor), and membrane conductance (K channel). Paul Greengard and Eric Kandel received the Nobel Prize for Medicine in 2000 (along with Arvid Carlsson) for their discoveries concerning signal transduction via PKA and phosphoprotein phosphatases in the nervous system. PKA is a tetrameric protein composed of two types of subunits: (1) a dimer of regulatory (R) subunits (either two RI subunits for type I PKA or two RII subunits for type II PKA) and (2) two catalytic subunits (C subunit). Two or more isoforms of the RI, RII, and C subunits have distinct tissue and developmental patterns of expression but appear to function similarly. The C subunits are 40-kDa proteins that contain the binding sites for protein substrates and ATP. The R subunits are 49- to 51-kDa proteins that contain two cAMP-binding sites. In addition, the R subunit dimer contains a region that interacts with cellular anchoring proteins that serve to localize PKA appropriately within the cell.

The binding of second messengers by PKA and the other second-messenger-regulated kinases relieves an inhibitory constraint and thus activates the enzymes (Fig. 10.11). cAMP binding leads to subunit dissociation thereby relieving the C subunit of its inhibitory R subunits, thereby activating the kinase. The steady-

**FIGURE 10.11** Activation of PKA by cAMP. An autoinhibitory segment (blue) of the regulatory subunit (R) dimer interacts with the substrate-binding domain of the catalytic (C) subunits of PKA, blocking access of substrates to their binding site. Binding of four molecules of cAMP reduces the affinity of R for C, resulting in dissociation of constitutively active C subunits.

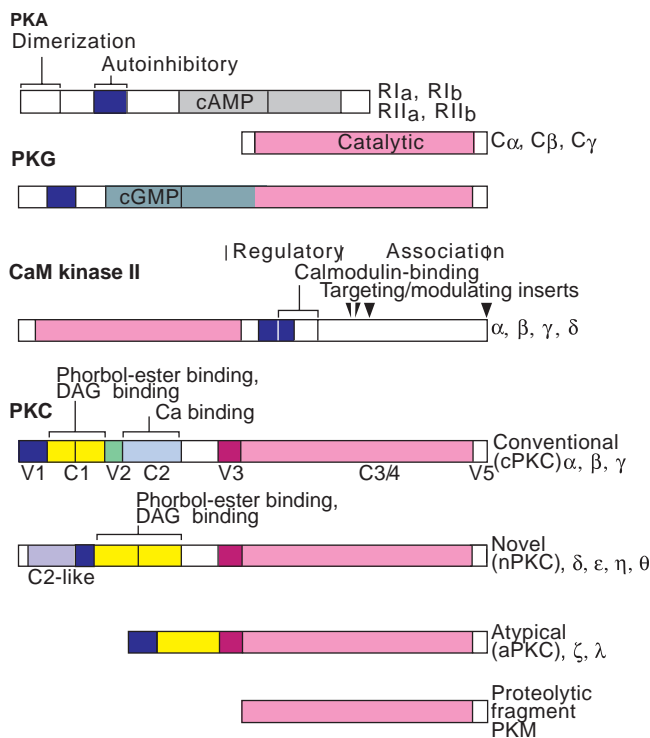

state level of cAMP determines the fraction of PKA that is in the dissociated or active form. In this way PKA decodes cAMP signals into the phosphorylation of proteins and the resultant change in various cellular processes.

PKA is a member of a large family of protein kinases that have in common a significant degree of homology in their catalytic domains and are likely derived from an ancestral gene (Fig. 10.12). This homology extends to the three-dimensional crystal structure based on X-ray crystallography of PKA and other kinases. The catalytic domain may be in a subunit distinct from the regulatory domain, as in PKA, or in the same subunit, as in PKC and the CaM kinases. The crystal structure of the C subunit complexed to a segment of protein kinase inhibitor (PKI), a selective high-affinity inhibitor of PKA, reveals that the C subunit is composed of two lobes. The N-terminal lobe contains a highly conserved region that binds  $Mg^{2+}$ -ATP in a cleft between the two lobes. A larger C-terminal lobe contains the protein-substrate recognition sites and the appropriate

amino acids for catalyzing transfer of the phosphoryl moiety from ATP to the substrate. Inhibition by PKI is diagnostic of PKA involvement; PKI contains an autoinhibitory sequence resembling PKA substrates and is positioned in the catalytic site like a substrate, thus blocking access for substrates.

PKA phosphorylates Ser or Thr at specific sites in dozens of proteins. The sequences of amino acids at the phosphorylation sites are not identical. Each kinase has a characteristic consensus sequence that forms the basis for distinct substrate specificities.

A regulatory theme common to PKA, CaM kinase II, and PKC is that their second messengers activate them by displacing an autoinhibitory domain from the active site (Kemp *et al.*, 1994). The R subunit blocks access of substrates by positioning a pseudosubstrate or autoinhibitory domain in the catalytic site. Binding of cAMP to the R subunit near this autoinhibitory domain must disrupt its binding to the C subunit, thus leading to dissociation of an active C subunit. CaM kinase II and PKC likewise have autoinhibitory segments that are near the second-messenger-binding sites and may be activated similarly (Fig. 10.12).

**FIGURE 10.12** Domain structure of protein kinases. Protein kinases are encoded by proteins with recognizable structural sequences that encode specialized functional domains. Each of the kinases (PKA, PKG, CaM kinase II, and PKC) has homologous catalytic domains that are kept inactive by the presence of an autoinhibitory segment (blue lines). Regulatory domains contain sites for binding second messengers such as cAMP, cGMP,  $Ca^{2+}$ -calmodulin, DAG, and  $Ca^{2+}$ -phosphatidylserine. Alternative splicing creates additional diversity.

### Multifunctional CaM Kinase II Decodes Diverse Signals That Elevate Intracellular $Ca^{2+}$

Most of the effects of  $Ca^{2+}$  in neurons and other cell types are mediated by calmodulin, and many of the effects of  $Ca^{2+}$ -calmodulin are mediated by protein phosphorylation-dephosphorylation (Schulman and Braun, 1999). The  $Ca^{2+}$ -signaling system contains a family of  $Ca^{2+}$ -calmodulin-dependent protein kinases with broad substrate specificity, including CaM kinases I, II, and IV; of these, CaM kinase II is the best characterized. CaM kinase II phosphorylates tyrosine hydroxylase, MAP-2, synapsin I, calcium channels,  $Ca^{2+}$ -ATPase, transcription factors, and glutamate receptors and thereby regulates synthesis of catecholamines, cytoskeletal function, synaptic release in response to high-frequency stimuli, calcium currents, calcium homeostasis, gene expression, and synaptic plasticity, respectively. This kinase is found in every tissue but is particularly enriched in neurons. It is found in the cytosol, in the nucleus, in association with cytoskeletal elements, and in postsynaptic thickening termed the postsynaptic density found in asymmetric synapses. It is a large multimeric enzyme, consisting of 12 subunits derived from four homologous genes ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ) that encode different isoforms of the kinase that range from 54 to 65 kDa per subunit.

The catalytic, regulatory, and targeting domains of CaM kinase II are all contained within a single polypeptide (Fig. 10.12). Following the catalytic domain on

the N-terminal half of each isoform is the regulatory domain, which contains an autoinhibitory domain with an overlapping calmodulin-binding sequence. The C-terminal end contains an association domain that allows 12 subunits (two rings of six catalytic domains each) to assemble into a multimer, as well as targeting sequences that direct the kinase to distinct intracellular sites.

Regulation of the kinase by autophosphorylation is a critical feature of CaM kinase II. The kinase is inactive in the basal state because an autoinhibitory segment distorts the active site and sterically blocks access to its substrates. Binding of  $\text{Ca}^{2+}$ -calmodulin to the calmodulin-binding domain of the kinase displaces the autoinhibitory domain from the catalytic site and thus activating the kinase by enabling ATP and protein substrates to bind. Displacement of this domain also exposes a binding site for anchoring proteins that the activated kinase can bind. If the kinase is activated, it can autophosphorylate Thr-286 (in  $\alpha$ -CaM kinase II). Phosphorylation disables the autoinhibitory segment by preventing it from reblocking the active site after calmodulin dissociates and thereby locks the kinase in a partially active state that is independent, or autonomous, of  $\text{Ca}^{2+}$ -calmodulin and can anchor to additional targets. Autophosphorylation prolongs the active state of the kinase, a potentiation that led to its description as a cognitive kinase.

CaM kinase II is targeted to distinct cellular compartments. Differences between the four genes encoding CaM kinase II and between the two or more isoforms that are encoded by each gene by apparent alternative splicing reside primarily in a variable region at the start of the association domain (Fig. 10.12). In some isoforms, this region contains an additional sequence that targets those isoforms to the nucleus. The major neuronal isoform,  $\alpha$ -CaM kinase II, is largely cytosolic but is also found associated with postsynaptic densities synaptic vesicles and may therefore have several targeting sequences. Targeting to the NMDA type glutamate receptor occurs only after calmodulin activates the kinase and exposes a binding site.

### Protein Kinase C Is the Principal Target of the PI Signaling System

Protein kinase C is a collective name for members of a relatively diverse family of protein kinases most closely associated with the PI-signaling system. PKC is a multifunctional Ser/Thr kinase capable of modulating many cellular processes, including exocytosis and endocytosis of neurotransmitter vesicles, neuronal plasticity, gene expression, regulation of cell growth and cell cycle, ion channels, and receptors. The role of

DAG generated during PI signaling was unclear until its link to PKC was established. Many PKC isoforms also require an acidic phospholipid such as phosphatidylserine for appropriate activation. The kinase is also of interest because it is the target of a class of tumor promoters called phorbol esters. They activate PKC by simulating the action of DAG, bypassing the normal receptor-based pathway, and inappropriately stimulating cell growth.

We now understand that the PKC family of kinases is diverse in structure and regulatory properties. PKC is monomeric (78–90 kDa) with catalytic, regulatory, and targeting domains all on one polypeptide (Fig. 10.12). The conventional isoforms (or cPKC), have all the following domains:

- VI, which contains the autoinhibitory or pseudosubstrate sequence
- C1, a cysteine rich domain that binds DAG and phorbol esters
- C2, a region necessary for  $\text{Ca}^{2+}$  sensitivity and for binding to phosphatidylserine and to anchoring proteins
- V3, a protease-sensitive hinge
- C3/4, the catalytic domain
- V5, which may also mediate anchoring

Another class of isoforms, termed novel PKCs (nPKC), lacks a true C2 domain and is therefore not  $\text{Ca}^{2+}$  sensitive. Another class is considered atypical (aPKC) because it lacks C2 and the first of two cysteine-rich domains that are necessary for DAG (or phorbol ester) sensitivity. This class is neither  $\text{Ca}^{2+}$  nor DAG sensitive. Not included is a DAG-interacting kinase originally designated as PKC- $\mu$  and now termed PKD because its catalytic domain is different from the other PKC isoforms.

Activation of PKC is best understood for the conventional isoforms. Generation of DAG resulting from stimulation of the PI-signaling pathway increases the affinity of cPKC isoforms for  $\text{Ca}^{2+}$  and phosphatidylserine. DAG, or specifically its *sn*-1,2-diacylglycerol isomer, is derived only from PI turnover, and it is the only isomer effective in activating PKC. Cell stimulation results in the translocation of cPKC from a variety of sites to the membrane or cytoskeletal elements where it interacts with PS- $\text{Ca}^{2+}$ -DAG at the membrane. Binding of the second messengers to the regulatory domain disrupts the nearby autoinhibitory domain, leading to a reversible activation of PKC by deinhibition, as is found for PKA and CaM kinase II. Translocation is not restricted to the plasma membrane. Upon activation some PKC isoforms reversibly translocate to intracellular sites enriched with anchoring proteins, termed receptors for activated C kinase (RACK).

Prolonged activation of PKC can be produced by the addition of phorbol esters, which simulate activation by DAG but remain in the cell until they are washed out. In a matter of hours to days, such persistent activation by phorbol esters leads to a degradation of PKC. This phenomenon is sometimes used experimentally to produce a PKC-depleted cell (at least for phorbol ester-binding isoforms) and thereafter to test for a loss of putative PKC functions.

### Spatial Localization Regulates Protein Kinases and Phosphatases

Protein kinases and protein phosphatases often are positioned spatially near their substrates or they translocate to their substrates upon activation to improve speed and specificity in response to neurotransmitter stimulation. For example, A Kinase Anchoring Protein 79 (AKAP79), although first identified with PKA binding, also has binding site for PKC and calcineurin (Klauck *et al.*, 1996). Another example of a signaling complex is the protein termed *yotiao*, which binds to the NMDA type glutamate receptor and serves as an anchor for both PKA and a phosphatase (PP-1).

The use of anchoring proteins has several consequences. First, rate of phosphorylation and specificity are enhanced when kinases or phosphatases are concentrated near intended substrates. Second, it increases the signal-to-noise ratio for substrates that are not near anchoring proteins by reducing basal state phosphorylation. For example, PKA is anchored on the Golgi away from the nucleus so that phosphorylation in the basal state or even after a brief stimulus produces little phosphorylation of nuclear proteins. Prolonged stimuli, however, enable some C subunits to diffuse passively through nuclear pores and regulate gene expression. Termination of the nuclear action of C subunits is aided by PKI, which acts to inhibit and export it back out of the nucleus. Third, anchoring can enable significant phosphorylation of nearby substrates at basal cAMP, such as a  $\text{Ca}^{2+}$  channel phosphorylated when its phosphorylation site is exposed during depolarization.

### The Cognitive Kinases

The ability of three major Ser/Thr kinases (PKA, CaM kinase II, and PKC) in brain to initiate or maintain synaptic changes that underlie learning and memory may require that they themselves undergo some form of persistent change in activity. Both their functional and molecular properties led to their description as cognitive kinases.

### cAMP-Dependent Protein Kinase

A role for PKA as a cognitive kinase can be seen in long-term facilitation of the gill-withdrawal reflex in *Aplysia* and in long-term potentiation in the rodent hippocampus. In motor neuron cultures, repeated or prolonged exposure to serotonin or cAMP leads to long-term facilitation because PKA becomes persistently active despite the fact that cAMP is no longer elevated (Chain *et al.*, 1999). During such activation there is a preferential degradation and decrease in the inhibitory RII subunits and thus a slight excess of C subunits that remain persistently active because of insufficient RII subunits. The C subunit then enters the nucleus and induces expression of one protein that facilitates further proteolysis of RII. In this interesting process, a molecular memory of appropriate stimulation by serotonin is encoded by a persistence of PKA activity that is regenerative.

### $\text{Ca}^{2+}$ -Calmodulin-Dependent Protein Kinase

CaM kinase II has features of a cognitive kinase because it has a molecular memory based on autophosphorylation and it phosphorylates proteins that modulate synaptic plasticity (Lisman *et al.*, 2002). The biochemical properties of CaM kinase II suggest mechanisms by which appropriate stimulus frequencies can generate an autonomous enzyme (Fig. 10.13). At low stimulus frequency, the time between stimuli is sufficient for calmodulin to dissociate and the kinase to

**FIGURE 10.13** Frequency-dependent activation of CaM kinase II. Autophosphorylation occurs when both neighboring subunits in a holoenzyme are bound to calmodulin. At a high frequency of stimulation (rapid  $\text{Ca}^{2+}$  spikes), the interspike interval is too short to allow significant dephosphorylation or dissociation of calmodulin, thereby increasing the probability of autophosphorylation with each successive spike. In a simplified CaM kinase with only six subunits, calmodulin-bound subunits are shown in pink and autophosphorylated subunits with trapped calmodulin are shown in red. Adapted from Hudmon and Schulman (2002).

be dephosphorylated, and the same submaximal activation will occur with each stimulus. At higher frequencies, however, some subunits will remain autophosphorylated and bound to calmodulin so successive stimuli will result in more calmodulin bound per holoenzyme, which will make autophosphorylation more probable because it requires two active proximate neighboring subunits. The enzyme is therefore able to decode the frequency of cellular stimulation and translate this into a prolonged activated state.

CaM kinase II phosphorylates a number of substrates that affect synaptic strength. Inhibition of CaM kinase II in hippocampal slices or just elimination of its autophosphorylation by an  $\alpha$ -CaM kinase II mouse knock-in in which the critical Thr was replaced by Ala blocks autonomy and the induction of long-term potentiation. These mice are deficient in learning spatial navigational cues, one of the functions of the rodent hippocampus. The basis for its role is uncertain but may be the phosphorylation of AMPA receptors and their recruitment to the membrane, leading to a greater postsynaptic response (Lisman *et al.*, 2002).

### Protein Kinase C

PKC can also be converted into a form that is independent, or autonomous, of its second messenger and can be described as a cognitive kinase. Physiological activation of PKC can lead to proteolytic removal of its inhibitory domain, thus converting it to a constitutively active kinase termed protein kinase M (PKM). However, during the persistent phase of long-term potentiation, some of the PKC is converted to PKM (Serrano *et al.*, 2005). PKC (and PKM) substrates associ-

ated with long-term potentiation include NMDA and AMPA receptors.

### Protein Tyrosine Kinases Take Part in Cell Growth and Differentiation

Protein kinases that phosphorylate tyrosine residues usually are associated with the regulation of cell growth and differentiation. Signal transduction by protein tyrosine kinases often includes a cascade of kinases phosphorylating other kinases, eventually activating Ser/Thr kinases, which carry out the intended modification of a cellular process. There are both receptor tyrosine kinases, activated by the binding of extracellular growth factors such as nerve growth factor and epidermal growth factor and soluble ones, activated indirectly by extracellular ligands such as c-Src.

### Protein Phosphatases Undo What Kinases Create

Protein phosphatases in neuronal signaling are categorized as either phosphoserine-phosphothreonine phosphatases (PSPs) or phosphotyrosine phosphatases (PTPs) (Hunter, 1995; Mansuy and Shenolikar, 2006). The enzymes catalyze the hydrolysis of the ester bond of the phosphorylated amino acids to release inorganic phosphate and the unphosphorylated protein. A limited number of multifunctional PSPs account for most of such phosphatase activity in cells (Hunter, 1995). They are categorized into six groups (1, 4, 5, 2A, 2B, and 2C) on the basis of their substrates, inhibitors, and divalent cation requirements (Table 10.1). Of these

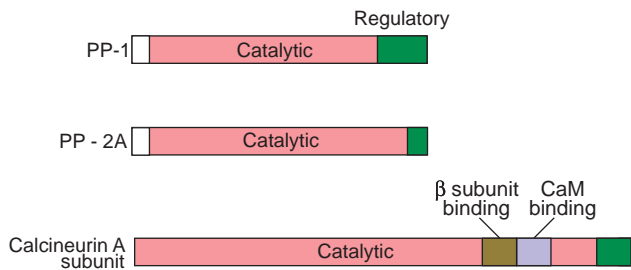

TABLE 10.1 Categories of Protein Phosphatases<sup>a</sup>

Phosphatase	Characteristic	Other Inhibitors
PP-1	Sensitive to phospho-inhibitor-1, phospho-DARPP-32, and inhibitor-2; has targeting subunits	Weakly sensitive to okadaic acid
PP-4	Nuclear	Highly sensitive to okadaic acid
PP-5	Nuclear	Mildly sensitive to okadaic acid
PP-2A	Regulatory subunits Does not require divalent cation	Highly sensitive to okadaic acid
PP-2B (calcineurin)	Ca <sup>2+</sup> /calmodulin-dependent CnB regulatory subunit	FK506, cyclosporin
PP-2C	Requires Mg <sup>2+</sup>	EDTA
Receptor PTPs <sup>b</sup>	Plasma membrane	Vanadate, tyrphosphitin, erbstatin
Nonreceptor PTPs	Various cellular compartments	Vanadate, tyrphosphitin
Dual specificity PTPs	Nuclear (e.g., cdc25A/B/C and VH family)	Vanadate

<sup>a</sup>From Hunter (1995).

<sup>b</sup>Protein phosphotyrosine phosphatases.

**FIGURE 10.14** Domain structure of the catalytic subunits of some Ser/Thr phosphatases. The three major phosphoprotein phosphatases, PP-1, PP-2A, and calcineurin, have homologous catalytic domains but differ in their regulatory properties.

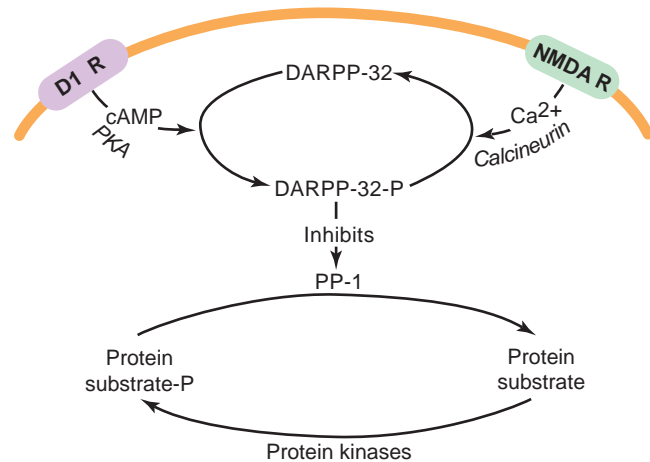

PSPs, only protein phosphatase 2B (PP-2B, or calcineurin) responds directly to a second messenger,  $\text{Ca}^{2+}$ . The specificity of PP-1 and PP-2A is particularly broad, and each can remove phosphates that were transferred by any of the protein kinases discussed herein as well as many other kinases. Phosphotyrosine phosphatases constitute a distinct and larger class of phosphatases, including PTPs with dual specificity for both phosphotyrosines and phosphoserine-phosphothreonines. PTPs are either soluble enzymes or membrane proteins with variable extra cellular domains that enable regulation by extracellular binding of either soluble or membrane-bound signals.

#### Structure and Regulation of PP-1 and Calcineurin

PP-1 and calcineurin are the best characterized phosphatases with regard to both structure and regulation. The domain structures of the catalytic subunits of PP-1 and calcineurin are depicted in Figure 10.14. PP-1 is a protein of 35–38 kDa; most of the sequence forms the catalytic domain; its C-terminal is the site of regulatory phosphorylation. The catalytic domains of PP-1, PP-2A, and calcineurin are highly homologous.

PP-1 and PP-2A normally are complexed in cells with specific anchoring or targeting subunits. Targeting of PP-1 can be modulated by phosphorylation of its targets. As PP-1 dissociates from targeting subunits, it becomes susceptible to inhibition by inhibitor-2.

Inhibition of PP-1 by two other inhibitors, inhibitor-1 and its homologue DARPP-32 (dopamine and cAMP-regulated phosphoprotein;  $M_r$  32,000), is conditional on their phosphorylation by either PKA or PKG (Fig. 10.15). Because the substrates for PKA and PP-1 overlap to a great extent, the rate and extent of phosphorylation of such substrates are enhanced by the ability of PKA to catalyze their phosphorylation while blocking their dephosphorylation via PP-1.

**FIGURE 10.15** Cross talk between kinases and phosphatases. The state of phosphorylation of protein substrates is regulated dynamically by protein kinases and phosphatases. In the striatum, for example, dopamine stimulates PKA, which converts DARPP-32 into an effective inhibitor of PP-1. This increases the steady-state level of phosphorylation of a hypothetical substrate subject to phosphorylation by a variety of protein kinases. This action can be countered by NMDA receptor stimulation by another stimulus that increases intracellular  $\text{Ca}^{2+}$  and activates calcineurin. PP-1 is de-inhibited and dephosphorylates the phosphorylated substrate when calcineurin deactivates DARPP-32-P. Adapted from Svenningsson *et al.* (2004).

Inhibitor-1, DARPP-32, and inhibitor-2 are all selective for PP-1. Highly selective inhibitors capable of penetrating the cell membrane are available for these phosphatases. Okadaic acid, a natural product of marine dinoflagellates, is a tumor promoter but, unlike phorbol esters, it acts on PP-2A and PP-1 rather than on PKC.

**Protein Phosphatase 1** The X-ray structure of the catalytic subunit of PP-1 bound to the toxin microcystin, a cyclic peptide inhibitor, reveals PP-1 to be a compact ellipsoid with hydrophobic and acidic surfaces forming a cleft for binding substrates. PP-1 is a metalloenzyme requiring two metals in the active site that likely take part in electrostatic interactions with the phosphate on substrates that aid in catalyzing the hydrolytic reaction. Substrate binding is blocked when phospho-inhibitor-1 or microcystin LR binds to this surface.

**Calcineurin (PP-2B)** Calcineurin is a  $\text{Ca}^{2+}$ -calmodulin-dependent phosphatase that is highly enriched in the brain. It is a heterodimer with a 60-kDa subunit (CnA) that contains an N-terminal catalytic domain similar to PP-1 and a C-terminal regulatory domain that includes an autoinhibitory segment, a calmodulin-

binding domain, and a binding site for the 19-kDa regulatory B subunit (CnB). CnB is a calmodulin-like  $\text{Ca}^{2+}$ -binding protein that binds to a hinge region of CnA. Some activation of calcineurin is attained by binding of  $\text{Ca}^{2+}$  to CnB. Stronger activation is obtained by the binding of  $\text{Ca}^{2+}$ -calmodulin. Additional regulation may be accorded by interaction of its hinge region with cyclophilin and FKBP (FK506-binding protein), proteins that bind the immunosuppressive agents cyclosporin and FK506, respectively.

The  $\text{Ca}^{2+}$ -calmodulin sensitivity of calcineurin and CaM kinase II are quite different. Weak or low-frequency stimuli may selectively activate calcineurin whereas strong or high-frequency stimuli activate CaM kinase II and calcineurin. This difference may play a role in the bidirectional control of synaptic strength (depression vs. potentiation) by low- and high-frequency stimulation.

### Protein Kinases, Protein Phosphatases, and Their Substrates Are Integrated Networks

Cross talk between protein kinases and protein phosphatases is critical to their ability to integrate inputs into neurons (Cohen, 1992). Such cross talk is exemplified by the interaction of cAMP and  $\text{Ca}^{2+}$  signals through PKA and calcineurin, respectively. The medium spiny neurons in the neostriatum receive cortical inputs from glutamatergic neurons that are excitatory and nigral inputs by dopaminergic neurons that inhibit them. A possible signal transduction scheme for this regulation is shown in Figure 10.15. The key to regulation is the bidirectional control of DARPP-32 phosphorylation (Svenningsson *et al.*, 2004). Glutamate activates calcineurin by increasing intracellular  $\text{Ca}^{2+}$ , leading to the dephosphorylation and inactivation of phospho-DARPP-32. This releases inhibition of PP-1, which can then dephosphorylate a variety of substrates, including  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, and lead to membrane depolarization. This is countered by dopamine, which stimulates cAMP formation and activation of PKA, which then converts DARPP-32 into its phosphorylated (i.e., PP-1 inhibitory) state. There are many other receptors and signaling integrated by these pathways. For example, adenosine, serotonin, and VIP act through their cognate receptors to elevate cAMP, similarly to dopamine at D1 receptors, whereas opiates can signal to inhibit the action of dopamine at D1 and adenosine at A2A receptors. Although PKA and calcineurin are acting in an antagonistic manner, they are not doing it by phosphorylating and dephosphorylating the ATPase. By their actions upstream, at the level of DARPP-32, the regulation of numerous target enzymes (e.g.,  $\text{Ca}^{2+}$  channels

and  $\text{Na}^+$  channels) in addition to the ATPase can be coordinated.

### Studying Cellular Processes Controlled by Phosphorylation-Dephosphorylation

Major goals of signal transduction research are to delineate pathways by which signals such as neurotransmitters transduce their signals to modify cellular processes. This is often the start of a process to identify targets for therapeutic intervention in disease. Cellular and biochemical assays can often identify the entire signaling pathway, from stimulation of receptor, to generation of a second-messenger activation of a kinase or phosphatase, change in the phosphorylation state of the substrate, and an ultimate change in its functional state. Such investigations utilize a variety of pharmacological inhibitors or activators of the signaling molecules complemented by genetic approaches that utilize transfection of activated forms of the kinases or phosphatases in question, siRNAs, transgenic animals, and mice with individual signaling components knocked out.

### Summary

The morphology of a cell is determined by protein constituents. Its function is regulated by the phosphorylation or dephosphorylation of the proteins. Phosphorylation modifies the function of regulatory proteins subsequent to their genetic expression. The activities of the protein kinases and protein phosphatases typically are regulated by second messengers and extracellular ligands. Kinases and phosphatases integrate and encode stimulation of a large group of cellular receptors. The number of possible effects is almost limitless and enables the tuning of cellular processes over a broad time scale. Most of the effects of  $\text{Ca}^{2+}$  in cells are mediated by calmodulin, which in turn mediates changes in protein phosphorylation-dephosphorylation. The phosphoinositol signaling system is mediated through PKC, which modulates many cellular processes from exocytosis to gene expression. All three classes of enzymes discussed have been described as cognitive kinases because they are capable of sustaining their activated states after their second-messenger stimuli have returned to basal levels. PKA has been implicated in learning and memory in *Aplysia* and in hippocampus, where it is involved in long-term potentiation. Protein phosphatases play an equally important role in neuronal signaling by dephosphorylating proteins. Cross talk between protein kinases and protein phosphatases is key to their ability to integrate inputs into neurons.

## INTRACELLULAR SIGNALING AFFECTS NUCLEAR GENE EXPRESSION

The first part of this chapter describes how signaling systems regulate the function of cellular proteins already expressed; another critical level of control exerted by these systems is their ability to regulate the synthesis of cellular proteins by regulating the expression of specific genes. For all living cells, regulation of gene expression by intracellular signals is a fundamental mechanism of development, homeostasis, and adaptation to the environment. Protein phosphorylation and regulation of gene expression by intracellular signals are the most important mechanisms underlying the remarkable degree of plasticity exhibited by neurons. Alterations in gene expression underlie many forms of long-term changes in neural functioning, with a time course that ranges from hours to many years.

### Interactions of Specific DNA Sequences with Regulatory Proteins Control Both Basal and Signal-Regulated Transcription

Information contained within DNA must be expressed through other molecules: RNA and proteins. The human genome contains approximately 25,000 genes that encode structural RNAs or protein-coding messenger RNAs (mRNAs). Regulated gene expression conferred by the nucleotide sequence of the DNA itself is called *cis* regulation because the control regions are linked physically on the DNA to regions that can potentially be transcribed. The *cis* regulatory sequences function by serving as high-affinity binding sites for regulatory proteins called transcription factors.

The transcription of specific genes into mRNA is carried out by a complex enzyme called RNA polymerase II. Roger Kornberg won the Nobel Prize in Chemistry in 2006 for his studies on the molecular basis for eukaryotic transcription. Transcription often is divided into three steps: initiation of RNA synthesis, RNA chain elongation, and chain termination. Extracellular signals, such as neurotransmitters, hormones, drugs, and growth factors generally control the transcription initiation step.

Transcription initiation requires two critical processes: (1) positioning of RNA polymerase II at the correct start site of the gene to be transcribed and (2) controlling the efficiency of initiations to produce the appropriate transcriptional rate for the circumstances of the cell (Tjian and Maniatis, 1994). The *cis*-regulatory elements that set the transcription start sites of genes are called the basal promoter. Other *cis*-

regulatory elements tether additional activator and repressor proteins to the DNA to regulate the overall transcriptional rate (Fig. 10.16).

### Sequence-Specific Transcription Factors

The promoters for RNA polymerase II transcribed genes contain a distinct basal promoter element on which a basal transcription complex is assembled. The basal promoter of most of these genes contains a sequence called a TATA box that is rich in the nucleotides adenine (A) and thymine (T) located between 25 and 30 bases upstream of the transcription start site.

To achieve significant levels of transcription, this multiprotein assembly requires help from sequence-specific transcriptional activators that recognize and bind distinct *cis*-regulatory elements. Functional *cis*-regulatory elements are generally 7–12 in length and structured as a palindrome, each of which is a specific binding site for one or more transcription factors. Each gene has a particular combination of *cis*-regulatory elements, the nature, number, and spatial arrangement of which determine the gene's unique pattern of expression, including the cell types in which it is expressed, the times during development in which it is expressed, and the level at which it is expressed in adults both basally and in response to physiological signals (Tjian and Maniatis, 1994).

Many transcription factors are active only as dimers or higher order complexes formed via a multimerization domain. Both partners in a dimer commonly contribute jointly to both the DNA-binding domain and the activation domain. Dimerization can be a mechanism of either positive or negative control of transcription.

**FIGURE 10.16** Schematic of a generalized RNA polymerase II promoter showing three separate *cis*-regulatory elements along a stretch of DNA. These elements are two hypothetical activator protein-binding sites and the TATA element. The TATA element is shown binding the TATA-binding protein (TBP). Multiple general transcription factors (IIA, IIB, etc.) and RNA polymerase II (pol II) associate with TBP. Each transcription factor comprises multiple individual proteins complexed together. This basal transcription apparatus recruits RNA polymerase II into the complex and also forms the substrate for interactions with the activator proteins binding to the activator elements shown. Activator 2 is shown to be a substrate for a protein kinase.

The effects of sequence-specific transcriptional activator and repressor factors frequently are mediated by adapter proteins (Fig. 10.17). In many cases, these adapter proteins are enzymes, such as histone acyl transferases and deacetylases, with the ability to modify the structure of the proteins associated with the DNA and modulate transcription (Fig. 10.17).

### A Significant Consequence of Intracellular Signaling Is the Regulation of Transcription

Intracellular signals play a major role in the regulation of gene expression, for example via nuclear translocation and/or phosphorylation of activator proteins. Signal-directed change in location or conformation of these proteins permit information obtained by the cell from its different signaling systems to regulate gene expression appropriate to the status of the cell.

#### Transcriptional Regulation by Intracellular Signals

Extracellular control of transcription requires a translocation step by which the signal is transmitted through the cytoplasm to the nucleus. Some transcription factors are themselves translocated to the nucleus. For example, the transcription factor NF- $\kappa$ B is retained in the cytoplasm by its binding protein I $\kappa$ B, which masks the NF- $\kappa$ B nuclear localization signal. Signal-regulated phosphorylation of I $\kappa$ B by PKC and other protein kinases leads to dissociation of NF- $\kappa$ B, permitting it to enter the nucleus. Other transcription factors must be directly phosphorylated or dephosphorylated to bind DNA. In many cytokine-signaling

pathways, plasma membrane receptor tyrosine phosphorylation of transcription factors known as signal transducers and activators of transcription (STATs) permits their multimerization, which in turn permits both nuclear translocation and construction of an effective DNA-binding site within the multimer. Yet other transcription factors, such as CREB (Fig. 10.17), already are bound to their cognate *cis*-regulatory elements and become able to activate transcription after phosphorylation by a kinase that translocates to the nucleus.

#### Role of cAMP and Ca<sup>2+</sup> in the Activation Pathways of Transcription

The cAMP second-messenger pathway regulates expression of a large number of genes via cAMP response elements (CREs). Phosphorylation of CRE-bound CREB on its Ser-133 by activated PKA that translocates to the nucleus recruits the adapter protein CBP. This, in turn, interacts with the basal transcription complex and modifies histones to enhance the efficiency of transcription. CREB also serves to illustrate the convergence of signaling pathways (Fig. 10.18). CREB Ser-133 phosphorylation not only is mediated by PKA but also by CaM kinase types II and IV and by RSK2, a kinase activated in growth factor pathways, including Ras and MAP kinase.

CREB illustrates yet another important principle of transcriptional regulation: CREB is a member of a family of related proteins. Many transcription factors are members of families; this permits complex forms of positive and negative regulation. CREB is closely related to other proteins called activating transcription factors (ATFs) and CRE modulators (CREMs). The dimerization domain used by CREB-ATF proteins and several other families of transcription factors is called a leucine zipper. The dimerization motif is an  $\alpha$  helix in which every seventh residue is a leucine; based on the periodicity of  $\alpha$  helices, the leucines line up along one face of the helix two turns apart. Dimerization juxtaposes the adjacent basic, DNA binding, regions of each of the partners. This combination of motifs is why this superfamily of proteins is referred to as basic leucine zipper proteins (bZIPs).

#### AP-1 Transcription Factors

Activator protein 1 (AP-1) is another family of bZIP transcription factors that play a central role in the regulation of neural gene expression by extracellular signals. The AP-1 family comprises multiple proteins that bind as heterodimers (and a few as homodimers) to the DNA sequence TGACTCA. Although the AP-1 sequence differs from the CRE sequence (TGACGTC) by only a single base, this one-base difference strongly

**FIGURE 10.17** Looping of DNA permits activator (or repressor) proteins binding at a distance to interact with the basal transcription apparatus. The basal transcription apparatus is shown as a single box (pol II complex) bound at the TATA element. The activator protein (CREB) is shown as having been phosphorylated. On phosphorylation, many activators, such as CREB, are able to recruit adaptor proteins that mediate between the activator and the basal transcription apparatus. An adaptor protein that binds phosphorylated CREB is called a CREB-binding protein (CBP).

**FIGURE 10.18** Signal transduction to the nucleus. In this schematic, activation of a neurotransmitter receptor activates cellular signals (G proteins and second-messenger systems). These signals, in turn, regulate the activation of protein kinases, which translocate to the nucleus. Within the nucleus, protein kinases can activate genes regulated by constitutively synthesized transcription factors. A subset of these genes encodes additional transcription factors (third messengers), which can then activate multiple downstream genes.

biases protein binding away from the CREB family of proteins. AP-1 sequences confer responsiveness to the PKC pathway. AP-1 proteins generally bind DNA as heterodimers composed of one member each of two different families of related bZIP proteins, the Fos family (c-Fos, Fra-1, Fra-2, and FosB) and the Jun family (c-Jun, JunB, and JunD), providing for a multiplicity of regulatory control.

### Cellular Immediate-Early Genes

Genes that are activated transcriptionally by synaptic activity, drugs, and growth factors often have been classified roughly into two groups. Genes, such as the *c-fos* gene itself, that are activated rapidly

(within minutes), transiently, and without requiring new protein synthesis often are described as cellular immediate-early genes (IEGs). Genes that are induced or repressed more slowly (within hours) and are dependent on new protein synthesis have been described as late-response genes. Several IEGs have been used as cellular markers of neural activation because they are markedly induced by depolarization (the critical signal being Ca<sup>2+</sup> entry) and second-messenger and growth factor pathways, permitting novel approaches to functional neuroanatomy (Chapter 39, Box 39.4).

The protein products of those cellular IEGs that function as transcription factors bind to *cis*-regulatory elements contained within a subset of late-response genes to activate or repress them (Fig. 10.18). In sum, neural genes that are regulated by extracellular signals are activated or repressed with varying time courses by reversible phosphorylation of constitutively synthesized transcription factors and by newly synthesized transcription factors, some of which are regulated as IEGs.

### Activation of the *c-fos* Gene

The *c-fos* gene is activated rapidly by neurotransmitters or drugs that stimulate the cAMP pathway or Ca<sup>2+</sup> elevation. Both pathways produce phosphorylation of transcription factor CREB. The *c-fos* gene contains three binding sites for CREB. The *c-fos* gene can also be induced by the Ras/MAP kinase pathway, which is activated by a number of growth factors. For example, neurotrophins, such as nerve growth factor (NGF), bind a family of receptor tyrosine kinases (Trks); NGF interacts with Trk A, which activates Ras. Ras then acts through a cascade of protein kinases (Chapter 21). Cross talk between neurotransmitter and growth factor-signaling pathways has been documented with increasing frequency and likely plays an important role in the precise tuning of neural plasticity to diverse environmental stimuli.

### Regulation of *c-Jun*

Expression of most of the proteins of the Fos and Jun families that constitute transcription factor AP-1 and the binding of AP-1 proteins to DNA is regulated by extracellular signals. Phosphorylation and activation of c-Jun can result from the action of Jun N-terminal kinase (JNK). JNK is a member of the mitogen activated protein kinase (MAPK) family of protein kinases. JNK also has been shown to be activated by neurotransmitters, including glutamate. Thus, AP-1-mediated transcription within the nervous system requires multiple steps, beginning with the activation of genes encoding AP-1 proteins.

### *Cytokines as Inducers of Gene Expression in the Nervous System*

With regard to function, the boundary between trophic, or growth, factors and cytokines in the nervous system has become increasingly arbitrary. However, cell-signaling mechanisms offer a useful means of distinction. Growth factors, such as neurotrophins (e.g., nerve growth factor, brain-derived neurotrophic factor, and neurotrophin 3), epidermal growth factor (EGF), and fibroblast growth factor (FGF), act through receptor protein tyrosine kinases, whereas cytokines, such as leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), and interleukin-6 (IL-6), act through nonreceptor protein tyrosine kinases.

LIF, CNTF, and IL-6 subserve a wide array of overlapping functions inside and outside the nervous system, including hematopoietic and immunologic functions outside the nervous system and regulation of neuronal survival, differentiation, and, in certain circumstances, plasticity within the nervous system. Their receptors contain a common signal-transducing subunit, gp130. Receptors for these cytokines consist of a signal-transducing  $\beta$  component, which includes gp130, and interacts with nonreceptor protein tyrosine kinases (PTKs) of the Janus kinase (Jak) family (e.g., Jak1, Jak2, and Tyk2). Some cytokine receptors interact only with a single Jak PTK whereas others interact with multiple Jak PTKs.

Signal transduction to the nucleus includes tyrosine phosphorylation by the Jak PTKs of one or more of the STAT proteins mentioned earlier. Upon phosphorylation, STAT proteins form dimers through the association of SH2 domains, an important type of protein interaction domain. Dimerization is thought to trigger translocation to the nucleus, where STATs bind their cognate cytokine response elements. Different STATs become activated by different cytokine receptors, not because of differential use of Jak PTKs, but because of specific coupling of certain STATs to certain receptors. Thus, for example, the IL-6 receptor preferentially activates STAT1 and STAT3; the CNTF receptor preferentially activates STAT3. Cytokine response elements, to which STATs bind, have now been identified within many neural genes, including vasoactive intestinal polypeptide and several other neuropeptide genes.

### *Steroid Hormone Receptors*

The differentiation of many cell types in the brain is established by exposure to steroids. Steroid hormones, including glucocorticoids, sex steroids, mineralocorticoids, retinoids, thyroid hormone, and vitamin D, are small lipid-soluble ligands that can diffuse across cell membranes. They act on their receptors

within the cell cytoplasm in marked distinction to the other types of intercellular signals described herein. Another unique feature of steroid hormones is that their receptors are themselves transcription factors. Each has a transcriptional-activation domain at its amino terminus, a DNA-binding domain, and a hormone-binding domain at its carboxy terminus. DNA-binding domains recognize specific palindromic DNA sequences, steroid hormone response elements, within the regulatory regions of specific genes.

After having been bound by hormone, activated steroid hormone receptors translocate into the nucleus, where they bind to their cognate response elements. Such binding then increases or decreases the rate at which these target genes are transcribed, depending on the precise nature and DNA sequence context of the element.

### **Summary**

The formation of long-term memories requires changes in gene expression and new protein synthesis. It is at transcription initiation that extracellular signals such as neurotransmitters, hormones, drugs, and growth factors exert their most significant control. The transcription is modulated by transcription factors that recruit the RNA polymerases to the DNA. For example, the critical nuclear translocation step in the activation of transcription factor CREB involves the catalytic subunit of PKA, which can phosphorylate CREB on entering the nucleus. In addition, increasing evidence indicates that at least some forms of long-term memory require new gene expression.

Genes that encode the transcription factors themselves may respond quickly or slowly. These genes have been coined third messengers in signal transduction cascades. Cross talk between neurotransmitter and growth factor-signaling pathways is likely to play an important role in the precise tuning of neuronal plasticity to diverse environmental stimuli.

The active, mature transcription complex is a remarkable architectural assembly of RNA polymerase II, transcription factors, and adaptors assembled at the basal promoter. Cells can exert exquisite control of the genes being transcribed in a variety of situations; for example, to govern appropriate entry or exit from the cell cycle, to maintain appropriate cellular identity, and to respond appropriately to extracellular signals.

Transcription can be regulated by many different extracellular signals modulated by a large array of signaling pathways (many including reversible phosphorylation) and a complex array of typically dimeric transcription factors. In this chapter, regulation has been illustrated by only a few of the families of

transcription factors. Those chosen appear to play important roles in the nervous system and illustrate many of the basic principles of gene regulation.

# Postsynaptic Potentials and Synaptic Integration

The study of synaptic transmission in the central nervous system (CNS) provides an opportunity to learn more about the diversity and richness of mechanisms underlying this process and to learn how some of the fundamental signaling properties of the nervous system, such as action potentials and synaptic potentials, work together to process information and generate behavior.

Postsynaptic potentials (PSPs) in the CNS can be divided into two broad classes on the basis of mechanisms and, generally, duration of these potentials. One class is based on the direct binding of a transmitter molecule(s) with a receptor-channel complex; these receptors are ionotropic. The structure of these receptors is discussed in detail in Chapter 9. The resulting PSPs are generally short-lasting and hence sometimes are called fast PSPs; they have also been referred to as “classical” because they were the first synaptic potentials to be recorded in the CNS (Eccles, 1964; Spencer, 1977). The duration of a typical fast PSP is about 20 ms.

The other class of PSPs is based on the indirect effect of a transmitter molecule(s) binding with a receptor. The receptors that produce these PSPs are metabotropic. As discussed in Chapter 9, the receptors activate G proteins (G-protein-coupled receptors; GPCRs) that affect the channel either directly or through additional steps in which the level of a second messenger is altered. The changes in membrane potential produced by metabotropic receptors can be long-lasting and therefore are called slow PSPs. The mechanisms for fast PSPs mediated by ionotropic receptors are considered first.

## IONOTROPIC RECEPTORS: MEDIATORS OF FAST EXCITATORY AND INHIBITORY SYNAPTIC POTENTIALS

### The Stretch Reflex Is Useful to Examine the Properties and Functional Consequences of Ionotropic PSPs

The stretch reflex, one of the simpler behaviors mediated by the central nervous system, is a useful example with which to examine the properties and functional consequences of ionotropic PSPs. The tap of a neurologist’s hammer to a ligament elicits a reflex extension of the leg, as illustrated in Figure 11.1. The brief stretch of the ligament is transmitted to the extensor muscle and is detected by specific receptors in the muscle and ligament (Chapter 29). Action potentials initiated in the stretch receptors are propagated to the spinal cord by afferent fibers (Chapter 29). The receptors are specialized regions of sensory neurons with somata located in the dorsal root ganglia just outside the spinal column. Axons of the afferents enter the spinal cord and make excitatory synaptic connections with at least two types of postsynaptic neurons. First, a synaptic connection is made to the extensor motor neuron. As the result of its synaptic activation, the motor neuron fires action potentials that propagate out of the spinal cord and ultimately invade the terminal regions of the motor axon at neuromuscular junctions. There, acetylcholine (ACh) is released, nicotinic ACh receptors are activated, an end plate potential (EPP) is produced, an action potential is initiated in the muscle cell, and the muscle cell is contracted, producing the

**FIGURE 11.1** Features of the vertebrate stretch reflex. Stretch of an extensor muscle leads to the initiation of action potentials in the afferent terminals of specialized stretch receptors. The action potentials propagate to the spinal cord through afferent fibers (sensory neurons). The afferents make excitatory connections with extensor motor neurons (E). Action potentials initiated in the extensor motor neuron propagate to the periphery and lead to the activation and subsequent contraction of the extensor muscle. The afferent fibers also activate interneurons that inhibit the flexor motor neurons (F).

reflex extension of the leg. Second, a synaptic connection is made to another group of neurons called interneurons (nerve cells interposed between one type of neuron and another). The particular interneurons activated by the afferents are inhibitory interneurons because activation of these interneurons leads to the release of a chemical transmitter substance that inhibits the flexion motor neuron. This inhibition tends to prevent an uncoordinated (improper) movement (i.e., flexion) from occurring. The reflex system illustrated in Figure 11.1 also is known as the monosynaptic stretch reflex because this reflex is mediated by a single (“mono”) excitatory synapse in the central nervous system. Spinal reflexes are described in greater detail in Chapter 29.

Figure 11.2 illustrates procedures that can be used to experimentally examine some of the components of synaptic transmission in the reflex pathway for the stretch reflex. Intracellular recordings are made from one of the sensory neurons, the extensor and flexor motor neurons, and an inhibitory interneuron. Normally, the sensory neuron is activated by stretch to the muscle, but this step can be bypassed by simply injecting a pulse of depolarizing current of sufficient magnitude into the sensory neuron to elicit an action potential. The action potential in the sensory neuron leads to a potential change in the motor neuron known as an excitatory postsynaptic potential (EPSP; Fig. 11.2).

Mechanisms responsible for fast EPSPs mediated by ionotropic receptors in the CNS are fairly well known. Moreover, the ionic mechanisms for EPSPs in the CNS

are essentially identical with the ionic mechanisms at the skeletal neuromuscular junction. Specifically, the transmitter substance released from the presynaptic terminal (Chapters 7 and 8) diffuses across the synaptic cleft, binds to specific receptor sites on the postsynaptic membrane (Chapter 9), and leads to a simultaneous increase in permeability to  $\text{Na}^+$  and  $\text{K}^+$ , which makes the membrane potential move toward a value of about 0 mV. However, the processes of synaptic transmission at the sensory neuron–motor neuron synapse and the motor neuron–skeletal muscle synapse differ in two fundamental ways: (1) in the transmitter used and (2) in the amplitude of the PSP. The transmitter substance at the neuromuscular junction is ACh, whereas that released by the sensory neurons is an amino acid, probably glutamate. Indeed, glutamate is the most common transmitter that mediates excitatory actions in the CNS. The amplitude of the postsynaptic potential at the neuromuscular junction is about 50 mV; consequently, each PSP depolarizes the postsynaptic cell beyond threshold so there is a one-to-one relation between an action potential in the spinal motor neuron and an action potential in the skeletal muscle cell. Indeed, the EPP must depolarize the muscle cell by only about 30 mV to initiate an action potential, allowing a safety factor of about 20 mV. In contrast, the EPSP in a spinal motor neuron produced by an action potential in an afferent fiber has an amplitude of only about 1 mV. The mechanisms by which these small PSPs can trigger an action potential in the postsynaptic neuron are discussed in a later section of this chapter and in Chapter 12.

**FIGURE 11.2** Excitatory (EPSP) and inhibitory (IPSP) postsynaptic potentials in spinal motor neurons. Idealized intracellular recordings from a sensory neuron, interneuron, and extensor and flexor motor neurons (MNs). An action potential in the sensory neuron produces a depolarizing response (an EPSP) in the extensor motor neuron. An action potential in the interneuron produces a hyperpolarizing response (an IPSP) in the flexor motor neuron.

## Macroscopic Properties of PSPs Are Determined by the Nature of Gating and Ion-Permeation Properties of Single Channels

### Patch-Clamp Techniques

Patch-clamp techniques (Hamill *et al.*, 1981), with which current flowing through single isolated receptors can be measured directly, can be sources of insight into both the ionic mechanisms and the molecular properties of PSPs mediated by ionotropic receptors. This approach was pioneered by Erwin Neher and Bert Sakman in the 1970s and led to their being awarded the Nobel Prize in Physiology or Medicine in 1991.

Figure 11.3A illustrates an idealized experimental arrangement of an “outside-out” patch recording of a single ionotropic receptor. The patch pipette contains a solution with an ionic composition similar to that of the cytoplasm, whereas the solution exposed to the outer surface of the membrane has a composition similar to that of normal extracellular fluid. The

electrical potential across the patch, and hence the transmembrane potential ( $V_m$ ), is controlled by the patch-clamp amplifier. The extracellular (outside) fluid is considered “ground.” Transmitter can be delivered by applying pressure to a miniature pipette filled with an agonist (in this case, ACh), and the current ( $I_m$ ) flowing across the patch of membrane is measured by the patch-clamp amplifier (Fig. 11.3). Pressure in the pipette that contains ACh can be continuous, allowing a constant stream of ACh to contact the membrane, or can be applied as a short pulse to allow a precisely timed and discrete amount of ACh to contact the membrane. The types of recordings obtained from such an experiment are illustrated in the traces in Figure 11.3. In the absence of ACh, no current flows through the channel (Fig. 11.3A). When ACh is applied continuously, current flows across the membrane (through the channel), but the current does not flow continuously; instead, small step-like changes in current are observed (Fig. 11.3B). These changes represent the probabilistic (random) opening and closing of the channel.

**FIGURE 11.3** Single-channel recording of ionotropic receptors and their properties. (A) Experimental arrangement for studying properties of ionotropic receptors. (B) Idealized single-channel currents in response to application of ACh.

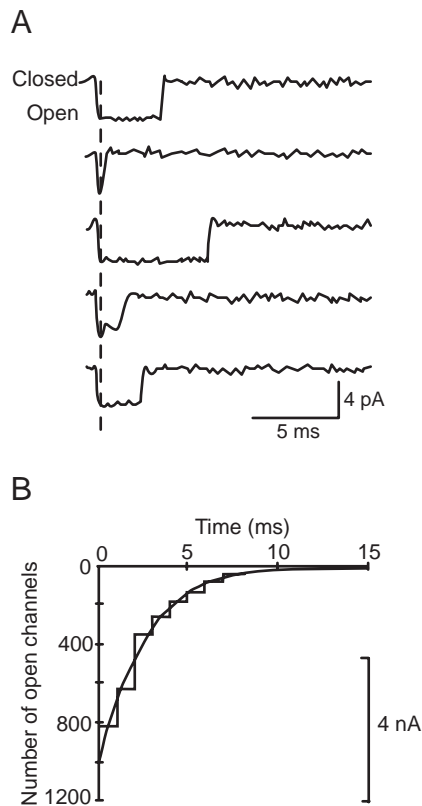

### Channel Openings and Closings

As a result of the type of patch-recording techniques heretofore described, three general conclusions about the properties of ligand-gated channels can be drawn. First, ACh, as well as other transmitters that activate ionotropic receptors, causes the opening of individual ionic channels (for a channel to open, usually two mol-

ecules of transmitter must bind to the receptor). Second, when a ligand-gated channel opens, it does so in an all-or-none fashion. Increasing the concentration of transmitter in the ejection microelectrode does not increase the permeability (conductance) of the channel; it increases its probability ( $P$ ) of being open. Third, the ionic current flowing through a single channel in its open state is extremely small (e.g.,  $10^{-12}$  A); as a result, current flowing through any single channel makes only a small contribution to the normal postsynaptic potential. Physiologically, when a larger region of the postsynaptic membrane, and thus more than one channel, is exposed to a released transmitter, the net conductance of the membrane increases due to the increased probability that a larger population of channels will be open at the same time. The normal PSP, measured with standard intracellular recording techniques (e.g., Fig. 11.2), is then proportional to the sum of the currents that flow through these many individual open channels. The properties of voltage-sensitive channels (see Chapter 6) are similar in that they, too, open in all-or-none fashion, and, as a result, the net effect on the cell is due to the summation of currents flowing through many individual open ion channels. The two types of channels differ, however, in that one is opened by a chemical agent, whereas the other is opened by changes in membrane potential.

### Statistical Analysis of Channel Gating and Kinetics of the PSP

The experiment illustrated in Figure 11.3B was performed with continuous exposure to ACh. Under such conditions, the channels open and close repeatedly. When ACh is applied by a brief pressure pulse to more accurately mimic the transient release from the presynaptic terminal, the transmitter diffuses away before it can cause a second opening of the channel. A set of data similar to that shown in Figure 11.4A would be obtained if an ensemble of these openings were collected and aligned with the start of each opening. Each individual trace represents the response to each successive "puff" of ACh. Note that, among the responses, the duration of the opening of the channel varies considerably—from very short (less than 1 ms) to more than 5 ms. Moreover, channel openings are independent events. The duration of any one channel opening does not have any relation to the duration of a previous opening. Figure 11.4B illustrates a plot that is obtained by adding 1000 of these individual responses. Such an addition roughly simulates the conditions under which a transmitter released from a presynaptic terminal leads to the near simultaneous activation of many single channels in the postsynaptic membrane. (Note that the addition of 1000 channels would produce

**FIGURE 11.4** Determination of the shape of the postsynaptic response from single-channel currents. (A) Each trace represents the response of a single channel to a repetitively applied puff of transmitter. Traces are aligned with the beginning of the channel opening (dashed line). (B) The addition of 1000 of the individual responses. If a current equal to 4 pA were generated by the opening of a single channel, then a 4-nA current would be generated by 1000 channels opening at the same time. Data are fitted with an exponential function having a time constant equal to  $1/\alpha$  (see text). Reprinted with permission from Sakmann (1992). American Association for the Advancement of Science, © 1992 The Nobel Foundation.

a synaptic current equal to about 4 nA.) This simulation is valid given the assumption that the statistical properties of a single channel over time are the same as the statistical properties of the ensemble at one instant of time (i.e., an ergodic process). The ensemble average can be fit with an exponential function with a decay time constant of 2.7 ms. An additional observation (discussed later) is that the value of the time constant is equal to the mean duration of the channel openings. The curve in Figure 11.4B is an indication of the probability that a channel will remain open for various times, with a high probability for short times and a low probability for long times.

The ensemble average of single-channel currents (Fig. 11.4B) roughly accounts for the time course of the EPSP. However, note that the time course of the aggregate synaptic current can be somewhat faster than that

of the excitatory postsynaptic potential in Figure 11.2. This difference is due to charging of the membrane capacitance by a rapidly changing synaptic current. Because the single-channel currents were recorded with the membrane voltage clamped, the capacitive current [ $I_c = C_m * (dV/dt)$ ] is zero. In contrast, for the recording of the postsynaptic potential in Figure 11.2, the membrane was not voltage clamped, and therefore as the voltage changes (i.e.,  $dV/dt$ ), some of the synaptic current charges the membrane capacitance (see Eq. 11.7).

Analytical expressions that describe the shape of the ensemble average of the open lifetimes and the mean open lifetime can be derived by considering that single-channel opening and closing is a stochastic process (Johnston and Wu, 1995; Sakmann, 1992). Relations are formalized to describe the likelihood (probability) of a channel being in a certain state. Consider the following two-state reaction scheme:

In this scheme,  $\alpha$  represents the rate constant for channel closing and  $\beta$  the rate constant for channel opening. The scheme can be simplified further if we consider a case in which the channel has been opened by the agonist and the agonist is removed instantaneously. A channel so opened (at time 0) will then close after a certain random time (Fig. 11.4). It can be shown that the mean open time =  $1/\alpha$  (Johnston and Wu, 1995; Sakmann, 1992).

### Gating Properties of Ligand-Gated Channels

Although statistical analysis can be a valuable source of insight into the statistical nature of the gating process and the molecular determinants of the macroscopic postsynaptic potential, the description in the preceding section is a simplification of the actual processes. Specifically, a more complete description must include the kinetics of receptor binding and unbinding and the determinants of the channel opening, as well as the fact that channels display rapid transitions between open and closed states during a single agonist receptor occupancy. Thus, the open states illustrated in Figures 11.3B and 11.4A represent the period of a burst of extremely rapid openings and closings. If the bursts of rapid channel openings and closings are thought of, and behave functionally, as a single continuous channel closure, the formalism developed in the preceding section is a reasonable approximation for many ligand-gated channels. Nevertheless, a more complex reaction scheme is necessary to quantitatively explain available data. Such a scheme would include the following states,

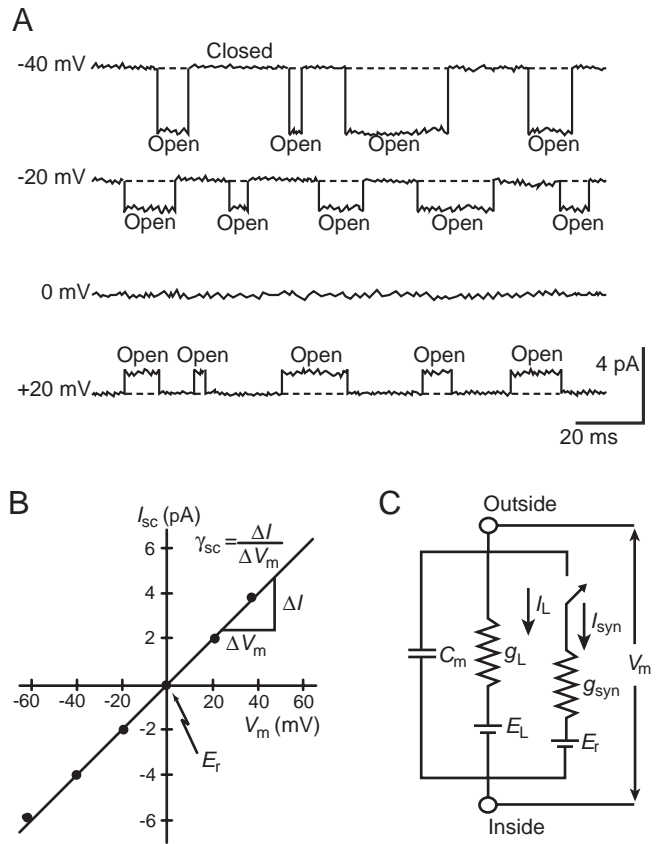

where R represents the receptor, A the agonist, and the  $\alpha$ ,  $\beta$ , and  $k$  values the forward and reverse rate constants for the various reactions.  $A_2R^*$  represents a channel opened as a result of the binding of two agonist molecules. The asterisk indicates an open channel. Note that the lower part of the reaction scheme is equivalent to the one developed earlier; that is,

With the use of probability theory, equations describing transitions between the states can be determined. The approach is identical to that used in the simplified two-state scheme. However, the mathematics and analytical expressions are more complex. For some receptors, additional states must be represented. For example, as described in Chapter 9, some ligand-gated channels exhibit a process of desensitization in which continued exposure to a ligand results in channel closure.

**Null (Reversal) Potential and Slope of I-V Relations**

What ions are responsible for the synaptic current that produces the EPSP? Early studies of the ionic mechanisms underlying the EPSP at the skeletal neuromuscular junction yielded important information. Specifically, voltage-clamp and ion-substitution experiments indicated that the binding of transmitter to receptors on the postsynaptic membrane led to a simultaneous increase in  $Na^+$  and  $K^+$  permeability that depolarized the cell toward a value of about 0 mV (Fatt and Katz, 1951; Takeuchi and Takeuchi, 1960). These findings are applicable to the EPSP in a spinal motor

**FIGURE 11.5** Voltage dependence of the current flowing through single channels. (A) Idealized recording of an ionotropic receptor in the continuous presence of agonist. (B) I-V relation of the channel in A. (C) Equivalent electrical circuit of a membrane containing that channel.  $\gamma_{sc}$ , single-channel conductance;  $I_L$ , leakage current;  $I_{sc}$ , single-channel current;  $g_L$ , leakage conductance;  $g_{syn}$ , macroscopic synaptic conductance;  $E_L$ , leakage battery;  $E_r$ , reversal potential.

neuron produced by an action potential in an afferent fiber and have been confirmed and extended at the single-channel level.

Figure 11.5 illustrates the type of experiment in which the analysis of single-channel currents can be a source of insight into the ionic mechanisms of EPSPs. A transmitter is delivered to the patch while the membrane potential is varied systematically (Fig. 11.5A). In the upper trace, the patch potential is -40 mV. The ejection of transmitter produces a sequence of channel openings and closings, the amplitudes of which are constant for each opening (i.e., about 4 pA). Now consider the case in which the transmitter is applied when the potential across the patch is -20 mV. The frequency of the responses, as well as the mean open lifetimes, is about the same as when the potential was at -40 mV, but now the amplitude of the single-channel currents is decreased uniformly. Even more interesting, when

the patch is depolarized artificially to a value of about 0 mV, an identical puff of transmitter produces no current in the patch. If the patch potential is depolarized to a value of about 20 mV and the puff is delivered again, openings are again observed, but the flow of current through the channel is reversed in sign; a series of upward deflections indicate outward single-channel currents. In summary, there are downward deflections (inward currents) when the membrane potential is at -40 mV, no deflections (currents) when the membrane is at 0 mV, and upward deflections (outward currents) when the membrane potential is moved to 20 mV.

The simple explanation for these results is that no matter what the membrane potential, the effect of the transmitter binding with receptors is to produce a permeability change that tends to move the membrane potential toward 0 mV. If the membrane potential is more negative than 0 mV, an inward current is recorded. If the membrane potential is more positive than 0 mV, an outward current is recorded. If the membrane potential is at 0 mV, there is no deflection because the membrane potential is already at 0 mV. At 0 mV, the channels are opening and closing as they always do in response to the agonist, but there is no net movement of ions through them. This 0-mV level is known as the synaptic null potential or reversal potential because it is the potential at which the sign of the synaptic current reverses. The fact that the experimentally determined reversal potential equals the calculated value obtained by using the Goldman-Hodgkin-Katz (GHK) equation (Chapter 6) provides strong support for the theory that the EPSP is due to the opening of channels that have equal permeabilities to  $\text{Na}^+$  and  $\text{K}^+$ . Ion-substitution experiments also confirm this theory. Thus, when the concentration of  $\text{Na}^+$  or  $\text{K}^+$  in the extracellular fluid is altered, the value of the reversal potential shifts in a way predicted by the GHK equation. (Some other cations, such as  $\text{Ca}^{2+}$ , also permeate these channels, but their permeability is low compared with that of  $\text{Na}^+$  and  $\text{K}^+$ .)

Different families of ionotropic receptors have different reversal potentials because each has unique ion selectivity. In addition, it should now be clear that the sign of the synaptic action (excitatory or inhibitory) depends on the value of the reversal potential relative to the resting potential. If the reversal potential of an ionotropic receptor channel is more positive than the resting potential, opening of that channel will lead to depolarization (i.e., an EPSP). In contrast, if the reversal potential of an ionotropic receptor channel is more negative than the resting potential, opening of that channel will lead to hyperpolarization; that is, an inhibitory postsynaptic potential (IPSP), which is the topic of a later section in this chapter.

Plotting the average peak value of single-channel currents ( $I_{sc}$ ) versus the membrane potential (trans-patch potential) at which they are recorded (Fig. 11.5B) can be a source of quantitative insight into the properties of the ionotropic receptor channel. Note that the current-voltage ( $I$ - $V$ ) relation is linear; it has a slope, the value of which is the single-channel conductance, and an intercept at 0 mV. This linear relation can be put in the form of Ohm's law ( $I = G * \Delta V$ ). Thus,

$$I_{sc} = \gamma_{sc} * (V_m - E_r), \quad (11.1)$$

where  $\gamma_{sc}$  is the single-channel conductance and  $E_r$  is the reversal potential (here, 0 mV).

### Summation of Single-Channel Currents

We now know that the sign of a synaptic action can be predicted by knowledge of the relation between the resting potential ( $V_m$ ) and the reversal potential ( $E_r$ ), but how can the precise amplitude be determined? The answer to this question lies in understanding the relation between synaptic conductance and extra synaptic conductances. These interactions can be rather complex (see Chapter 12), but some initial understanding can be obtained by analyzing an electrical equivalent circuit for these two major conductance branches. We first need to move from a consideration of single-channel conductances and currents to that of macroscopic conductances and currents. The postsynaptic membrane contains thousands of any one type of ionotropic receptor, and each of these receptors could be activated by transmitter released by a single action potential in a presynaptic neuron. Because conductances in parallel add, the total conductance change produced by their simultaneous activation would be

$$g_{syn} = \gamma_{sc} P * N^* \quad (11.2)$$

where  $\gamma_{sc}$ , as before, is the single-channel conductance,  $P$  is the probability of opening of a single channel (controlled by the ligand), and  $N$  is the total number of ligand-gated channels in the postsynaptic membrane. The macroscopic postsynaptic current produced by the transmitter released by a single presynaptic action potential can then be described by

$$I_{syn} = g_{syn} * (V_m - E_r). \quad (11.3)$$

Equation 11.3 can be represented physically by a voltage ( $V_m$ ) measured across a circuit consisting of a resistor ( $g_{syn}$ ) in series with a battery ( $E_r$ ). An equivalent circuit of a membrane containing such a conductance is illustrated in Figure 11.5C. Also included in this circuit is a membrane capacitance ( $C_m$ ), a resistor representing the leakage conductance ( $g_L$ ), and a battery ( $E_L$ ) representing the leakage potential. (Voltage-dependent  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{K}^+$  channels that

contribute to the generation of the action potential have been omitted for simplification.)

The simple circuit allows the simulation and further analysis of the genesis of the PSP. Closure of the switch simulates the opening of the channels by transmitter released from some presynaptic neuron (i.e., a change in  $P$  of Eq. (2) from 0 to 1). When the switch is open (i.e., no agonist is present and the ligand-gated channels are closed), the membrane potential ( $V_m$ ) is equal to the value of the leakage battery ( $E_L$ ). Closure of the switch (i.e., the agonist opens the channels) tends to polarize the membrane potential toward the value of the battery ( $E_r$ ) in series with the synaptic conductance. Although the effect of the channel openings is to depolarize the postsynaptic cell toward  $E_r$  (0 mV), this value is never achieved because ligand-gated receptors are only a small fraction of the ion channels in the membrane. Other channels (such as the leakage channels, which are not affected by the transmitters) tend to hold the membrane potential at  $E_L$  and prevent the membrane potential from reaching the 0-mV level. In terms of the equivalent electrical circuit (Fig. 11.5C),  $g_L$  is much greater than  $g_{syn}$ .

An analytical expression that can be a source of insight into the production of an EPSP by the engagement of a synaptic conductance can be derived by examining the current flowing in each of the two conductance branches of the circuit in Figure 11.5C. As shown previously (Eq. 11.3), current flowing in the branch representing the synaptic conductance is equal to

$$I_{syn} = g_{syn} * (V_m - E_r).$$

Similarly, the current flowing through the leakage conductance is equal to

$$I_L = g_L * (V_m - E_L) \quad (11.4)$$

By conservation of current, the two currents must be equal and opposite. Therefore,

$$g_{syn} * (V_m - E_r) = -g_L * (V_m - E_L)$$

Rearranging and solving for  $V_m$ , we obtain

$$V_m = \frac{g_{syn}E_r + g_LE_L}{g_{syn} + g_L} \quad (11.5)$$

Note that when the synaptic channels are closed (i.e., switch open),  $g_{syn}$  is 0 and

$$V_m = E_L$$

Now consider the case of ligand-gated channels being opened by the release of transmitter from a presynaptic neuron (i.e., switch closed) and a neuron with  $g_L = 10$  nS,  $E_L = -60$  mV,  $g_{syn} = 0.2$  nS, and  $E_r = 0$  mV.

Then

$$\begin{aligned} V_m &= \frac{(0.2 \times 10^{-9} * 0) + (10 \times 10^{-9} * -60)}{10.2 \times 10^{-9}} \\ &= -59 \text{ mV} \end{aligned}$$

Thus, as a result of the closure of the switch, the membrane potential has changed from its initial value of  $-60$  mV to a new value of  $-59$  mV; that is, an EPSP of 1 mV has been generated.

The preceding analysis ignored membrane capacitance ( $C_m$ ), the charging of which makes the synaptic potential slower than the synaptic current. Thus, a more complete analytical description of the postsynaptic factors underlying the generation of a PSP must account for the fact that some of the synaptic current will flow into the capacitive branch of the circuit. Again, by conservation of current, the sum of the currents in the three branches must equal 0. Therefore,

$$0 = C_m \frac{dV_m}{dt} + I_L + I_{syn}, \quad (11.6)$$

$$0 = C_m \frac{dV_m}{dt} + g_L * (V_m - E_L) + g_{syn}(t) * (V_m - E_r), \quad (11.7)$$

where  $C_m (dV_m/dt)$  is the capacitive current.

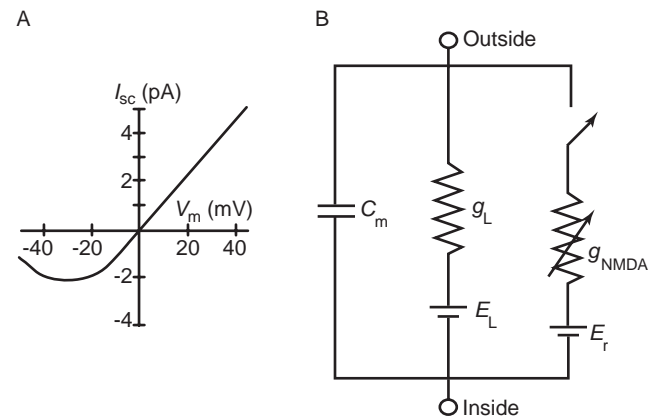

By solving for  $V_m$  and integrating the differential equation, we can determine the magnitude and time course of a PSP. An accurate description of the kinetics of the PSP requires that the simple switch closure (all-or-none engagement of the synaptic conductance) be replaced with an expression [ $g_{syn}(t)$ ] that describes the dynamics of the change in synaptic conductance with time.

### Nonlinear I-V Relations of Some Ionotropic Receptors

For many PSPs mediated by ionotropic receptors, the current-voltage relation of the synaptic current is linear or approximately linear (Fig. 11.5B). Such ohmic relations are typical of nicotinic ACh channels and AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionate) glutamate channels (as well as many receptors mediating IPSPs). The linear I-V relation is indicative of a channel whose conductance is not affected by the potential across the membrane. Such linearity should be contrasted with the steep voltage dependency of the conductance of channels underlying the initiation and repolarization of action potentials (Chapter 6).

NMDA (N-methyl-D-aspartate) glutamate channels are a class of ionotropic receptors that have nonlinear current-voltage relations. At negative potentials, the channel conductance is low even when glutamate is bound to the receptor. As the membrane is depolar-

ized, conductance increases and current flowing through the channel increases, resulting in the type of I–V relation illustrated in Figure 11.6A. This nonlinearity is represented by an arrow through the resistor representing this synaptic conductance in the equivalent circuit of Figure 11.6B. The nonlinear I–V relation of the NMDA receptor can be explained by a voltage-dependent block of the channel by  $Mg^{2+}$  (Fig. 11.7). At normal values of the resting potential, the pore of the channel is blocked by  $Mg^{2+}$ . Thus, even when glutamate binds to the receptor (Fig. 11.7B), the blocked channel prevents ionic flow (and an EPSP). The block can be relieved by depolarization, which presumably displaces  $Mg^{2+}$  from the pore (Fig. 11.7B). When the pore is unblocked, cations (i.e.,  $Na^+$ ,  $K^+$ , and  $Ca^{2+}$ ) can flow readily through the channel, and this flux is manifested in the linear part of the I–V relation (Fig. 11.6A). AMPA channels (Fig. 11.7A) are not blocked by  $Mg^{2+}$  and have linear I–V relations (Fig. 11.5B).

**FIGURE 11.6** (A) I–V relation of the NMDA receptor. (B) Equivalent electrical circuit of a membrane containing NMDA receptors.

**FIGURE 11.7** Features of AMPA and NMDA glutamate receptors. (A) AMPA receptors: (left) in the absence of agonist, the channel is closed, and (right) glutamate binding leads to channel opening and an increase in  $Na^+$  and  $K^+$  permeability. AMPA receptors that contain the GluR2 subunit are impermeable to  $Ca^{2+}$ . (B) NMDA receptors: (left) in the absence of agonist, the channel is closed; (middle) the presence of agonist leads to a conformational change and channel opening, but no ionic flux occurs because the pore of the channel is blocked by  $Mg^{2+}$ ; and (right) in the presence of depolarization, the  $Mg^{2+}$  block is removed and the agonist-induced opening of the channel leads to changes in ion flux (including  $Ca^{2+}$  influx into the cell).

### *Inhibitory Postsynaptic Potentials Decrease the Probability of Cell Firing*

Some synaptic events decrease the probability of generating action potentials in the postsynaptic cell. Potentials associated with these actions are called inhibitory postsynaptic potentials. Consider the inhibitory interneuron illustrated in Figure 11.2. Normally, this interneuron is activated by summing EPSPs from converging afferent fibers. These EPSPs summate in space and time such that the membrane potential of the interneuron reaches threshold and fires an action potential. This step can be bypassed by artificially depolarizing the interneuron to initiate an action potential. The consequences of that action potential from the point of view of the flexor motor neuron are illustrated in Figure 11.2. The action potential in the interneuron produces a transient increase in the membrane potential of the motor neuron. This transient hyperpolarization (the IPSP) looks very much like the EPSP, but it is reversed in sign.

What are the ionic mechanisms for these fast IPSPs and what is the transmitter substance? Because the membrane potential of the flexor motor neuron is about  $-65\text{ mV}$ , one might expect an increase in the conductance to some ion (or ions) with an equilibrium potential (reversal potential) more negative than  $-65\text{ mV}$ . One possibility is  $\text{K}^+$ . Indeed, the  $\text{K}^+$  equilibrium potential in spinal motor neurons is about  $-80\text{ mV}$ ; thus, a transmitter substance that produced a selective increase in  $\text{K}^+$  conductance would lead to an IPSP. The  $\text{K}^+$ -conductance increase would move the membrane potential from  $-65\text{ mV}$  toward the  $\text{K}^+$  equilibrium potential of  $-80\text{ mV}$ . Although an increase in  $\text{K}^+$  conductance mediates IPSPs at some inhibitory synapses (see later), it does not at the synapse between the inhibitory interneuron and the spinal motor neuron. At this particular synapse, the IPSP seems to be due to a selective increase in  $\text{Cl}^-$  conductance. The equilibrium potential for  $\text{Cl}^-$  in spinal motor neurons is about  $-70\text{ mV}$ . Thus, the transmitter substance released by the inhibitory neuron diffuses across the cleft and interacts with receptor sites on the postsynaptic membrane. These receptors are normally closed, but when opened they become selectively permeable to  $\text{Cl}^-$ . As a result of the increase in  $\text{Cl}^-$  conductance, the membrane potential moves from a resting value of  $-65\text{ mV}$  toward the  $\text{Cl}^-$  equilibrium potential of  $-70\text{ mV}$ .

As in the sensory neuron–spinal motor neuron synapse, the transmitter substance released by the inhibitory interneuron in the spinal cord is an amino acid, but in this case the transmitter is glycine. The toxin strychnine is a potent antagonist of glycine recep-

tors. Although glycine originally was thought to be localized to the spinal cord, it is also found in other regions of the nervous system. The most common transmitter associated with inhibitory actions in many areas of the brain is  $\gamma$ -aminobutyric acid (GABA; see Chapter 7).

GABA receptors are divided into three major classes:  $\text{GABA}_A$ ,  $\text{GABA}_B$ , and  $\text{GABA}_C$  (Bormann and Fiegenspan, 1995; Billinton *et al.*, 2001; Bowery, 1993; Cherubini and Conti, 2001; Gage, 1992; Moss and Smart, 2001). As discussed in Chapter 9,  $\text{GABA}_A$  receptors are ionotropic receptors, and, like glycine receptors, binding of transmitter leads to an increased conductance to  $\text{Cl}^-$ , which produces an IPSP.  $\text{GABA}_A$  receptors are blocked by bicuculline and picrotoxin. A particularly striking aspect of  $\text{GABA}_A$  receptors is their modulation by anxiolytic benzodiazepines. Figure 11.8 illustrates the response of a neuron to GABA before and after treatment with diazepam (Bormann, 1988). In the presence of diazepam, the response is potentiated greatly. In contrast to  $\text{GABA}_A$  receptors that are pore-forming channels,  $\text{GABA}_B$  receptors are G-protein coupled (see also Chapter 9).  $\text{GABA}_B$  receptors can be coupled to a variety of different effector mechanisms in different neurons. These mechanisms include decreases in  $\text{Ca}^{2+}$  conductance, increases in  $\text{K}^+$  conductance, and modulation of voltage-dependent A-type  $\text{K}^+$  current. In hippocampal pyramidal neurons, the  $\text{GABA}_B$ -mediated IPSP is due an increased in  $\text{K}^+$  conductance. Baclofen is a potent agonist of  $\text{GABA}_B$  receptors, whereas phaclofen is a selective antagonist.  $\text{GABA}_C$  receptors are pharmacologically distinct from  $\text{GABA}_A$  and  $\text{GABA}_B$  receptors and are found predominantly in the vertebrate retina.  $\text{GABA}_C$  receptors, like  $\text{GABA}_A$  receptors, are  $\text{Cl}^-$  selective pores.

Ionotropic receptors that lead to the generation of IPSPs and ionotropic receptors that lead to the generation of EPSPs have biophysical features in common. Indeed, analyses of the preceding section are generally applicable. A quantitative understanding of the effects of the opening of glycine or  $\text{GABA}_A$  receptors can be obtained by using the electrical equivalent circuit of Figure 11.5C and Eq. 11.5, with the values of  $g_{\text{syn}}$  and  $E_r$  appropriate for the respective ionotropic receptor. Interactions between excitatory and inhibitory conductances can be modeled by adding additional branches to the equivalent circuit (see Fig. 11.15D and Chapter 12).

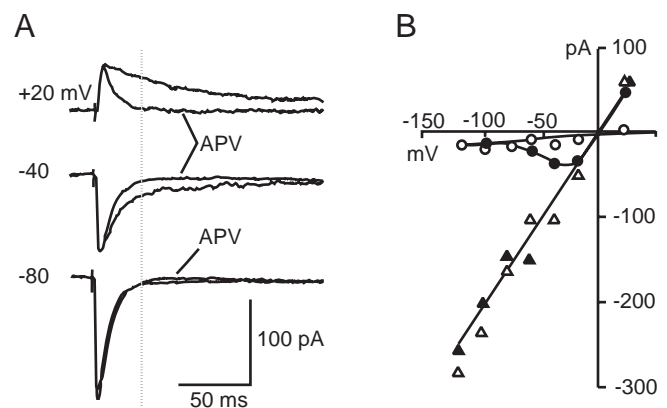

### *Some PSPs Have More Than One Component*

The transmitter released from a presynaptic terminal diffuses across the synaptic cleft, where it binds to ionotropic receptors. In many cases, the postsynaptic

**FIGURE 11.8** Potentiation of GABA responses by benzodiazepine ligands. (A) Brief application (bar) of GABA leads to an inward  $\text{Cl}^-$  current in a voltage-clamped spinal neuron. (B) In the presence of diazepam, the response is enhanced significantly. From Bormann (1988).

receptors are homogeneous. In other cases, the same transmitter activates more than one type of receptor. A major example of this type of heterogeneous postsynaptic action is the simultaneous activation by glutamate of NMDA and AMPA receptors on the same postsynaptic cell. Figure 11.9 illustrates such a dual-component glutamatergic EPSP in the CA1 region of the hippocampus. The cell is voltage clamped at various fixed holding potentials, and the macroscopic synaptic currents produced by activation of the presynaptic neurons are recorded. The experiment is performed in the presence and absence of the agent 2-amino-5-phosphonovalerate (APV), which is a specific blocker of NMDA receptors. When the cell is held at a potential of 20 or  $-40$  mV, APV leads to a dramatic reduction of the late, but not the early, phase of the excitatory postsynaptic current (EPSC). In contrast, when the potential is held at  $-80$  mV, the EPSC is unaffected by APV. These results indicate that PSP consists of two components: (1) an early AMPA-mediated

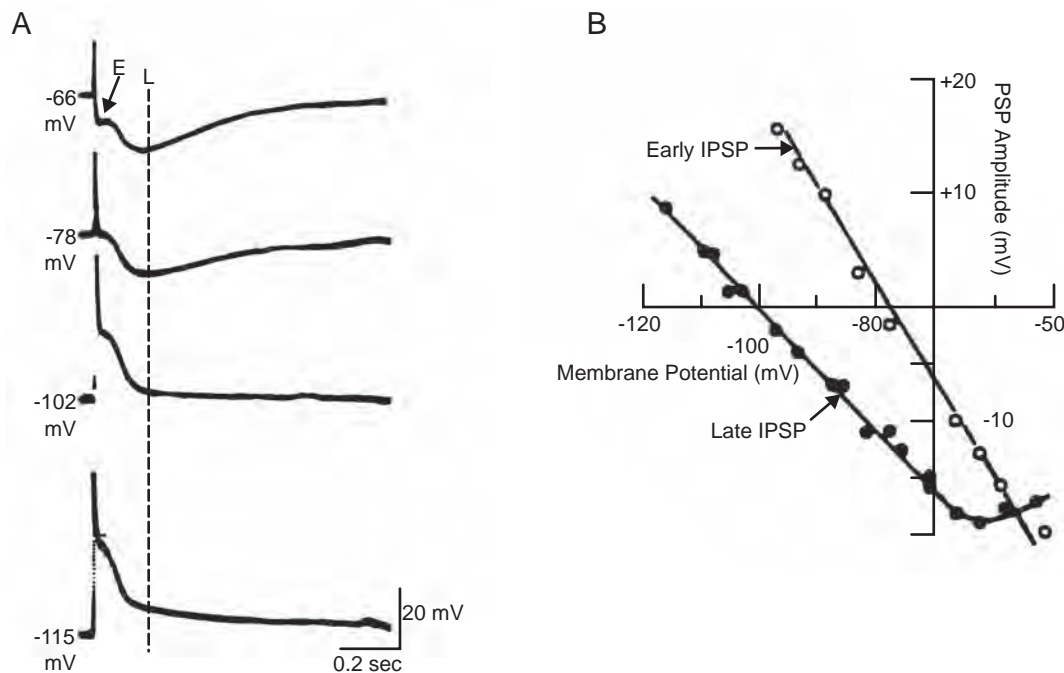

**FIGURE 11.9** Dual-component glutamatergic EPSP. (A) The excitatory postsynaptic current was recorded before and during the application of APV at the indicated membrane potentials. (B) Peak current-voltage relations are shown before ( $\blacktriangle$ ) and during ( $\triangle$ ) the application of APV. Current-voltage relations measured 25 ms after the peak of the EPSC (dotted line in (A)); before ( $\bullet$ ) and during ( $\circ$ ) application of APV are also shown. Reprinted with permission from Hestrin *et al.* (1990).

component and (2) a late NMDA-mediated component. In addition, results indicate that conductance of the non-NMDA component is linear, whereas conductance of the NMDA component is nonlinear. The I-V relations of the early (peak) and late (at approximately 25ms) components of the EPSC are plotted in Figure 11.9 (Hestrin *et al.*, 1990).

Dual-component IPSPs also are observed in the CNS, but here the transmitter (GABA) that mediates the inhibitory actions may be released from different neurons that converge on a common postsynaptic neuron. Stimulation of afferent pathways to the hippocampus results in an IPSP in a pyramidal neuron, which has a fast initial inhibitory phase followed by a slower inhibitory phase (Fig. 11.10). Application of GABA<sub>A</sub> antagonists blocks the early inhibitory phase, whereas the GABA<sub>B</sub> receptor antagonist phaclofen blocks the late inhibitory phase (not shown). Early and late IPSPs can also be distinguished based on their ionic mechanisms. Hyperpolarizing the membrane potential to  $-78$  mV nulls the early response, but at this value of membrane potential the late response is still

hyperpolarizing (Figs. 11.10A and 11.10B). Hyperpolarizing the membrane potential to values more negative than  $-78$  mV reverses the sign of the early response, but the slow response does not reverse until the membrane is made more negative than about  $-100$  mV (Thalmann, 1988). The reversal potentials are consistent with a fast Cl<sup>-</sup>-mediated IPSP, mediated by fast opening of GABA<sub>A</sub> receptors and a slower K<sup>+</sup>-mediated IPSP mediated by G-protein GABA<sub>B</sub> receptors.

Dual-component PSPs need not be strictly inhibitory or excitatory. For example, a presynaptic cholinergic neuron in the mollusk *Aplysia* produces a diphasic excitatory-inhibitory (E-I) response in its postsynaptic follower cell. The response can be simulated by local discrete application of ACh to the postsynaptic cell (Fig. 11.11) (Blankenship *et al.*, 1971). The ionic mechanisms underlying this synaptic action were investigated in ion-substitution experiments, which revealed that the dual response is due to an early Na<sup>+</sup>-dependent component followed by a slower Cl<sup>-</sup>-dependent component. Molecular mechanisms underlying such slow synaptic potentials are discussed next.

**FIGURE 11.10** Dual-component IPSP. (A) Intracellular recordings from a pyramidal cell in the CA3 region of the rat hippocampus in response to activation of mossy fiber afferents. With the membrane potential of the cell at the resting potential, afferent stimulation produces an early (E) and late (L) IPSP. With increased hyperpolarizing produced by injecting constant current into the cell, the early component reverses first. At more negative levels of the membrane potential, the late component also reverses. This result indicates that the ionic conductance underlying the two phases is distinct. (B) Plots of the change in amplitude of the early (measured at 25ms) and the late (measured at 200ms, dashed line in A) response as a function of membrane potential. Reversal potentials of the early and late components are consistent with a GABA<sub>A</sub>-mediated chloride conductance and a GABA<sub>B</sub>-mediated potassium conductance, respectively. From Thalmann (1988).

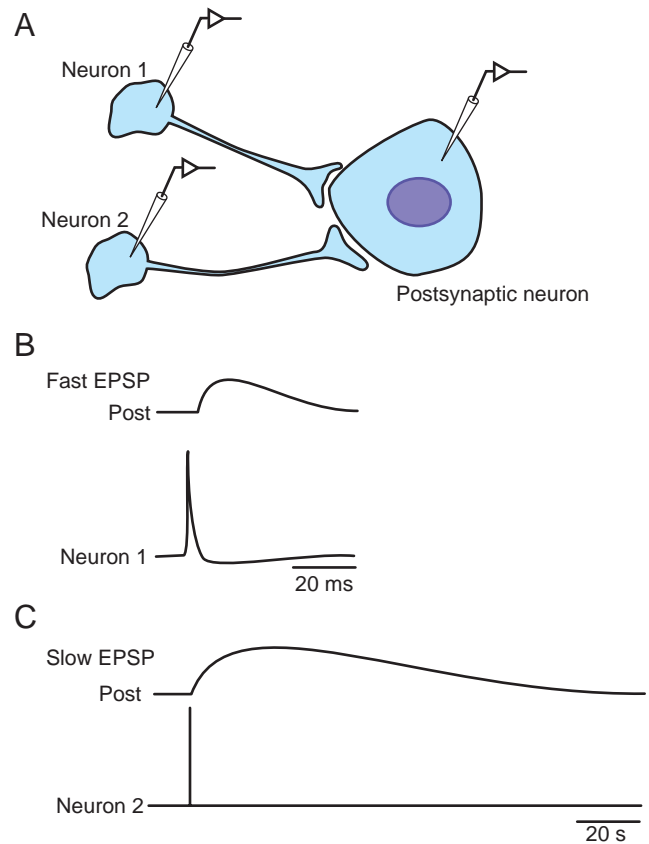

**FIGURE 11.11** Dual-component cholinergic excitatory-inhibitory response. (A) Control in normal saline. Ejection of ACh produces a rapid depolarization followed by a slower hyperpolarization. (B) In  $\text{Na}^+$ -free saline, ACh produces a purely hyperpolarizing response, indicating that the depolarizing component in normal saline includes an increase in  $g_{\text{Na}^+}$ . (C) In  $\text{Cl}^-$ -free saline, ACh produces a purely depolarizing response, indicating that the hyperpolarizing component in normal saline includes an increase in  $g_{\text{Cl}^-}$ . Reprinted with permission from Blankenship *et al.* (1971).

## Summary

Synaptic potentials mediated by ionotropic receptors are the fundamental means by which information is transmitted rapidly between neurons. Transmitters cause channels to open in an all-or-none fashion, and the currents through these individual channels summate to produce the macrosynaptic postsynaptic potential. The sign of the postsynaptic potential is determined by the relationship between the membrane potential of the postsynaptic neuron and the ion selectivity of the ionotropic receptor.

## METABOTROPIC RECEPTORS: MEDIATORS OF SLOW SYNAPTIC POTENTIALS

A common feature of the types of synaptic actions heretofore described is the direct binding of the transmitter with the receptor-channel complex. An entirely separate class of synaptic actions has as its basis the indirect coupling of the receptor with the channel. Two major types of coupling mechanisms have been identified: (1) coupling of the receptor and channel through an intermediate regulatory protein, such as a G-protein; and (2) coupling through a diffusible

**FIGURE 11.12** Fast and slow synaptic potentials. (A) Idealized experiment in which two neurons (1 and 2) make synaptic connections with a common postsynaptic follower cell (Post). (B) An action potential in neuron 1 leads to a conventional fast EPSP with a duration of about 30 ms. (C) An action potential in neuron 2 also produces an EPSP in the postsynaptic cell, but the duration of this slow EPSP is more than three orders of magnitude greater than that of the EPSP produced by neuron 1. Note the change in the calibration bar.

second-messenger system. Because coupling through a diffusible second-messenger system is the most common mechanism, it is the focus of this section.

A comparison of the features of direct, fast ionotropic-mediated and indirect, slow metabotropic-mediated synaptic potentials is shown in Figure 11.12. Slow synaptic potentials are not observed at every postsynaptic neuron, but Figure 11.12A illustrates an idealized case in which a postsynaptic neuron receives two inputs, one of which produces a conventional fast EPSP and the other of which produces a slow EPSP. An action potential in neuron 1 leads to an EPSP in the postsynaptic cell with a duration of about 30 ms (Fig. 11.12B). This type of potential might be produced in a spinal motor neuron by an action potential in an afferent fiber. Neuron 2 also produces a postsynaptic

potential (Fig. 11.12C), but its duration (note the calibration bar) is more than three orders of magnitude greater than that of the EPSP produced by neuron 1.

How can a change in the postsynaptic potential of a neuron persist for many minutes as a result of a single action potential in the presynaptic neuron? Possibilities include a prolonged presence of the transmitter due to continuous release, to slow degradation, or to slow reuptake of the transmitter, but the mechanism here involves a transmitter-induced change in the metabolism of the postsynaptic cell. Figure 11.13 compares the general mechanisms for fast and slow synaptic potentials. Fast synaptic potentials are produced when a transmitter substance binds to a channel and produces a conformational change in the channel, causing it to become permeable to one or more ions (both  $\text{Na}^+$  and  $\text{K}^+$  in Fig. 11.13A). The increase in permeability leads to a depolarization associated with the EPSP. The duration of the synaptic event critically depends on the amount of time during which the transmitter substance remains bound to the receptors. Acetylcholine, glutamate, and glycine remain bound only for a very short period. These transmitters are removed by diffusion, enzymatic breakdown, or reuptake into the presynaptic cell. Therefore, the duration of the synaptic potential is directly related to the lifetimes of the opened channels, and these lifetimes are relatively short (see Fig. 11.4B).

One mechanism for a slow synaptic potential is shown in Figure 11.13B. In contrast with the fast PSP for which the receptors are actually part of the ion channel complex, channels that produce slow synaptic potentials are not coupled directly to the transmitter receptors. Rather, the receptors are separated physically and exert their actions indirectly through changes in metabolism of specific second-messenger systems. Figure 11.13B illustrates one type of response in *Aplysia* for which the cAMP-protein kinase A (PKA) system is the mediator, but other slow PSPs use other second-messenger kinase systems (e.g., the protein kinase C system). In the cAMP-dependent slow synaptic responses in *Aplysia*, transmitter binding to membrane receptors activates G-proteins and stimulates an increase in the synthesis of cAMP. Cyclic AMP then leads to the activation of cAMP-dependent protein kinase (PKA), which phosphorylates a channel protein or protein associated with the channel (Siegelbaum *et al.*, 1982). A conformational change in the channel is produced, leading to a change in ionic conductance. Thus, in contrast with a direct conformational change produced by the binding of a transmitter to the receptor-channel complex, in this case, a conformational change is produced by protein phosphorylation. Indeed, phosphorylation-dependent channel regula-

tion is a fairly general feature of slow PSPs. However, channel regulation by second messengers is not produced exclusively by phosphorylation. In one family of ion channels, the channels are gated or regulated directly by cyclic nucleotides. These cyclic nucleotide-gated channels require cAMP or cGMP to open but have other features in common with members of the superfamily of voltage-gated ion channels (Kaupp, 1995; Zimmermann, 1995).

Another interesting feature of slow synaptic responses is that they are sometimes associated with decreases rather than increases in membrane conductance. For example, the particular channel illustrated in Figure 11.13B is selectively permeable to  $\text{K}^+$  and is normally open. As a result of the activation of the second messenger, the channel closes and becomes less permeable to  $\text{K}^+$ . The resultant depolarization may seem paradoxical, but recall that the membrane potential is due to a balance between resting  $\text{K}^+$  and  $\text{Na}^+$  permeability.  $\text{K}^+$  permeability tends to move the membrane potential toward the  $\text{K}^+$  equilibrium potential ( $-80\text{mV}$ ), whereas  $\text{Na}^+$  permeability tends to move the membrane potential toward the  $\text{Na}^+$  equilibrium potential ( $55\text{mV}$ ). Normally,  $\text{K}^+$  permeability predominates, and the resting membrane potential is close to, but not equal to, the  $\text{K}^+$  equilibrium potential. If  $\text{K}^+$  permeability is decreased because some of the channels close, the membrane potential will be biased toward the  $\text{Na}^+$  equilibrium potential and the cell will depolarize.

At least one reason for the long duration of slow PSPs is that second-messenger systems are slow (from seconds to minutes). Take the cAMP cascade as an example. Cyclic AMP takes some time to be synthesized, but, more importantly, after synthesis, cAMP levels can remain elevated for a relatively long period (minutes). The duration of the elevation of cAMP depends on the actions of cAMP-phosphodiesterase, which breaks down cAMP. However, duration of an effect could outlast the duration of the change in the second messenger because of persistent phosphorylation of the substrate protein(s). Phosphate groups are removed from substrate proteins by protein phosphatases. Thus, the net duration of a response initiated by a metabotropic receptor depends on the actions of not only the synthetic and phosphorylation processes, but also the degradative and dephosphorylation processes.

Activation of a second messenger by a transmitter can have a localized effect on the membrane potential through phosphorylation of membrane channels near the site of a metabotropic receptor. The effects can be more widespread and even longer lasting than depicted in Figure 11.13B. For example, second messengers and

**FIGURE 11.13** Ionotropic and metabotropic receptors and mechanisms of fast and slow EPSPs. (A, left) Fast EPSPs are produced by binding of the transmitter to specialized receptors that are directly associated with an ion channel (i.e., a ligand-gated channel). When the receptors are unbound, the channel is closed. (A, right) Binding of the transmitter to the receptor produces a conformational change in the channel protein such that the channel opens. In this example, the channel opening is associated with a selective increase in the permeability to Na<sup>+</sup> and K<sup>+</sup>. The increase in permeability results in the EPSP shown in the trace. (B, left) Unlike fast EPSPs, which are due to the binding of a transmitter with a receptor-channel complex, slow EPSPs are due to the activation of receptors (metabotropic) that are not coupled directly to the channel. Rather, coupling takes place through the activation of one of several second-messenger cascades, in this example, the cAMP cascade. A channel that has a selective permeability to K<sup>+</sup> is normally open. (B, right) Binding of the transmitter to the receptor (R) leads to the activation of a G-protein (G) and adenylyl cyclase (AC). The synthesis of cAMP is increased, cAMP-dependent protein kinase (protein kinase A, PKA) is activated, and a channel protein is phosphorylated. The phosphorylation leads to closing of the channel and the subsequent depolarization associated with the slow EPSP shown in the trace. The response decays due to both the breakdown of cAMP by cAMP-dependent phosphodiesterase and the removal of phosphate from channel proteins by protein phosphatases (not shown).

protein kinases can diffuse and affect more distant membrane channels. Moreover, a long-term effect can be induced in the cell by altering gene expression. For example, protein kinase A can diffuse to the nucleus, where it can activate proteins that regulate gene expression. Detailed descriptions of second messengers and their actions are given in Chapter 10.

### Summary

In contrast to the rapid responses mediated by ionotropic receptors, responses mediated by metabotropic receptors are generally relatively slow to develop and persistent. These properties arise because metabotropic responses can involve the activation of second-messenger systems. By producing slow changes in the resting potential, metabotropic receptors provide long-term modulation of the effectiveness of responses generated by ionotropic receptors. Moreover, these receptors, through the engagement of second-messenger systems, provide a vehicle by which a presynaptic cell cannot only alter the membrane potential, but also produce widespread changes in the biochemical state of a postsynaptic cell.

## INTEGRATION OF SYNAPTIC POTENTIALS

The small amplitude of the EPSP in spinal motor neurons (and other cells in the CNS) poses an interesting question. Specifically, how can an EPSP with an amplitude of only 1 mV drive the membrane potential of the motor neuron (i.e., the postsynaptic neuron) to threshold and fire the spike in the motor neuron that is necessary to produce the contraction of the muscle? The answer to this question lies in the principles of temporal and spatial summation.

When the ligament is stretched (Fig. 11.1), many stretch receptors are activated. Indeed, the greater the stretch, the greater the probability of activating a larger number of the stretch receptors; this process is referred to as recruitment. However, recruitment is not the complete story. The principle of frequency coding in the nervous system specifies that the greater the intensity of a stimulus, the greater the number of action potentials per unit time (frequency) elicited in a sensory neuron. This principle applies to stretch receptors as well. Thus, the greater the stretch, the greater the number of action potentials elicited in the stretch receptor in a given interval and therefore the greater the number of EPSPs produced in the motor neuron

from that train of action potentials in the sensory cell. Consequently, the effects of activating multiple stretch receptors add together (spatial summation), as do the effects of multiple EPSPs elicited by activation of a single stretch receptor (temporal summation). Both of these processes act in concert to depolarize the motor neuron sufficiently to elicit one or more action potentials, which then propagate to the periphery and produce the reflex.

### Temporal Summation Allows Integration of Successive PSPs

Temporal summation can be illustrated by firing action potentials in a presynaptic neuron and monitoring the resultant EPSPs. For example, in Figures 11.14A and 11.14B, a single action potential in sensory neuron 1 produces a 1-mV EPSP in the motor neuron. Two action potentials in quick succession produce two EPSPs, but note that the second EPSP occurs during the falling phase of the first, and the depolarization associated with the second EPSP adds to the depolarization produced by the first. Thus, two action potentials produce a summated potential that is about 2 mV in amplitude. Three action potentials in quick succession would produce a summated potential of about 3 mV. In principle, 30 action potentials in quick succession would produce a potential of about 30 mV and easily drive the cell to threshold. This summation is strictly a passive property of the cell. No special ionic conductance mechanisms are necessary. Specifically, the postsynaptic conductance change ( $g_{\text{syn}}$  in Eq. 11.3) produced by the second of two successive action potentials adds to that produced by the first. In addition, the postsynaptic membrane has a capacitance and can store charge. Thus, the membrane temporarily stores the charge of the first EPSP, and the charge from the second EPSP is added to that of the first.

However, the “time window” for this process of temporal summation very much depends on the duration of the postsynaptic potential, and temporal summation is possible only if the presynaptic action potentials (and hence postsynaptic potentials) are close in time to each other. The time frame depends on the duration of changes in the synaptic conductance and the time constant (Chapter 5). Temporal summation, however, rarely is observed to be linear as in the preceding examples, even when the postsynaptic conductance change ( $g_{\text{syn}}$  in Eq. 11.3) produced by the second of two successive action potentials is identical with that produced by the first (i.e., no presynaptic facilitation or depression) and the synaptic current is slightly less because the first PSP reduces the driving force

**FIGURE 11.14** Temporal and spatial summation. (A) Intracellular recordings are made from two idealized sensory neurons (SN1 and SN2) and a motor neuron (MN). (B) Temporal summation. A single action potential in SN1 produces a 1-mV EPSP in the MN. Two action potentials in quick succession produce a dual-component EPSP, the amplitude of which is approximately 2 mV. (C) Spatial summation. Alternative firing of single action potentials in SN1 and SN2 produce 1-mV EPSPs in the MN. Simultaneous action potentials in SN1 and SN2 produce a summated EPSP, the amplitude of which is about 2 mV.

$(V_m - E_r)$  for the second. Interested readers should try some numerical examples.

### Spatial Summation Allows Integration of PSPs from Different Parts of a Neuron

Spatial summation (Fig. 11.14C) requires a consideration of more than one input to a postsynaptic neuron. An action potential in sensory neuron 1 produces a 1-mV EPSP, just as it did in Figure 11.14B.

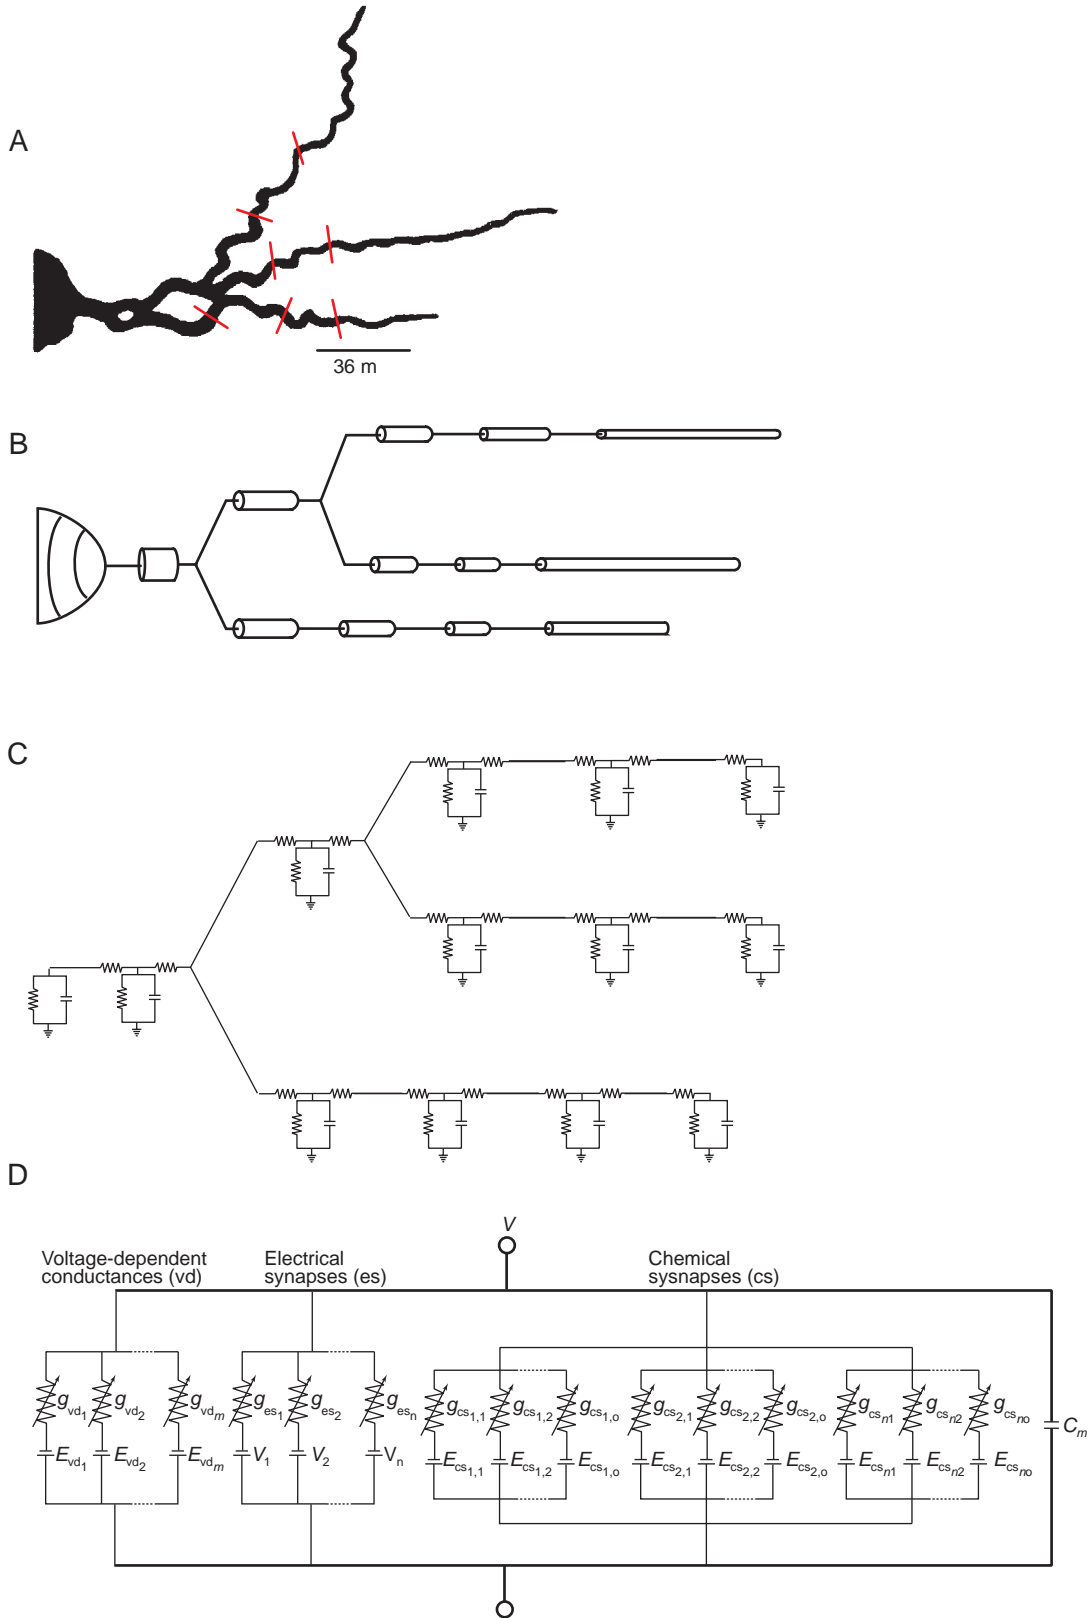

Similarly, an action potential in a second sensory neuron by itself also produces a 1-mV EPSP. Now, consider the consequences of action potentials elicited simultaneously in sensory neurons 1 and 2. The net EPSP is equal to the summation of the amplitudes of the individual EPSPs. Here, the EPSP from sensory neuron 1 is 1 mV, the EPSP from sensory neuron 2 is 1 mV, and the summated EPSP is approximately 2 mV (Fig. 11.14C). Thus, spatial summation is a mechanism by which synaptic potentials generated at different sites can summate. Spatial summation in nerve cells is influenced by the space constant—the ability of a potential change produced in one region of a cell to spread passively to other regions of a cell (see Chapter 5).

### Summary

Whether a neuron fires in response to synaptic input depends, at least in part, on how many action potentials are produced in any one presynaptic excitatory pathway and on how many individual convergent excitatory input pathways are activated. The summation of EPSPs in time and space is only part of the process, however. The final behavior of the cell is also due to the summation of inhibitory synaptic inputs in time and space, as well as to the properties of the voltage-dependent currents (Fig. 11.15) in the soma and along the dendrites (Koch and Segev, 1989; Ziv *et al.*, 1994). For example, voltage-dependent conductances such as A-type  $K^+$  conductance have a low threshold for activation and can thus oppose the effectiveness of an EPSP to trigger a spike. Low-threshold  $Na^+$  and  $Ca^{2+}$  channels can boost an EPSP. Finally, we need to consider that spatial distribution of the various voltage-dependent channels, ligand-gated receptors, and metabotropic receptors is not uniform. Thus, each segment of the neuronal membrane can perform selective integrative functions. Clearly, this system has an enormous capacity for the local processing of information and for performing logical operations.

The flow of information in dendrites and the local processing of neuronal signals are discussed in Chapter 12. Several software packages are available for the development and simulation of realistic models of single neurons and neural networks. One, Simulator for Neural Networks and Action Potentials (SNNAP) (<http://snnap.uth.tmc.edu/>), provides mathematical descriptions of ion currents, intracellular second messengers, and ion pools, and allows simulation of current flow in multicompartment models of neurons.

## Complex Information Processing in Dendrites

A hallmark of neurons is the variety of their dendrites. The branching patterns are dazzling and the size range astounding, from the large trees of cortical pyramidal neurons to the tiny size of a retinal bipolar cell, which would fit comfortably within the cell body of a pyramidal neuron (see Fig. 12.1). A main challenge in modern neuroscience is understanding the molecular and functional properties of these structures, and their significance for information processing by neurons.

Information processing by spread of electrical current through passive branching structures has already been discussed in Chapter 5. It is being increasingly recognized that the methods introduced by Wilfrid Rall for passive properties provide the essential basis for understanding the much more complex types of information processing that can occur through the distribution of active properties within the branching tree.

In this chapter we apply the Rall approach to ask the fundamental questions: (1) what are the principles of information processing in these dendritic trees with their elaborate branching patterns, distributed connectivity, and nonlinear properties, and (2) how are these dendrites with these properties adapted for the operational tasks of a specific neuron type within the microcircuits characteristic of that region?

### STRATEGIES FOR STUDYING COMPLEX DENDRITES

Strategies for answering these two questions may be illustrated by the synaptic organization of two cell types, the mitral and granule cells of the olfactory bulb,

shown in the lower left-hand corner of Figure 12.1. A first step in the modern approach is to break down a complex dendritic tree into functional compartments so that the integrative actions within the tree can be identified at successive levels of functional organization. As illustrated in Figure 12.2, these levels start with the individual synapse, which may be on a dendritic branch, as in the mitral cell, or on a dendritic spine, as in the granule cell. The next level is in terms of local patterns of synaptic connections. Successive levels involve larger extents of dendritic branches, until one reaches the level of distinct dendritic compartments, as in the case of the mitral cell, of distal tuft, primary dendrite, and secondary dendrites. At each level a dendritic compartment includes as well the cells interacting synaptically with that compartment. At the highest level is the global summation at the axon hillock and the global output through the axon. A similar analysis applies to the granule cell, except that it lacks an axon.

This approach allows one to identify the synaptic interactions within a dendritic tree as constituting a hierarchy, within which the specific pattern of interactions at a given level forms the fundamental integrative unit for the next level in the hierarchy. These integrative units are sometimes referred to as *microcircuits*, defined as a specific pattern of interactions performing a specific functional operation (Shepherd, 1978). In a computer microcircuit, a particular circuit configuration can be useful in many different contexts; similarly, in the brain, this gives the hypothesis that a particular microcircuit may be useful in different cells in different contexts at the equivalent level of organization. By this means the principles of information processing across different cell types in different regions and phyla can be identified. We will use this

approach to parse the organization of the dendrites of representative cell types, including those in Figure 12.1.

## BUILDING PRINCIPLES STEP BY STEP

As discussed in Chapter 5, the neuron processes information through five basic types of activity: intrinsic, reception, integration, encoding, and output. We saw that understanding how these activities are integrated within the neuron starts with the rules of passive

current spread. Many of the principles were worked out first in the dendrites of neurons that lack axons or the ability to generate action potentials. There are many examples in invertebrate ganglia. In vertebrates, they include the retinal amacrine cell and the olfactory granule cell. These studies have shown that a dendritic tree by itself is capable of performing many basic functions required for information processing, such as the generation of intrinsic activity, input-output functions for feature extraction, parallel processing, signal-to-noise enhancement, and oscillatory activity. These cells demonstrate that there is no one thing that dendrites do; they do whatever is required to process

**FIGURE 12.2** Compartmentalization (dashed lines) of olfactory bulb neurons to identify the functional subunits of dendrites and their relation to different levels of synaptic organization. information within their particular neuron or neuronal circuit, with or without an axon.

We also need to recognize that information in dendrites can take many forms. There are actions of neuropeptides on membrane receptors and internal cytoplasmic or nuclear receptors; actions of second and third messengers within the neuron; movement of substances within the dendrites by diffusion or by active transport; and changes occurring during development. All these types of cellular traffic and information flow in dendrites are coming under direct study (Matus and Shepherd, 2000; Stuart *et al.*, 2008). The student should review these subjects in earlier chapters. This chapter focuses on information processing in dendrites involving electrical signaling mechanisms by synapses and voltage-gated channels.

We will focus on how this takes place in neurons with axons. Neurons with axons may be classified into two groups, as suggested originally by Camillo Golgi in 1873: those with long axons and those with short axons. Long axon (output) cells tend to be larger than short axon (local) cells, and therefore have been more accessible to experimental analysis. Indeed, virtually everything known about the functional relations

between dendrites and axons has been obtained from studies of long axon cells. Consequently, much of what we *think* we understand about those relations in short axon cells is only by inference.

As noted in the analysis of the passive properties of neurons in Chapter 5, there are a number of sites on the Web that support the analysis of complex neurons and their active dendrites. For orientation to the molecular properties of dendritic compartments of different neurons discussed in this chapter, consult [senselab.med.yale.edu/neurondb](http://senselab.med.yale.edu/neurondb); for computational models based on those properties, consult [senselab.med.yale.edu/modeldb](http://senselab.med.yale.edu/modeldb). For the structures of dendrites, see [synapse-web.org](http://synapse-web.org); cell centered database, and [neuromorpho.org](http://neuromorpho.org).

## AN AXON PLACES CONSTRAINTS ON DENDRITIC PROCESSING

As we saw in Chapter 5 (Fig. 5.1), the neuron has five essential functions related to signal processing: generation, reception, integration, encoding, and

output. The presence of an axon places critical constraints on the dendritic processing that leads to axonal output.

The first principle is: If a neuron has an axon, it has only one. This near universal “single axon rule” is remarkable and still little understood. It results from developmental mechanisms that provide for differentiation of a single axon from among early undifferentiated processes. These mechanisms are being analyzed especially in neuronal cultures (Craig and Banker, 1994). The principle means that for dendritic integration to lead to output from the neuron to distant targets, all the activity within the dendrites eventually must be funneled into the origin of the axon in the single axon hillock. Therefore, in these cells the flow of information in dendrites has an overall orientation. Ramon y Cajal and the classical anatomists called this the Law of Dynamic Polarization of the neuron (Cajal, 1911; summarized in Shepherd, 1991). We thus have a **principle of global output**:

In order to transfer information between regions, the information distributed at different sites within a dendritic tree of an output neuron must be encoded, for global output at a single site at the origin of the axon.

A related principle is that the main function of the axon in long axon cells is to support the generation of action potentials in the axon hillock-initial segment region. By definition, action potentials there have thresholds for generation; thus, the **principle of frequency encoding of global output** in an axonal neuron is:

The results of dendritic integration affect the output through the axon by initiating or modulating action potential generation in the axon hillock-initial segment. Global output from dendritic integration is therefore encoded in impulse frequency in a single axon.

Classically it has been known that the axons of most output neurons are so long that the only significant signals reaching their axon terminals are the digital all-or-nothing action potentials carrying a frequency code. However, biology always produces exceptions. Recent research has shown that the synaptic potentials within the soma-dendrites may spread sufficiently in some axons to modulate the membrane potentials of the axon terminals (Shu *et al.*, 2006). This effect would presumably be most significant in short axon cells, where, as noted earlier, our understanding of signal processing is most limited. In these cells, it appears that the axon may carry the outcome of soma-dendritic integration mainly in a digital (impulse frequency) form, but with a contribution from analog (synaptic potential amplitude) signals.

A further consequence of the spatial separation of dendrites and axon is that some of the activity within a dendritic tree will be below threshold for activating an axonal action potential; we thus have the **principle of subthreshold dendritic activity**:

A considerable amount of subthreshold activity, including local active potentials, can affect the integrative states of the dendrites and any local outputs, but not necessarily directly or immediately affect the global output of the neuron.

We turn now to the functional properties that allow dendritic trees to process information within these constraints.

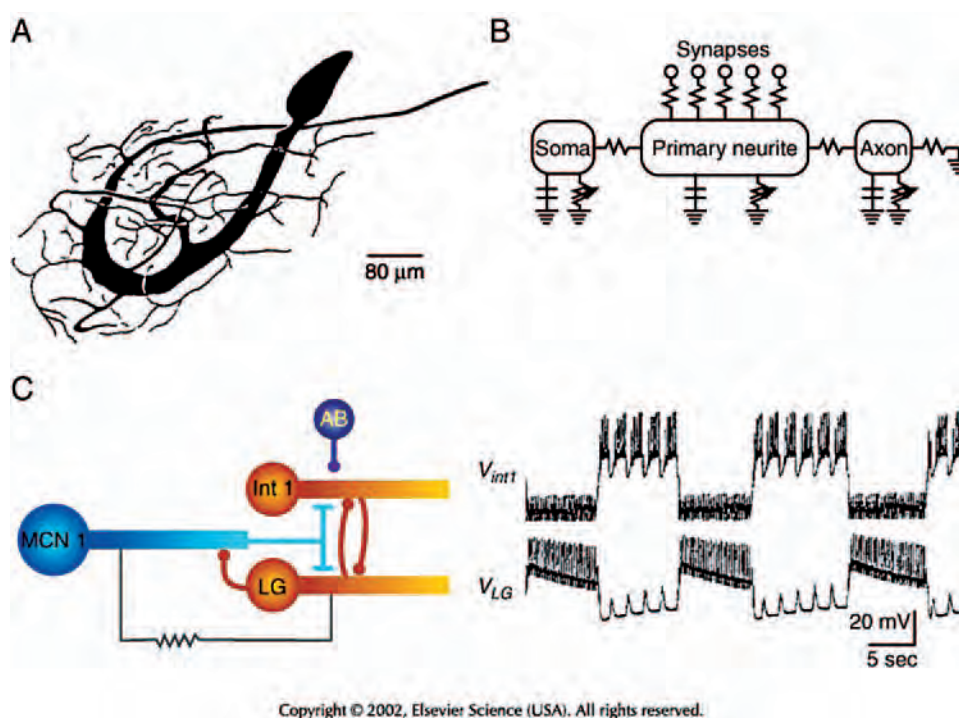

## DENDRODENDRITIC INTERACTIONS BETWEEN AXONAL CELLS

We first recognize, from the example in Figure 12.2, that axonal cells as well as anaxonal cells can have outputs through their dendrites. This is against the common wisdom, which assumes that if a neuron has an axon, all the output goes through the axon. There are many examples in invertebrates.

### Neurite-Neurite Synapses in Lobster Stomatogastric Ganglion

One of the first examples in invertebrates was in the stomatogastric ganglion of the lobster (Selverston *et al.*, 1976). Neurons were recorded intracellularly and stained with Procion yellow. Serial electron micrographic reconstructions showed the synaptic relations between stained varicosities in the processes and their neighbors (the processes are equivalent to dendrites, but often are referred to as neurites in the invertebrate literature). In many cases, a varicosity could be seen to be not only presynaptic to a neighboring varicosity, but also postsynaptic to that same process. It was concluded that synaptic inputs and outputs are distributed over the entire neuritic arborization. Polarization was not from one part of the tree to another. Bifunctional varicosities appeared to act as local input-output units, similar to the manner in which granule cell spines appear to operate (see later). Similar organization has been found in other types of stomatogastric neurons (Fig. 12.3A).

Sets of these local input-output units, distributed throughout the neuritic tree, participate in the generation and coordination of oscillatory activity involved in controlling the rhythmic movements of the stomach. In a current model of this oscillatory circuit, these interactions are mutually inhibitory (Fig. 12.3B).

**FIGURE 12.3** Local synaptic input-output sites are widely found within the neuropil of invertebrate ganglia. (A) Output neuron with many neurite branches in the gastric mill ganglion of the lobster, (B) compartmental representation of stomatogastric neuron, (C) model of rhythm-generating circuit of the gastric mill of the lobster, involving neurite-neurite interactions. A and B from Golowasch and Marder (1992); C from Manor *et al.* (1999).

In summary, a cell with an axon can have local outputs through its dendrites, as well as distant outputs through its axon, which may be involved in specific local functions such as generating oscillatory circuits.

### PASSIVE DENDRITIC TREES CAN PERFORM COMPLEX COMPUTATIONS

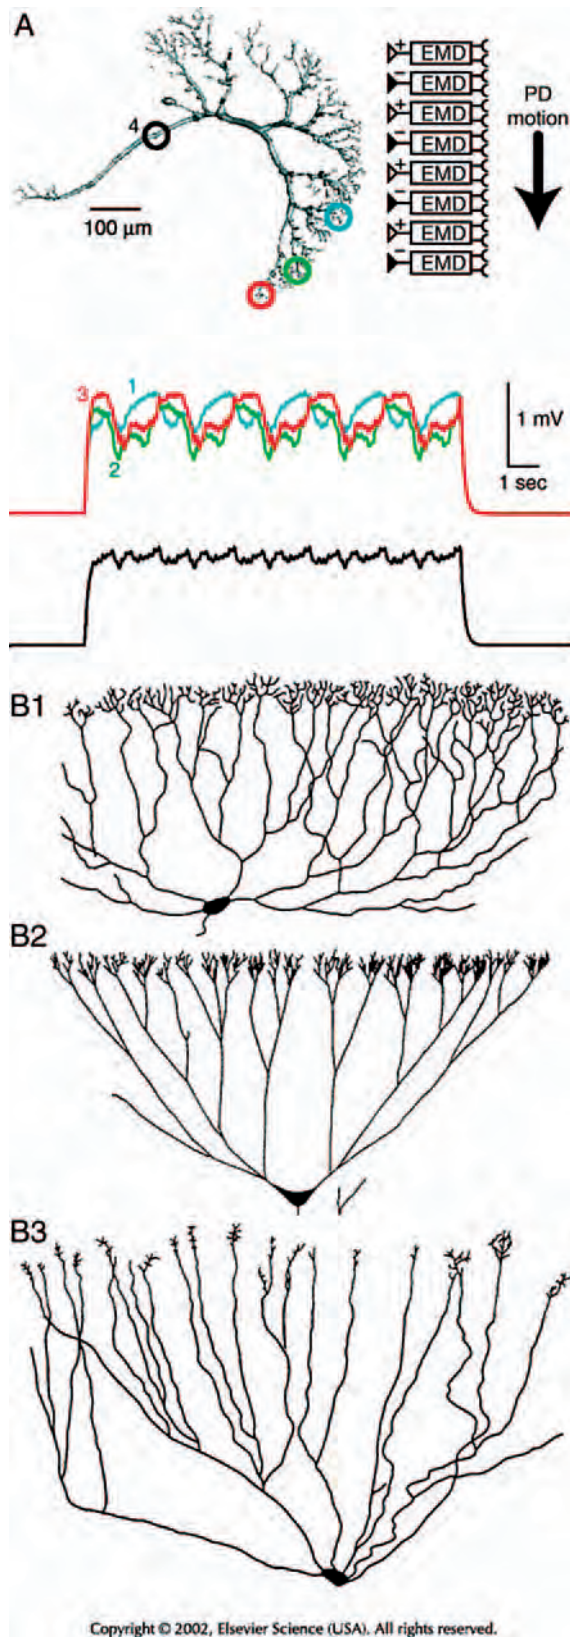

Another principle that carries over from axonless cells is the ability of the dendrites of axonal cells to carry out complex computations with mostly passive properties. This is exemplified by neurons that are motion detectors.

Motion detection is a fundamental operation carried out by the nervous systems of most species; it is essential for detecting prey and predator alike. In invertebrates, motion detection has been studied especially in the brain of the blowfly. In the lobula plate of the third optic neuropil are tangential cells (LPTCs) that respond to preferential direction (PD) of motion with increased depolarization due to sequential responses across their dendritic fields. This response has been modeled by Reichardt and colleagues by a series of elementary

motion detectors (HMDs) in the dendrites. A compartmental model (Single and Borst, 1998) reproduces the experimental results and theoretical predictions by showing how local modulations at each HMD are smoothed by integration in the dendritic tree to give a smoothed high-fidelity global output at the axon (Fig. 12.4A). In the model, spatial integration is largely independent of specific electrotonic properties but depends critically on the geometry and orientation of the dendritic tree.

In vertebrates, motion detection is built into the visual pathway at various stages in different species: the retina, midbrain (optic tectum), and cerebral cortex. Studies in the optic tectum have revealed cells with splayed uniplanar dendritic trees and specialized distal appendages that appear highly homologous across reptiles, birds, and mammals (Fig. 12.4B) (Luksch *et al.*, 1998). Physiological studies are needed to test the hypothesis that these cells perform operations through their dendritic fields similar to those of LPTC cells in the insect. To the extent that this is borne out, it will support a principle of motion detection through spatially distributed dendritic computations that is conserved across vertebrates and invertebrates.

Directional selectivity of dendritic processing was predicted by Rall (1964) from his studies of dendritic electrotonus (Chapter 5). In an electrotonic cable, summation of EPSPs moving away from a recording site produces a plateau of ever-decreasing potentials, whereas summation of EPSPs moving toward a recording site produces an accumulating peak of potential. This is one of several possible mechanisms that are under current investigation in different cell types.

### SEPARATION OF DENDRITIC FIELDS ENHANCES COMPLEX INFORMATION PROCESSING

An important feature of many types of neuron is a separation of their dendritic fields, which has important functional consequences. We saw this in the compartmental organization of the mitral cell (Figs. 12.1 and 12.2), where the primary dendritic tuft receives the olfactory nerve input whereas the secondary dendritic branches are specialized for a completely different function, self and lateral inhibition, as we explain later.

Pyramidal cells in the cerebral cortex also show a clear separation into apical and basal dendrites (Figs. 12.1 and 12.2). The apical dendrite extends across different layers, allowing fibers within those layers from different cells to modulate the transfer of activity from the distal tuft toward the cell body. This kind of modulation is absent in the mitral cell but key in the pyramidal neuron.

Within the basal dendrites, the placement of inputs is critical. An example has been shown in experiments in which excitatory and inhibitory inputs can be independently targeted to the same or different dendritic branches. As illustrated in Figure 12.5, synaptic inhibition has little effect on synaptic excitation when the two are targeted to different branches, but a profound effect when on the same branches. This is a clear example of the interaction of synaptic conductances illustrated in Figure 5.13.

**FIGURE 12.4** Dendritic systems as motion detectors. (A) A computational model of a motion detector neuron in the visual system of the fly, consisting of elementary motion detector (EMD) units in its dendritic tree activated by the preferential direction (PD) of motion. Local modulations of the individual EMDs are integrated in the dendritic tree to give smooth global output in the axon (Single and Borst, 1998). (B) Dendritic trees of neurons in the optic tectum of lizard (B1), chick (B2), and gray squirrel (B3). The architecture of the dendritic branching patterns and distal specialization for the reception of retinal inputs is highly homologous (references in Luksch *et al.*, 1998).

**FIGURE 12.5** Importance of the locations of interacting synaptic responses within a dendritic field. Left, Excitation and inhibition converging on the same dendritic branches produces sharp reduction of the excitatory response recorded at the soma (see electrode). Right, inhibition on a different set of branches has little effect in reducing the excitatory response recorded at the soma. This illustrates a practical application of the principle illustrated in Figure 5.13 for electrotonic relations between synaptic conductances in individual branches. From Mel and Schiller (2004).

As a final example, cells with separate dendritic fields are critical for selectively summing their synaptic inputs to mediate directional selectivity in the auditory system (Overholt *et al.*, 1992).

### DISTAL DENDRITES CAN BE CLOSELY LINKED TO AXONAL OUTPUT

An obvious problem for a neuron with an axon is that the distal branches of dendritic trees are a long distance from the site of axon origin at or near the cell body. The common perception is that these distal dendrites are too distant from the site of axonal origin and impulse generation to have more than a slow and weak background modulation of impulse output, and that the only synapses that can bring about rapid signal processing by the neuron are those located on the soma or proximal dendrites.

This perception is so ingrained in our visual impression of what is near and far that it is difficult to accept

that it is wrong. It is disproved, however, by many kinds of neurons in which specific inputs are located preferentially on their distal dendrites. An example is the mitral (and tufted) cells in the olfactory bulb, which we have met in Figures 12.1 and 12.2. In this cell the input from the olfactory nerves ends on the most distal dendritic branches in the glomeruli; in rat mitral cells, this may be 400–500  $\mu\text{m}$  or more from the cell body, in turtle, 600–700  $\mu\text{m}$ . The same applies to their targets, the pyramidal neurons of the olfactory cortex, where the input terminates on the spines of the most distal dendrites in layer I. In many other neurons, a given type of input terminates over much or all of the dendritic tree; such is the case, for example, for climbing fiber and parallel fiber inputs to the cerebellar Purkinje cells. All these neuron types are shown in Figure 12.1.

How do distal dendrites in these neurons effectively control axonal output? Some of the important properties underlying this ability are summarized in Table 12.1. We consider several examples next, and in later sections.

## Large Diameter Dendrites

The simplest way to enhance spread of a signal through dendrites is by a large diameter. It already has been illustrated for the spread of current in a branching cable in Chapter 5 (Fig. 5.4). However, space is at a premium in the central nervous system, so there is a tradeoff between diameter and length. This is why other membrane properties become important in overcoming distance.

## High Specific Membrane Resistance

A key property is the specific membrane resistance ( $R_m$ ) of the dendritic membrane. The functional significance of  $R_m$  is discussed in Chapter 5 (see Fig. 5.3). Traditionally, the argument was that if  $R_m$  is relatively low, the characteristic length of the dendrites will be relatively short, the electrotonic length will be correspondingly long, and synaptic potentials will therefore decrement sharply in spreading toward the axon hillock. However, as discussed in Chapter 5, intracellular recordings indicated that  $R_m$  is sufficiently high that the electrotonic lengths of most dendrites are relatively short, in the range of 1–2 (Johnston and Wu, 1995), and patch recordings suggest much higher  $R_m$  values, indicating electrotonic lengths less than 1. Thus, a relatively high  $R_m$  seems adequate for close electrotonic linkage between distal dendrites and somas, at least in the steady state.

## Low K Conductances

An important factor controlling effective membrane resistance is K conductances. Chapter 5 discusses how a K channel,  $I_{Kv}$ , can affect the summation of EPSPs in striatal spiny cells. There is increasing evidence that dendritic input conductance is controlled by different types of K currents (Midtgaard *et al.*, 1993; Magee,

1999). When dendritic K conductances are turned off,  $R_m$  increases and dendritic coupling to the soma is enhanced. These conductances also control back-propagating action potentials, as discussed in Chapter 5 and earlier chapters.

## Large Synaptic Conductances

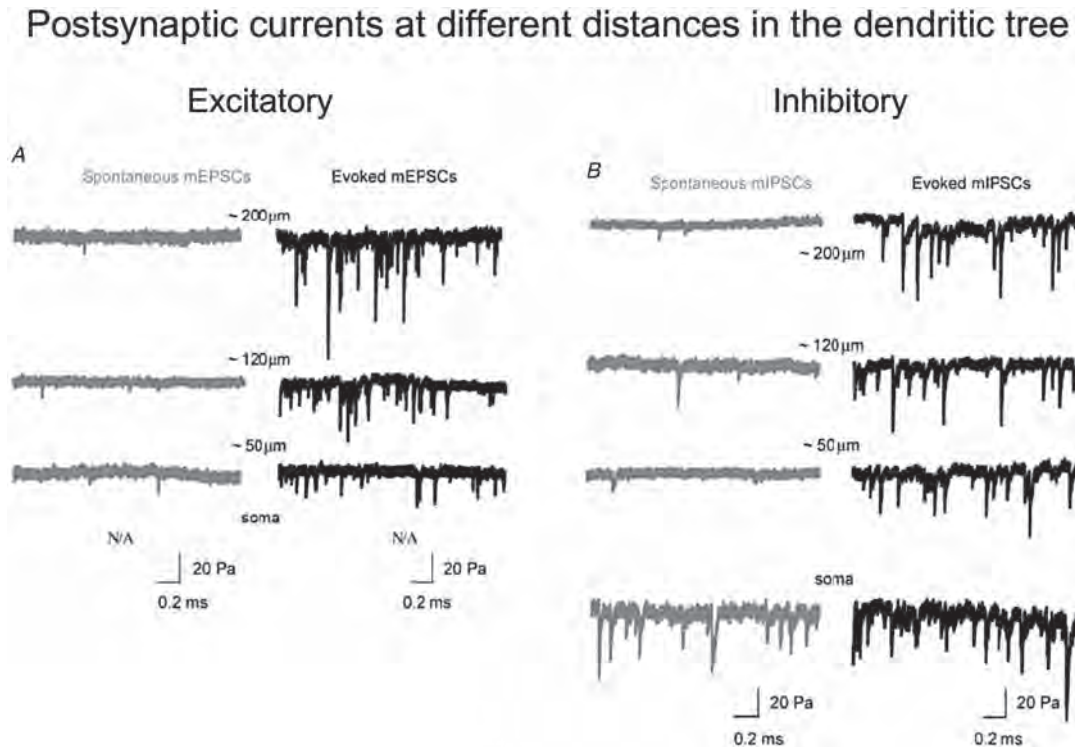

A potentially important property is the amplitude of the conductance generated by the synapse itself. Early studies showed that in motor neurons, distal excitatory synaptic potentials were many times the amplitude of proximal synapses (Redman and Walmsley, 1983). This would account for the fact that the unitary synaptic response recorded at the soma slows with increasing distance in the dendrites, but maintains a constant amplitude of approximately 100  $\mu$ V. A corresponding increase in synaptic conductance has been shown in the distal dendrites of cortical pyramidal neurons (Magee, 2000). Patch recordings show that, whereas inhibitory postsynaptic currents (IPSCs) are similar in amplitude whether recorded from the distal dendrites or the soma, excitatory postsynaptic currents (EPSCs) are larger when recorded from distal dendrites than from the soma (Fig. 12.6). It is hypothesized that this reflects receptor channels composed of different subunits, for which there is increasing evidence. Research is needed to determine which synaptic protein subunits are involved to give these differences in conductance in specific cells.

## Voltage-Gated Depolarizing Conductances

For transient responses, the electrotonic linkage becomes weaker because of the filtering effect of the capacitance of the membrane, and it is made worse by a higher  $R_m$ , which increases the membrane time constant, thereby slowing the spread of a passive potential (Chapter 5). This disadvantage can be overcome by depolarizing voltage-gated conductances: Na, Ca, or both. These add a wide variety of signal processing mechanisms to dendrites. As indicated in Table 12.1, they include boosting EPSP amplitudes, generating large-amplitude slow pacemaker potentials underlying the spontaneous activity of a neuron, supporting full back-propagating or forward propagating action potentials in the dendrites, forming “hot spots” that set up fast prepotentials at branch points in the distal dendrites, and functioning as coincidence detectors. Interactions between active sites, such as spines with voltage-gated conductances, can give rise to a sequence of activation of those sites, resulting in “pseudosaltatory conduction” through the dendritic tree between active sites or active clusters of sites.

TABLE 12.1 Properties That Increase the Effectiveness of Distal Synapses in Effecting Axonal Output

Higher membrane resistance
Larger distal synaptic conductances
Voltage-gated channels:
increase EPSP amplitude
generate large amplitude slow action potentials
give rise to forward propagating full action potential
are local “hot spots” that set up fast prepotentials
function as coincidence detectors to summate responses
mediate “pseudosaltatory conduction” toward the soma through individual active sites or clusters

**FIGURE 12.6** Larger excitatory synaptic currents may be present in distal dendrites. A. Spontaneous and evoked miniature excitatory postsynaptic currents (mEPSCs) in patch recordings at three distances from the soma. Note the increase in amplitude with increasing distance. B. Same for inhibitory mIPSCs. Note relatively constant amplitudes with distance. From Andrasfalvy and Mody (2006).

Some of these active properties also contribute to complex information processing capabilities, including logic operations, as discussed further later.

### Summary

These examples illustrate an important principle of distal dendritic processing:

Distal dendrites can mediate relatively rapid, specific information processing, even at the weakest levels of detection, in addition to slower modulation of overall neuronal activity. The spread of potentials to the site of global output from the axon is enhanced by multiple passive and active mechanisms.

## DEPOLARIZING AND HYPERPOLARIZING DENDRITIC CONDUCTANCES INTERACT DYNAMICALLY

We see that depolarizing conductances increase the excitability of distal dendrites and the effectiveness of distal synapses, whereas K conductances reduce the excitability and control the temporal characteristics of

the dendritic activity. This balance is thus crucial to the functions of dendrites. Figure 12.7 summarizes data showing how these conductances vary along the extents of the dendrites of mitral cells, hippocampal and neocortical pyramidal neurons, and Purkinje cells.

The significance of a particular density of channel needs to be judged in relation to the electrotonic properties discussed in Chapter 5. For instance, a given conductance has more effect on membrane potential in smaller distal branches because of the higher input resistance (Fig. 5.14). Dendritic conductances are crucial in setting the intrinsic excitability state of the neuron. In the motor neuron, for example, the neuron can alternate between bistable states dependent on the activation of dendritic metabotropic glutamate receptors (Svirskie *et al.*, 2001). The significance of these and other conductance interactions for the firing properties of different cell types is discussed later.

These combinations of ionic conductances occur within the larger framework of the morphological types of dendritic trees, particularly whether they arise from thick or thin trunks. This has given rise to a classification of dendritic types on integrative principles that cuts across the traditional classification of neuron types (Migliore and Shepherd, 2002, 2005). This is a

Nature Reviews | Neuroscience

FIGURE 12.7 Graphs of the distribution of different types of intrinsic membrane conductances along the dendritic trees in different types of neurons. From Migliore and Shepherd (2002).

first step toward a deeper insight into canonical types of input-output operations that are carried out by dendritic trees.

As noted earlier, the combinations of properties within different dendritic compartments of a given neuron type can be searched in an online database ([senselab.med.yale.edu/neurondb](http://senselab.med.yale.edu/neurondb)) and models based on these compartmental representations of many types of neurons can be accessed and run at [senselab.med.yale.edu/modeldb](http://senselab.med.yale.edu/modeldb).

## Summary

The combination of conductances at different levels of the dendritic tree involves a delicate balance between depolarizing and hyperpolarizing actions acting over different time periods. These combinations vary in different morphological types of neurons. They also contribute to a new classification of dendrites according to a principle of multiple criteria for dendritic classification:

Dendritic trees can be categorized functionally on the basis of a combination of branch morphology, functional ionic current type, and genetic channel subunit type. These categories appear to define canonical integrative properties that extend across classical morphological categories.

## THE AXON HILLOCK-INITIAL SEGMENT ENCODES GLOBAL OUTPUT

In cells with long axons, activity in the dendrites eventually leads to activation and modulation of action potential output in the axon. A key question is the

precise site of origin of this action potential. This question was one of the first to be addressed in the rise of modern neuroscience; the historical background is summarized in Box 12.1.

These studies established the classical model: the lowest threshold site for action potential generation is in the *axonal initial segment*.

Definitive analysis was achieved by Stuart and Sakmann (1994) using dual patch recordings from cortical pyramidal neurons under differential contrast microscopy. This approach has provided the breakthrough for subsequent analyses of dendritic properties and their coupling to the axon (see later). As shown in Figure 12.10, with depolarization of the distal dendrites by injected current or excitatory synaptic inputs, a large amplitude depolarization is produced in the dendrites, which spreads to the soma. Despite its lower amplitude, soma depolarization is the first to initiate the action potential. Subsequent studies with triple patch electrodes have shown that the action potential actually arises first in the initial segment and first node.

## MULTIPLE IMPULSE INITIATION SITES ARE UNDER DYNAMIC CONTROL

In addition to the evidence for action potential initiation in the axon hillock, another line of work has provided evidence for shifting of the site under dynamic conditions. This line began with extracellular recordings of a “population spike” that appears to propagate along the apical dendrites toward the cell body in hippocampal pyramidal cells (Andersen, 1960). This was supported by the recording in these

## BOX 12.1

## CLASSICAL STUDIES OF THE ACTION POTENTIAL INITIATION SITE

Fuortes and colleagues (1957) were the first to deduce that an EPSP spreads from the dendrites through the soma to initiate the action potential in the region of the axon hillock and the initial axon segment. They suggested that the action potential has two components: (1) an A component that normally is associated with the axon hillock and initial segment and (2) a B component that normally is associated with retrograde invasion of the cell body. Because the site of action potential initiation can shift under different membrane potentials, they preferred the noncommittal terms "A" and "B" for the two components as recorded from the cell body. In contrast, Eccles (1957) referred to the initial component as the initial-segment (IS) component and to the second component as the somadendritic (SD) component (Fig. 12.8).

Apart from the motor neuron, the best early model for intracellular analysis of neuronal mechanisms was the crayfish stretch receptor, described by Eyzaguirre and Kuffler (1955). Intracellular recordings from the cell body showed that stretch causes a depolarizing receptor potential equivalent to an EPSP, which spreads through the cell to initiate an action potential. It was first assumed that this action potential arose at or near the cell body. Edwards and Ottoson (1958), working in Kuffler's laboratory, tested this postulate by recording the local extracellular current in order to locate precisely the site of inward

current associated with action potential initiation. Surprisingly, this site turned out to be far out on the axon, some 200  $\mu\text{m}$  from the cell body (Fig. 12.9). This result showed that potentials generated in the distal dendrites can spread all the way through the dendrites and soma well out into the initial segment of the axon to initiate impulses. It further showed that the action potential recorded at the cell body is the backward spreading impulse from the initiation site. Edwards and Ottoson's study was important in establishing the basic model of impulse initiation in the axonal initial segment.

cells of "fast prepotentials" at dendritic "hot spots" (Spencer and Kandel, 1961), and by current source density calculations in cortical pyramidal neurons (Herreras, 1990). In recordings from dendrites in tissue slices in CA1 hippocampal pyramidal neurons, weak synaptic potentials elicited action potentials near the cell body (Richardson *et al.*, 1987), but this site shifted to proximal dendrites with stronger synaptic excitation (Turner *et al.*, 1991). This confirmed the suggestion of M.G.F. Fuortes and K. Frank that the site can shift under different stimulus conditions, and was consistent with the stretch receptor, where larger receptor potentials shift the initiation site closer to the cell body.

The olfactory mitral cell is a favorable model for studying this question, because it is unusual in that all its excitatory inputs are restricted to its distal dendritic tuft. As illustrated in Chapter 5 (Fig. 5.15), at weak

levels of electrical shocks to the olfactory nerves, the site of action potential initiation is at or near the soma, as in the classical model. The action potential is due to Na channels distributed along the extent of the primary dendrite.

As the level of distal excitatory input is increased, dual-patch recordings show clearly that the action potential initiation site shifts gradually from the soma to the distal dendrite (Fig. 5.15). Thus the site of impulse initiation is not fixed in the mitral cell, but varies with the intensity of distal excitatory input balanced against the difference in density of Na channels between initial segment and the apical dendrite. This shift was discussed in Chapter 5 because it is governed by the longitudinal gradient of spread of the passive electrotonic potential along the dendrite. The site can also be shifted to distal dendrites by synaptic inhibition applied to the soma through dendrodendritic synapses.

**FIGURE 12.8** Classical evidence for the site of action potential initiation. Intracellular recordings were from the cell body of the motor neuron of an anesthetized cat. (A) Differential blockade of an antidromic impulse by adjusting the membrane potential by holding currents. Recordings reveal the sequence of impulse invasion in the myelinated axon (recordings at  $-87$  mV, two amplifications), the initial segment of the axon (first component of the impulse beginning at  $-82$  mV), and the soma–dendritic region (large component beginning at  $-78$  mV). (B) Sites of the three regions of impulse generation (M, myelinated axon; IS, initial segment; SD, soma and dendrites); arrows show probable sites of impulse blockade in A. (C) Comparison of intracellular recordings of impulses generated antidromically (AD), synaptically (orthodromically, OD), and by direct current injection (IC). Lower traces indicate electrical differentiation of these recordings showing the separation of the impulse into the same two components and indicating that the sequence of impulse generation from the initial segment into the soma–dendritic region is the same in all cases. From Eccles (1957).

## Summary

The low threshold of the initial axonal segment favors it being the site of action potential output for a wide range of dendritic activity, but the site can shift with strongly depolarizing dendritic input. This introduces the **principle of the dynamic control of action potential initiation**:

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 12.9** Classical demonstration of the site of impulse initiation in the stretch receptor cell of the crayfish. Moderate stretch of the receptor muscle generated a receptor potential that spread from the dendrites across the cell body into the axon. Paired electrodes recorded the longitudinal extracellular currents at positions A–D, showing the site of the trigger zone (green region). The excitability curve (shown at the top), obtained by passing current between the electrodes and finding the current ( $I$ ) intensity needed to evoke an impulse response, also shows the trigger zone to be several hundred micrometers out on the axon. From Ringham (1971).

The site of global output through action potential initiation from a neuron can shift between first axon node, initial segment, axon hillock, soma, proximal dendrites, and distal dendrites, depending on the dynamic state of dendritic excitability.

## RETROGRADE IMPULSE SPREAD INTO DENDRITES CAN HAVE MANY FUNCTIONS

In addition to identifying the preferential site for action potential initiation in the axonal initial segment, the experiments of Stuart and Sackmann (1994) showed clearly that the action potential does not merely spread passively back into the dendrites but actively back-propagates. Note that we distinguish between passive electrotonic “spread” and active “propagation” of the action potential (see Box 5.3 in Chapter 5).

What is the function of the dendritic action potential? Experimental evidence shows that it can have a variety of functions.

**FIGURE 12.10** Direct demonstration of the impulse-initiation zone and back-propagation into dendrites using dual-patch recordings from soma and dendrites of a layer V pyramidal neuron in a slice preparation of the rat neocortex. (A) Depolarizing current injection in either the soma or the dendrite elicits an impulse first in the soma. (B) The same result is obtained with synaptic activation of layer I input to distal dendrites. Note the close similarity of these results to the earlier findings in the motor neuron (Fig. 12.8). From Stuart and Sakmann (1994).

## Dendrodendritic Inhibition

A specific function for an action potential propagating from the soma into the dendrites was first suggested for the olfactory mitral cell, where mitral-to-granule dendrodendritic synapses are triggered by the action potential spreading from the soma into the secondary dendrites (Fig. 12.11A, B). Because of the delay in activating the reciprocal inhibitory synapses from the granule cells, self-inhibition of the mitral cell occurs in the wake of the passing impulse; the two do not collide. The mechanism operates similarly with both active back-propagation and passive electrotonic

spread into the dendrites, as tested in computer simulations. Functions of dendrodendritic inhibition include center-surround antagonism mediating the abstraction of molecular determinants underlying the discrimination of different odor molecules, storing of olfactory memories at the reciprocal synapses, and generation of oscillating activity in mitral and granule cell populations (Shepherd *et al.*, 2004; Egger and Urban, 2006).

## Intercolumnar Connectivity

Recent research has given new insight into the function of the action potential in the mitral cell lateral dendrite. Because the action potential can propagate away from the cell body throughout the length of the dendrite (Fig. 12.11; Xiong and Chen, 2002), it enables activation of granule cells independent of distance. Connectivity of mitral cells to distant groups of granule cells, arranged in columns in relation to glomeruli, has been demonstrated by pseudorabies viral tracing (Willhite *et al.*, 2006), and activation of distant granule cells by means of such connectivity has been shown in realistic computational studies (Migliore and Shepherd, 2007). This has led to the hypothesis that the lateral dendrite can function to activate ensembles of granule cell columns processing similar aspects of an odor map, with the added flexibility that the dendrite can be modulated by granule cell inhibition throughout its length (Fig. 12.11A). The diagram in B thus provides an updated representation of the functional subunits and microcircuits formed by the mitral and granule cells shown in Figures 12.1 and 12.2.

## Boosting Synaptic Responses

In several types of pyramidal neurons, active dendritic properties appear to boost action potential invasion so that summation with EPSPs occurs that makes the EPSPs more effective in spreading to the soma.

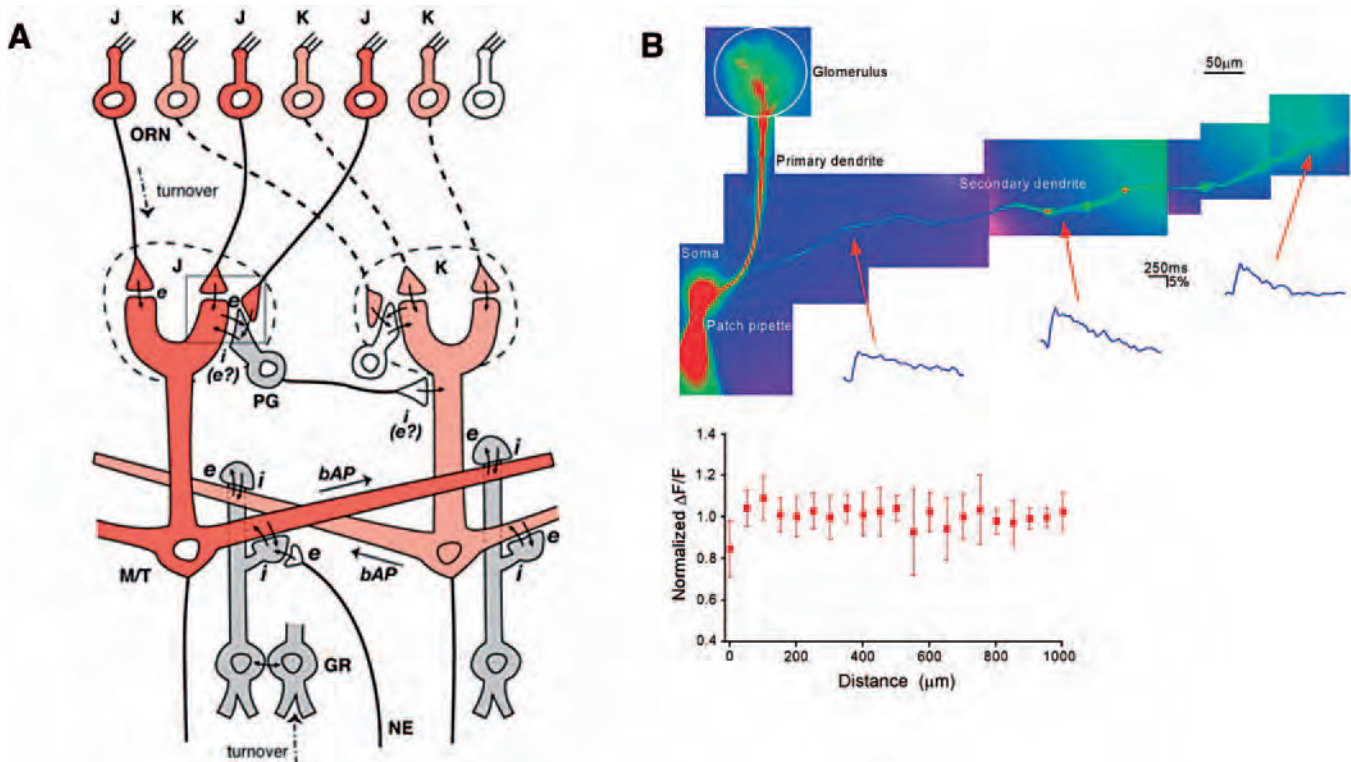

## Resetting Membrane Potential

A possible function of a back-propagating action potential is that the  $\text{Na}^+$  and  $\text{K}^+$  conductance increases associated with active propagation wipe out the existing membrane potential, resetting the membrane potential for new inputs.

## Synaptic Plasticity

The action potential in the dendritic branches presumably depolarizes the spines (because of the favorable impedance matching, as discussed in Chapter 5), which means that the impulse depolarization would

**FIGURE 12.11** Dendrodendritic interactions in the olfactory bulb. (A) An action potential in the mitral cell body sets up a back-spreading/back-propagating impulse into the secondary dendrites, activating both feedback and lateral inhibition of the mitral cells by columns of granule cells acting through the dendrodendritic pathway. From Shepherd *et al.* (2007). (B) Ability of an action potential to invade the length of a secondary dendrite, as shown by Ca fluorescence. Fluorescence measurements are plotted in the graph below, showing full propagation up to 1000 microns. From Xiong and Chen (2002).

summate with the synaptic depolarization of the spines. This process would enable the spines to function as coincidence detectors and implement changes in synaptic plasticity (see Hebbian synaptic mechanisms in Chapter 49). This postulate has been tested by electrophysiological recordings (Spruston *et al.*, 1995) and  $\text{Ca}^{2+}$  imaging (Yuste *et al.*, 1994). Activity-dependent changes of dendritic synaptic potency are not seen with passive retrograde depolarization but appear to require actively propagating retrograde impulses (Spruston *et al.*, 1995).

### Frequency Dependence

Trains of action potentials generated at the soma-axon hillock can invade the dendrites to varying extents. Proximal dendrites appear to be invaded throughout a high-frequency burst, whereas distal dendrites appear to be invaded mainly by the early action potentials (Regehr *et al.*, 1989; Callaway and Ross, 1995; Yuste *et al.*, 1994; Spruston *et al.*, 1995).

Activation of  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  conductances by early impulses may effectively switch off the distal dendritic compartment.

### Retrograde Actions at Synapses

The retrograde action potential can contribute to the activation of neurotransmitter release from the dendrites. The clearest example of this is the olfactory mitral cell as already described. Dynorphin released by synaptically stimulated dentate granule cells can affect the presynaptic terminals (Simmons *et al.*, 1995). In the cerebral cortex there is evidence that GABAergic interneuronal dendrites act back on axonal terminals of pyramidal cells and that glutamatergic pyramidal cell dendrites act back on axonal terminals of the interneurons (Zilberter, 2000). The combined effects of the axonal and dendritic compartments of both neuronal types regulate the normal excitability of pyramidal neurons and may be a factor in the development of cortical hyperexcitability and epilepsy.

## Conditional Axonal Output

Because of the long distance between distal dendrites and initial axonal segment, we may hypothesize that the coupling between the two is not automatic. Indeed, conditional coupling dependent on synaptic inputs and intrinsic activity states at intervening dendritic sites appears to be fundamental to the relation between local dendritic inputs and global axonal output (Spruston, 2000).

## Summary

The action potential arising at the initial axonal segment has two functions: propagating into the axon to carry the global output to the axon terminals, and propagating retrogradely through the soma into the dendrites. In the dendrites the action potential can carry out many distinct functions, as described above.

When the retrograde action potential has been activated by EPSPs spreading from the dendrites, we call the action potential back-propagating; that is, back toward the site of the initial input. When the retrograde action potential propagates through the soma into previously unactivated dendrites, we can still call it back-propagating, in the sense of backward with regard to the law of dynamic polarization, which, when applied to the overall flow of activity, is from distal dendrites to soma and axon; or we can consider it as propagating retrogradely, to distinguish it from back-propagating toward a distal input site.

## EXAMPLES OF HOW VOLTAGE-GATED CHANNELS ENHANCE DENDRITIC INFORMATION PROCESSING

It is commonly believed that active dendrites are a modern concept, but in fact this idea is as old as Cajal; he assumed that dendrites conduct impulses like axons do. However, with the first intracellular recordings in the 1950s, it appeared that dendritic membranes were mostly passive. We have noted that studies since then increasingly have documented the widespread distribution and numerous functions of voltage-gated channels in dendritic membranes.

These channels are the principle means for enhancing the information processing capabilities of complex dendrites. Detailed analysis of active dendritic properties began with computational studies of olfactory mitral cells and experimental studies of cerebellar Purkinje cells. Since then, studies of active dendritic prop-

erties have proliferated, particularly since introduction of the patch recording method. Several types of neurons have provided important models for the possible functional roles of active dendritic properties.

## Purkinje Cells

The cerebellar Purkinje cell has the most elaborate dendritic tree in the nervous system, with more than 100,000 dendritic spines receiving synaptic inputs from parallel fibers and mossy fibers. The basic distribution of active properties in the Purkinje cell was indicated by the pioneering experiments of Llinas and Sugimori (1980) in tissue slices (Fig. 12.12). The action potential in the cell body and axon hillock is due mainly to fast  $\text{Na}^+$  and delayed  $\text{K}^+$  channels; there is also a  $\text{Ca}^{2+}$  component. The action potential correspondingly has a large amplitude in the cell body and decreases by electrotonic decay in the dendrites. In contrast, recordings in the dendrites are dominated by slower "spike" potentials that are  $\text{Ca}^{2+}$  dependent due to a P-type  $\text{Ca}^{2+}$  conductance (Fig. 12.12). These spikes are generated from a plateau potential due to a persistent  $\text{Na}_p$  current.

There are two distinct operating modes of the Purkinje cell in relation to its distinctive inputs. Climbing fibers mediate strong depolarizing EPSPs throughout most of the dendrites that appear to give rise to

**FIGURE 12.12** Classical demonstration of the difference between soma and dendritic action potentials. (A) Drawing of a Purkinje cell in the cerebellar slice. (B) Intracellular recordings from the soma showing fast  $\text{Na}^+$  spikes. (C–E) Intracellular recordings from progressively more distant dendritic sites; fast soma spikes become small due to electrotonic decrement and are replaced by large-amplitude dendritic  $\text{Ca}^{2+}$  spikes. Spread of these spikes to the soma causes an inactivating burst that interrupts the soma discharge. Adapted from Llinas and Sugimori (1980).

synchronous  $\text{Ca}^{2+}$  dendritic action potentials throughout the dendritic tree, which then spread to the soma to elicit the bursting “complex spike” in the axon hillock. In contrast, parallel fibers are active in small groups, giving rise to smaller populations of individual EPSPs possibly targeted to particular dendritic regions (compartments).

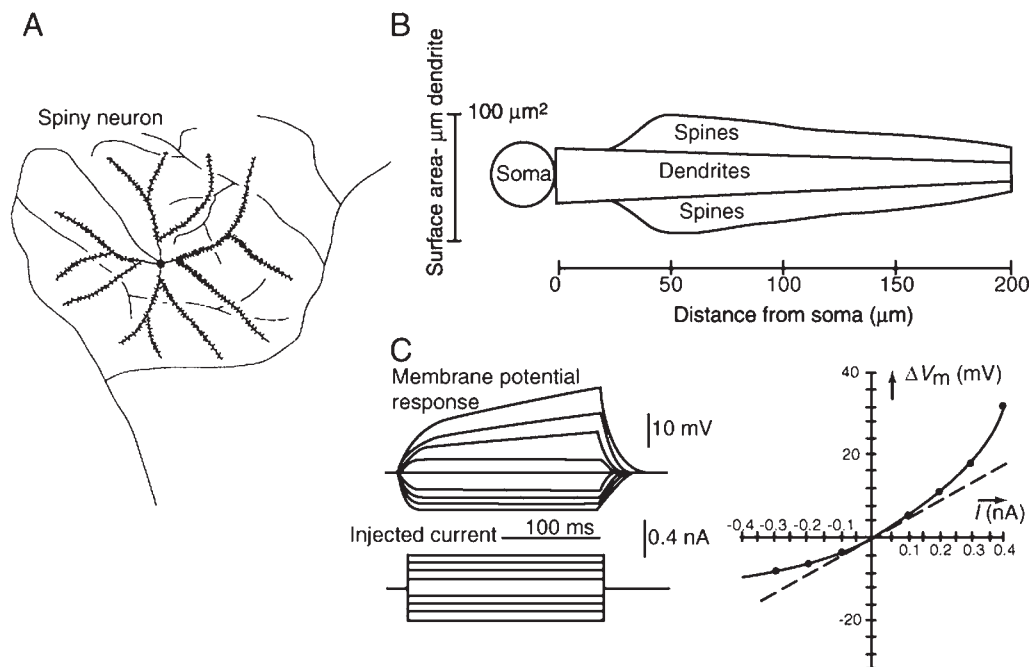

The Purkinje cell thus illustrates several of the principles we have discussed. *Subthreshold amplification* through active dendritic properties may enhance the effect of a particular set of input fibers in controlling or modulating the frequency of Purkinje cell action potential output in the axon hillock. The Purkinje cell is subjected to *local inhibitory control* by stellate cell synapses targeted to specific dendritic compartments, and to *global inhibitory control* of axonal output by basket cell synapses on the axonal initial segment.

### Medium Spiny Cell

A different instructive example of the role of active dendritic properties is found in the medium spiny cell of the neostriatum (Figs. 12.13A). The passive electrotonic properties of this cell are described in Chapter 5 (Fig. 5.12). Inputs to a given neuron from the cortex are widely distributed, meaning that a given neuron must

summate a significant number of synaptic inputs before generating an impulse response. The responsiveness of the cell is controlled by its cable properties; individual responses in the spines are filtered out by the large capacitance of the many dendritic spines so that individual EPSPs recorded at the soma are small.

With synchronous specific inputs, larger summated EPSPs depolarize the dendritic membrane strongly. The dendritic membrane contains inwardly rectifying channels ( $I_h$ ) (Fig. 12.13C), which reduce their conductance upon depolarization and thereby increase the effective membrane resistance and shorten the electrotonic length of the dendritic tree. Large depolarization also activates HT  $\text{Ca}^{2+}$  channels, which contribute to large-amplitude, slow depolarizations. These combined effects change the neuron from a state in which it is insensitive to small noisy inputs into a state in which it gives a large response to a specific input and is maximally sensitive to additional inputs. Through this voltage-gated mechanism, a neuron can enhance the effectiveness of distal dendritic inputs, not by boosting inward  $\text{Na}^+$  and  $\text{K}^+$  currents, but by reducing outward shunting  $\text{K}^+$  currents. This exemplifies the principle of dynamic control over dendritic properties through interactions involving  $\text{K}$  conductances mentioned earlier.

From Wilson (1998).

## Pyramidal Neurons

Active properties of the apical dendrite of hippocampal pyramidal neurons have been documented amply by patch recordings (Magee and Johnston, 1995). In contrast to the Purkinje cell, both fast  $\text{Na}^+$  and  $\text{Ca}^{2+}$  conductances have been shown throughout the dendritic tree of the pyramidal neuron by electrophysiological and dye-imaging methods (Fig. 12.7). Activation of low-threshold  $\text{Na}^+$  channels is believed to play an important role in triggering the higher-threshold  $\text{Ca}^{2+}$  channels. Similar results have been obtained in studies of pyramidal neurons of the cerebral cortex.

At the simplest level, the output pattern of a neuron depends on its dendritic properties and their interaction with the soma. This is exemplified by the generation of a burst response in a pyramidal neuron. EPSPs spread through the dendrite, activating fast  $\text{Na}^+$  and then high-threshold (HT)  $\text{Ca}^{2+}$  channels that give a subthreshold boost to the EPSP. The enhanced EPSP spreads to the soma-axon hillock, triggering a  $\text{Na}^+$  action potential. This propagates into the axon and also back-propagates into the dendrites, eliciting a slower all-or-nothing  $\text{Ca}^{2+}$  action potential. This large-amplitude, slow depolarization then spreads through the dendrites and back to the soma, triggering a train of action potentials that form a burst response.

This sequence of events is simulated most accurately by a realistic multicompartmental model of the dendritic tree. However, the essence can be contained in a two-compartment model representing the soma and dendritic compartments (Fig. 12.14). The model

sequence emphasizes not only the importance of the interplay between the different types of channels, but also the critical role of the compartmentalization of the neuron into dendritic and somatic compartments so that they can interact in controlling the intensity and time course of the impulse output.

This simpler model would argue that the specific form of the input-output transformation does not depend on a specific distribution of active channels in the dendritic tree.  $\text{Na}^+$  and  $\text{Ca}^{2+}$  channels in fact are distributed widely in pyramidal neuron dendrites. In computational simulations, grouping channels in different distributions may have little effect on the input-output functions of a neuron (Mainen and Sejnowski, 1995). However, there is evidence that subthreshold amplification by voltage-gated channels may tend to occur in the more proximal dendrites of some neurons (Yuste and Denk, 1995). In addition, the dendritic trees of some neurons clearly are divided into different anatomical and functional subdivisions, as discussed in the next section.

## Summary

These are only a few examples of the range of operations carried out by complex dendrites. These dendritic operations are embedded in the circuits that control behavior. Thus, for each neuron, the dendritic tree constitutes an expanded unit essential to the circuits' underlying behavior.

## DENDRITIC SPINES ARE MULTIFUNCTIONAL MICROINTEGRATIVE UNITS

Much of the complex processing that takes place in dendrites involves inputs through dendritic spines, the tiny outcroppings from the dendritic surface. Their electrotonic properties were described in relation to Fig. 5.14. The very small size of dendritic spines has made it difficult to study them directly. However, examples already have been given of spines with complex information processing capacities, such as granule cell spines in the olfactory bulb and spines of medium spiny neurons in the striatum. In cortical neurons, spines have been implicated in cognitive functions from observations of dramatic changes in spine morphology in relation to different types of mental retardation and different hormonal exposures.

One of the most fertile hypotheses, by Rall and Rinzel (1974), is that changes in the dimensions of the spine stem control the effectiveness of coupling of

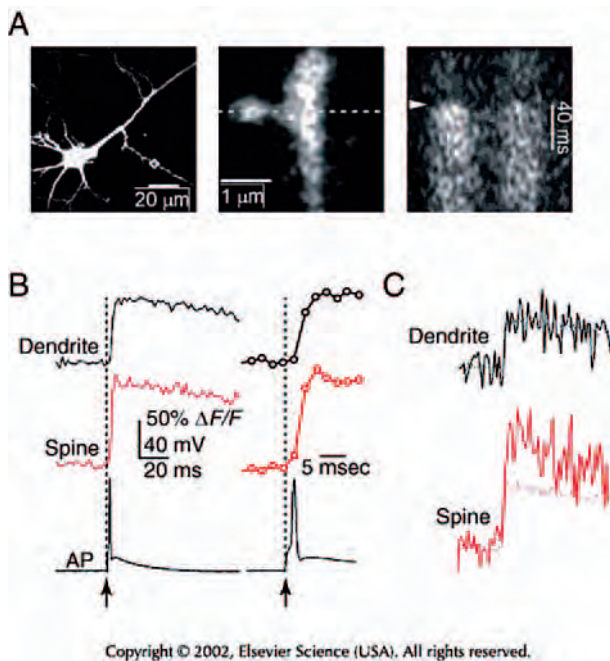

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 12.14** Generation of a burst response by interactions between soma and dendrites. From Pinsky and Rinzel (1994).

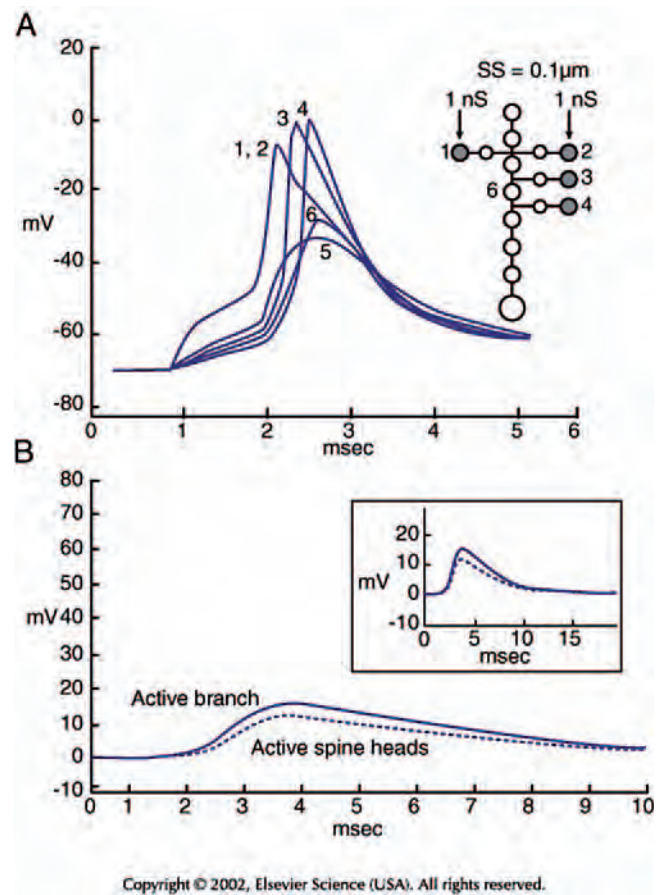

the synaptic response in the spine head to the rest of the dendritic branch, and could therefore provide a mechanism for learning and memory (see also Harris and Krater, 1994; Shepherd, 1996; Yuste and Denk, 1995). For example, an activity-dependent decrease in stem diameter could increase the input resistance of the spine head, increasing an EPSP amplitude, which could have local effects on subsequent responses, and it can also decrease the coupling to the parent dendrite. In addition to these electrotonic effects, a decrease in stem diameter could also increase the biochemical compartmentalization of the spine head (Fig. 5.14).

Computational models have been very useful in testing these hypotheses, as well as suggesting other possible functions, such as the dynamic changes of electrotonic structure in medium spiny cells of the basal ganglia (see earlier discussion). With the development of more powerful light microscopic methods, such as two-photon laser confocal microscopy, it has become possible to test these hypotheses directly by imaging  $\text{Ca}^{2+}$  fluxes in individual spines in relation to synaptic inputs and neuronal activity (Fig. 12.15).

**FIGURE 12.15** Calcium transients can be imaged in single dendritic spines in a rat hippocampal slice. (A) Fluo-4, a calcium-sensitive dye, injected into a neuron enables an individual spine to be imaged under two-photon microscopy. (B) An action potential (AP) induces an increase in  $\text{Ca}^{2+}$  in the dendrite and a larger increase in the spine (averaged responses). (C) Fluctuation analysis indicated that spines likely contain up to 20 voltage-sensitive Ca channels; single channel openings could be detected, which had a high (0.5) probability of opening following a single action potential. From Sabatini and Svoboda (2000).

Evidence for active properties of dendrites has suggested that the spines may also have active properties. Thus, spines may be devices for nonlinear thresholding operations, either through voltage-gated ion channels (Fig. 12.7) or through voltage-dependent synaptic properties such as N-methyl-D-aspartate (NMDA) receptors. This could powerfully enhance the information processing capabilities of spiny dendrites. As an example, computational simulations have shown that logic operations are inherent in coincidence detection by active dendritic sites such as spines. The example is an AND operation performed by two dendritic spines

**FIGURE 12.16** Logic operations are inherent in coincidence detection by active dendritic sites. The example is an AND operation performed by two dendritic spines with Hodgkin-Huxley-type active kinetics, with intervening passive dendritic membrane. (A) Simultaneous synaptic input of 1 nS conductance to spines 1 and 2 gives rise to action potentials within both spines, which spread passively to activate action potentials in spines 3 and 4. Sequential coincidence detection by active spines can thus bring boosted synaptic responses close to the soma. From Shepherd and Brayton (1987). (B) Recording of boosted spine responses at the soma shows their similarity to the slow time course of classical EPSPs due to the electrotonic properties of the intervening dendritic membrane (see text). SS, spine stem diameter. From Shepherd *et al.* (1989).

with Hodgkin–Huxley-type active kinetics, with intervening passive dendritic membrane. As illustrated in Figure 12.16, simultaneous synaptic input of 1 nS conductance to spines 1 and 2 gives rise to action potentials within both spines, which spread passively to activate action potentials in spines 3 and 4. Sequential coincidence detection by active spines can thus bring boosted synaptic responses close to the soma.

Further computational experiments have shown that spines can function as OR gates or as AND-NOT gates, which together with AND gates, provide the basic operations for a digital computer. This shows that simple logic operations are inherent in dendrites, a starting point for investigating the actual kinds of information processing that the brain uses.

In addition to these functions underlying normal functioning of dendrites, the morphological characteristics of a spine may be used to isolate functional properties that result from pathological processes. One such suggestion is that spines may function as compartments to isolate changes at the synapse, such as influx

of excess  $\text{Ca}^{2+}$  that occurs in ischemia due to stroke, which lead to degenerative changes that are harmful to the rest of the neuron (Volfovsky *et al.*, 1999).

The range of functions that have been hypothesized for spines is partly a reflection of how little direct evidence we have of specific properties of spines. It also indicates that the answer to the question “What is the function of the dendritic spine?” is unlikely to be only one function, but rather a range of functions that is tuned in a given neuron to the specific operations of that neuron. The spine is increasingly regarded as a microcompartment that integrates a range of functions (Harris and Kater, 1994; Shepherd, 1996; Yuste and Denk, 1995). A spiny dendritic tree thus is covered with a large population of microintegrative units. As discussed previously, the effect of any given one of these units on the action potential output of the neuron therefore should not be assessed with regard only to the far-off cell body and axon hillock, but rather with regard first to its effect on its neighboring microintegrative units.

**FIGURE 12.17** Summary of some of the functions of dendritic tree of cortical pyramidal neurons that have been demonstrated experimentally and computationally and discussed in this chapter. From Mel and Schiller (2003).

## SUMMARY: THE DENDRITIC TREE AS A COMPLEX INFORMATION PROCESSING SYSTEM

Dendrites are the primary information processing substrate of the neuron. They allow the neuron wide flexibility in carrying out the operations needed for processing information in the spatial and temporal domains within nervous centers. The main constraints

on these operations are the rules of passive electrotonic spread (Chapter 5), and the rules of nonlinear thresholding at multiple sites within the complex geometry of dendritic trees. Many specific types of information processing can be demonstrated in dendrites, such as logic operations, motion detection, oscillatory activity, lateral inhibition, and network control of sensory processing and motor control. These types are possible for both cells without axons and cells with axons, the latter operating in addition within constraints that govern

(B) Conversion to a representation in terms of logic nodes and interconnections. (C) Comparison with the concept introduced by McCulloch and Pitts (1943) of the neuron as a functional node for carrying out logic operations, but in which the dendritic tree is ignored and the entire neuron is reduced to a single computational node,  $e$ , excitatory synapse;  $i$ , inhibitory synapse. From Shepherd (1994).

## Mapping a multinode dendrite neuron Into a two-layer neural network

**FIGURE 12.19** How can the kinds of complex operations illustrated in Figures 12.17 and 12.18 be incorporated into network models? One way is illustrated here, in which the input-output operations of the thin oblique dendritic branches of the apical dendrite of a CA1 pyramidal neuron are represented, together with the summing node at the soma, as a two-layer neural network. From Poirazi *et al.* (2003).

local vs. global outputs and sub- vs. suprathreshold activities. Several of these operations, as reviewed earlier in the chapter, are summarized in the diagram of Figure 12.17.

Spines add a dimension of local computation to dendritic function that is especially relevant to mechanisms for learning and memory. Although spines seem to distance synaptic responses from directly affecting axonal output, many cells demonstrate that distal spine inputs carry specific information.

The key to understanding how all parts of the dendritic tree, including its distal branches and spines, can participate in mediating specific types of information processing is to recognize the tree as a complex system of active nodes. From this perspective, if a spine can affect its neighbor, and that spine has its neighbor, a dendritic tree becomes a cascade of decision points, with multiple cascades operating over multiple overlapping time scales (Fig. 12.18A, B). Far from being a single node, as in the classical concept of McCulloch and Pitts (1943) (Fig. 12.18C) and classical neural network models, the complex neuron is a system of nodes in itself, within which the dendrites constitute a kind of neural microchip for complex computations.

The global output becomes the summation of all the logic operations taking place in the dendrites (Shepherd and Brayton, 1987). The neuron as a single node, so feeble in its information processing capacities, is replaced by the neuron as a powerful complex multinodal system.

The range of operations of which this complex system is capable continues to expand. A formal representation of the dendrite as a multinodal system has been applied to the ensemble of thin oblique dendrites that are emitted by the apical dendrite of a CA1 pyramidal neuron. As shown in Figure 12.19, these thin dendrites, as with spines in Figure 12.18, can be represented by individual summing nodes. The cell can then be mapped onto a two-layer “neural network,” in which the first layer consists of the synaptic inputs to the oblique nodes, whose outputs are then summed at the cell body for final thresholding and global output (Poirazi *et al.*, 2003). Most of the input to the oblique dendrites is believed to be involved in the generation of long-term potentiation, a candidate model for learning and memory. The two-layer conceptual approach thus may be a bridge between realistic multicompartmental models and single node neural networks in the

study of brain mechanisms in learning and memory. Exploring the information processing capacities of the brain at the level of real dendritic systems, by both experimental and theoretical methods, thus presents one of the most exciting challenges for neuroscientists at present and into the future.

## Brain Energy Metabolism

All the processes described in this textbook require energy. Ample clinical evidence indicates that the brain is exquisitely sensitive to perturbations of energy metabolism. This chapter covers the topics of energy delivery, production, and utilization by the brain. Careful consideration of the basic mechanisms of brain energy metabolism is an essential prerequisite to a full understanding of the physiology and pathophysiology of brain function. Abnormalities in brain energy metabolism are observed in a variety of pathological conditions such as neurodegenerative diseases, stroke, epilepsy, and migraine. The chapter reviews the features of brain energy metabolism at the global, regional, and cellular levels and extensively describes recent advances in the understanding of neuro-glial metabolic cooperation. A particular focus is the cellular and molecular mechanisms that tightly couple neuronal activity to energy consumption. This tight coupling is at the basis of functional brain-imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging.

### ENERGY METABOLISM OF THE BRAIN AS A WHOLE ORGAN

#### Glucose Is the Main Energy Substrate for the Brain

The human brain constitutes only 2% of the body weight, yet the energy-consuming processes that ensure proper brain function account for approximately 25% of total body glucose utilization. With a few exceptions that will be reviewed later, glucose is the obligatory energy substrate of the brain. In any tissue, glucose can follow various metabolic pathways;

in the brain, glucose is almost entirely oxidized to CO<sub>2</sub> and water through its sequential processing by glycolysis (Fig. 13.1), the tricarboxylic acid (TCA) cycle (Fig. 13.2), and the associated oxidative phosphorylation, which yield, on a molar basis, between 30 and 36 ATP per glucose, depending on the coupling efficiency of oxidative phosphorylation. Indeed, the oxygen consumption of the brain, which accounts for almost 20% of the oxygen consumption of the whole organism, is 160 mmol per 100 g of brain weight per minute and roughly corresponds to the value determined for CO<sub>2</sub> production. This O<sub>2</sub>/CO<sub>2</sub> relation corresponds to what is known in metabolic physiology as a respiratory quotient of nearly 1 and demonstrates that carbohydrates, and glucose in particular, are the exclusive substrates for oxidative metabolism.

This rather detailed information of whole brain energy metabolism was obtained using an experimental approach in which the concentration of a given substrate in the arterial blood entering the brain through the carotid artery is compared with that present in the venous blood draining the brain through the jugular vein (Kety and Schmidt, 1948). If the substrate is utilized by the brain, the arteriovenous (A-V) difference is positive; in certain cases, the A-V difference may be negative, indicating that metabolic pathways resulting in the production of the substrate predominate. In addition, when the rate of cerebral blood flow (CBF) is known, the steady-state rate of utilization of the substrate can be determined per unit time and normalized per unit brain weight according to the following relation:  $CMR = CBF (A-V)$ , where CMR is the cerebral metabolic rate of a given substrate.

This approach was pioneered by Seymour Kety and C. F. Schmidt in the late 1940s and was further developed in the 1950s and 1960s. In normal adults,

**FIGURE 13.1** Glycolysis (Embden-Meyerhof pathway). Glucose phosphorylation is regulated by hexokinase, an enzyme inhibited by glucose 6-phosphate. Glucose must be phosphorylated to glucose 6-phosphate to enter glycolysis or to be stored as glycogen. Two other important steps in the regulation of glycolysis are catalyzed by phosphofructokinase and pyruvate kinase. Their activity is controlled by the levels of high-energy phosphates, as well as of citrate and acetyl-CoA. Pyruvate, through lactate dehydrogenase, is in dynamic equilibrium with lactate. This reaction is essential to regenerate  $\text{NAD}^+$  residues necessary to sustain glycolysis downstream of glyceraldehyde 3-phosphate. PCr, phosphocreatine.

**FIGURE 13.2** Tricarboxylic acid cycle (Krebs' cycle) and oxidative phosphorylation. Pyruvate entry into the cycle is controlled by pyruvate dehydrogenase activity that is inhibited by ATP and NADH. Two other regulatory steps in the cycle are controlled by isocitrate and  $\alpha$ -ketoglutarate dehydrogenase, whose activity is controlled by the levels of high-energy phosphates.

CBF is approximately 57 ml per 100 g of brain weight per minute, and the calculated glucose utilization by the brain is 31 mmol per 100 g of brain weight per minute, as determined with the A-V difference method (Kety and Schmidt, 1948). This value is slightly higher than that predicted from the rate of oxygen consumption of the brain. Thus, in an organ such as the brain with a respiratory quotient of 1, the stoichiometry would predict that 6 mmol of oxygen are needed to fully oxidize 1 mmol of the six-carbon molecule of glucose; given an oxygen consumption rate of 160 mmol per 100 g of brain weight per minute, the predicted glucose utilization would be 26 mmol per 100 g of brain

weight per minute (160:6), yet the actual measured rate is 31 mmol. What then is the fate of the excess 4.4 mmol? First, glucose metabolism may proceed, to a very limited extent, only through glycolysis, resulting in the production of lactate without oxygen consumption (see Fig. 13.1); glucose can also be incorporated into glycogen (Fig. 13.1). Second, glucose is an essential constituent of macromolecules such as glycolipids and glycoproteins present in neural cells. Finally, glucose enters the metabolic pathways that result in the synthesis of three key neurotransmitters of the brain: glutamate, GABA, and acetylcholine (see Chapter 7).

## Ketone Bodies Become Energy Substrates for the Brain in Particular Circumstances

In particular circumstances, substrates other than glucose can be utilized by the brain. For example, breastfed neonates have the capacity to utilize the ketone bodies acetoacetate (AcAc) and D-3-hydroxybutyrate (3-HB), in addition to glucose, as energy substrates for the brain. This capacity is an interesting example of a developmentally regulated adaptive mechanism because maternal milk is highly enriched in lipids, resulting in a lipid-to-carbohydrate ratio much higher than that present in postweaning nutrients. Indeed, lipids account for approximately 55% of the total calories contained in human milk, in contrast with 30 to 35% for a balanced postweaning diet. In addition to the ketone bodies AcAc and 3-HB, other products of lipid metabolism, relevant to brain metabolic processes, are free fatty acids. Acetoacetate, 3-HB, and free fatty acids can all be processed to acetyl-CoA, thus providing ATP through the TCA cycle (Fig. 13.3). We will see later that brain energy metabolism is highly compartmentalized, with certain metabolic pathways specifically localized in a given cell type. It is therefore not surprising that whereas ketone bodies can be oxidized by neurons, oligodendrocytes, and astrocytes, the  $\beta$ -oxidation of free fatty acids is localized exclusively in astrocytes.

Another consideration regarding the lipid-rich diet provided during the suckling period relates to its contribution to the process of myelination. The question is whether the polar lipids and cholesterol that make

up myelin are derived from dietary sources or are synthesized within the brain. Evidence shows that brain lipids can be synthesized from blood-borne precursors such as ketone bodies. In addition, when suckling rats are fed a diet low in ketones, carbon atoms for lipogenesis can also be provided by glucose. To summarize, ketone bodies and AcAc are energy substrates, as well as precursors for lipogenesis during the suckling period; however, the developing brain appears to be metabolically quite flexible because glucose, in addition to its energetic function, can be metabolized to generate substrates for lipid synthesis.

Starvation and diabetes are two situations in which the availability of glucose to tissues is inadequate and in which plasma ketone bodies are elevated because of enhanced lipid catabolism. Under these conditions, the adaptive mechanisms described for breast-fed neonates become operative in the brain, allowing it to utilize AcAc or 3-HB as energy substrates.

## Mannose, Lactate, and Pyruvate Serve as Instructive Cases

A number of metabolic intermediates have been tested as alternative substrates to glucose for brain energy metabolism. Among the numerous molecules tested, mannose is the only one that can sustain normal brain function in the absence of glucose. Mannose crosses the blood-brain barrier readily and, in two enzymatic steps, is converted into fructose 6-phosphate, an intermediate of the glycolytic pathway (Fig. 13.1). However, mannose is not normally present in the blood and therefore is not considered a physiological substrate for brain energy metabolism.

Lactate and pyruvate can be sources of insight into the intrinsic properties of isolated brain tissue versus those of the brain as an organ receiving substrates from the circulation. Lactate and pyruvate can sustain the synaptic activity of isolated brain preparations, usually thin slices, maintained *in vitro* in a physiological medium lacking glucose (Schurr, 2006). *In vivo*, until recently, it was thought that their permeability across the blood-brain barrier was limited, hence preventing circulating lactate or pyruvate to substitute for glucose to maintain brain function adequately. However, evidence from magnetic resonance spectroscopy (MRS) experiments indicates that the permeability of circulating lactate across the blood-brain barrier may actually be higher than previously thought (Hassel and Brathe, 2000); in addition, the presence of monocarboxylate transporters on intraparenchymal brain capillaries has been documented (Pierre and Pellerin, 2005). Thus there is a need for the reappraisal of the

**FIGURE 13.3** Relationship between lipid metabolism and the TCA cycle. Under particular dietary conditions, such as lactation in newborns or fasting in adults, the ketone bodies acetoacetate and D-3-hydroxybutyrate and circulating fatty acids can provide substrates to the TCA cycle after conversion into acetyl-CoA. Carbon atoms for lipid synthesis can be provided by glucose through citrate produced in the TCA cycle, a particularly relevant process for the developing brain.

use by the brain of monocarboxylates. For example, during vigorous exercise resulting in increases in blood lactate, the brain takes up lactate and glucose in equal amounts; lactate is then fully oxidized by the brain parenchyma (Dalsgaard, 2006). Furthermore, artificially raising lactate concentration from 0.6 (physiological value) to 4mM (as observed in moderate-to-high exercise) markedly decreases glucose utilization by the brain as determined in humans with  $^{18}\text{F}$ -2-deoxyglucose Positron Emission Tomography (Smith *et al.*, 2003). Overall these data support the notion that plasma lactate can be an energy substrate for the human brain. In addition, if formed within the brain parenchyma from glucose that has crossed the blood-brain barrier, lactate and pyruvate may in fact become the preferential energy substrates for activated neurons (see later).

### Summary

Glucose is the obligatory energy substrate for brain, and it is almost entirely oxidized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . This simple statement summarizes, with few exceptions, over four decades of careful studies of brain energy metabolism at organ and regional levels. Under ketogenic conditions, such as starvation and diabetes and during breastfeeding, ketone bodies may provide an energy source for the brain. Lactate and pyruvate, formed from glucose within the brain parenchyma, are adequate energy substrates as well.

## TIGHT COUPLING OF NEURONAL ACTIVITY, BLOOD FLOW, AND ENERGY METABOLISM

A striking characteristic of the brain is its high degree of structural and functional specialization. Thus, when we move an arm, motor areas and their related pathways are activated selectively (see Chapter 28); intuitively, one can predict that as “brain work” increases locally (e.g., in motor areas), the energy requirements of the activated regions will increase in a temporally and spatially coordinated manner. Because energy substrates are provided through the circulation, blood flow should increase in the modality-specific activated area. More than a century ago, the British neurophysiologist Charles Sherrington showed, in experimental animals, increases in blood flow localized to the parietal cortex in response to sensory stimulation (Roy and Sherrington, 1890). He postulated that “the brain possesses intrinsic mechanisms by which its vascular supply can be varied

locally in correspondence with local variations of functional activity.” With remarkable insight, he also proposed that “chemical products of cerebral metabolism” produced in the course of neuronal activation could provide the mechanism to couple activity with increased blood flow.

### Which Mechanisms Couple Neuronal Activity to Blood Flow?

Since Sherrington’s seminal work, the search for the identification of chemical mediators that can couple neuronal activity with local increases in blood flow has been intense. These signals can be broadly grouped into two categories: (1) molecules or ions that transiently accumulate in the extracellular space *after* neuronal activity and (2) specific neurotransmitters that mediate the coupling *in anticipation* or at least *in parallel* with local activation (neurogenic mechanisms). The increases in extracellular  $\text{K}^+$ , adenosine, and lactate and the related changes in pH are all a consequence of increased neuronal activity, and all have been considered mediators of neuro-vascular coupling because of their vasoactive effects (Villringer and Dirnagl, 1995). However, the spatial and temporal resolution achieved by these mediators may not be sufficient to entirely account for the activity-dependent coupling between neuronal activity and blood flow. Indeed, these vasoactive agents are formed with a certain delay (seconds) after the initiation of neuronal activity and can diffuse at considerable distance. In this respect, neurogenic mechanisms appear to be better fitted. Brain microvessels are richly innervated by neuronal fibers. These fibers may have an extrinsic origin (e.g., in the autonomic ganglia) or be part of neuronal circuits intrinsic to the brain, such as local interneurons or long projections that originate in the brainstem (e.g., those containing monoaminergic neurotransmitters). In addition, functional receptors coupled to signal transduction pathways have been identified for several neurotransmitters on intraparenchymal microvessels. Neurotransmitters with potential roles in coupling neuronal activity with blood flow include the amines noradrenaline, serotonin, and acetylcholine and the peptides vasoactive intestinal peptide, neuropeptide Y (NPY), calcitonin gene-related peptide (CGRP), and substance P (SP). The neurogenic mode of neurovascular coupling implies that vasoactive neurotransmitters are released from perivascular fibers as excitatory afferent volleys activate a discrete and functionally defined brain volume (Hamel, 2006).

An attractive addition to the list of potential mediators for coupling neuronal activity to blood flow is

nitric oxide (NO). Indeed, NO is an ideal candidate; it is formed locally by neurons and glial cells under the action of a variety of neurotransmitters likely to be released by depolarized afferents to an activated brain area. Nitric oxide is a diffusible and potent vasodilator whose short half-life spatially and temporally restricts its domain of action. However, in several experimental models in which the activity of NO synthase, the enzyme responsible for NO synthesis, was inhibited, a certain degree of coupling was still observed, indicating that NO is probably only one of the regulators of local blood flow acting in synergy with others (Hamel, 2006).

Recent *in vitro* and *in vivo* experiments have provided evidence that astrocytes may play a key role in neurovascular coupling. Indeed as will be elaborated in greater detail in the section devoted to neurometabolic coupling (e.g., Figure 13.8), astrocytes occupy a strategic position between capillaries and the neuropil. Through receptors and reuptake sites for neurotransmitters, notably glutamate, they can sense synaptic activity and couple it to vascular response. The molecular mediators of the astrocyte-dependent hyperemia that accompanies activation include prostanoids and adenosine (Koheler *et al.*, 2006).

In summary, several products of activity-dependent neuronal and glial metabolism such as lactate, H<sup>+</sup>, adenosine, prostanoids, and K<sup>+</sup> have vasoactive effects and are therefore putative mediators of coupling, although the kinetics and spatial resolution of this mode do not account for all the observed phenomena. As attractive as it is, an exclusively neurogenic mode of coupling neuronal activity to blood flow is unlikely and, moreover, still awaits firm functional confirmation *in vivo*. Nitric oxide is undoubtedly a key element in coupling, particularly in view of the fact that glutamate, the principal excitatory neurotransmitter, triggers a receptor-mediated NO formation in neurons and glia; this is consistent with the view that whenever a functionally defined brain area is activated and glutamate is released by the depolarized afferents, NO may be formed, thus providing a direct mechanism contributing to the coupling between activity and local increases in blood flow. Astrocytes appear to function as intermediary processor in neurovascular coupling (Koheler *et al.*, 2006).

Through the activity-linked increase in blood flow, more substrates—namely, glucose and oxygen—necessary to meet the additional energy demands are delivered to the activated area per unit time. The cellular and molecular mechanisms involved in oxygen consumption and glucose utilization are treated in a later section.

## Blood Flow and Energy Metabolism Can Be Visualized in Humans

Modern functional brain-imaging techniques enable the *in vivo* monitoring of human blood flow and the two indices of energy metabolism: glucose utilization and oxygen consumption (Raichle and Mintun, 2006). For instance, with the use of PET and appropriate positron-emitting isotopes such as <sup>18</sup>F and <sup>15</sup>O, basal rates, as well as activity-related changes in local blood flow or oxygen consumption, can be studied using <sup>15</sup>O-labeled water or <sup>15</sup>O, respectively. Local rates of glucose utilization (also defined as local cerebral metabolic rates for glucose (LCMRglu)) can be determined with <sup>18</sup>F-labeled 2-deoxyglucose (2-DG) (Phelps *et al.*, 1979). The use of 2-DG as a marker of LCMRglu was pioneered by Louis Sokoloff and associates at the National Institutes of Health, first in laboratory animals (Sokoloff, 1981). The method is based on the fact that 2-DG crosses the blood–brain barrier, is taken up by brain cells, and is phosphorylated by hexokinase with kinetics similar to that for glucose; however, unlike glucose 6-phosphate, 2-deoxyglucose 6-phosphate cannot be metabolized further and therefore accumulates intracellularly (Fig. 13.4).

For studies in laboratory animals, tracer amounts of radioactive 2-DG are injected intravenously; the animal is subjected to the behavioral paradigms of interest and sacrificed at the end of the experiment. Serial thin sections of the brain are prepared and processed for autoradiography. This autoradiographic method provides, after appropriate corrections, an accurate measurement of LCMRglu with a spatial resolution of approximately 50–100 μm. Using this method, researchers have determined LCMRglu in virtually all structurally and functionally defined brain structures in various physiological and pathological states, including sleep, seizures, and dehydration, and after a variety of pharmacological treatments (Sokoloff, 1981). Furthermore, glucose utilization increases in the pertinent brain areas during motor tasks or activation of pathways subserving specific modalities, such as visual, auditory, olfactory, or somatosensory stimulation (Sokoloff, 1981). For example, in mice, sustained stimulation of the whiskers results in marked increases in LCMRglu in discrete areas of the primary sensory cortex called the barrel fields, where each whisker is represented with an extreme degree of topographical specificity (see Chapter 25). Basal glucose utilization of the gray matter as determined by 2-DG autoradiography varies, depending on the brain structure, between 50 and 150 μmol per 100 g of wet weight per minute in the rat.

**FIGURE 13.4** Structure and metabolism of glucose and 2-deoxyglucose (2-DG). 2-DG is transported into cells through glucose transporters and phosphorylated by hexokinase to glucose 6-phosphate without significant further processing or dephosphorylation back to glucose. Therefore, when labeled radioactively, 2-DG used in tracer concentrations is a valuable marker of glucose uptake and phosphorylation, which directly indicates glucose utilization.

In humans, LCMRglu determined by PET with the use of  $^{18}\text{F}$ -2-DG is approximately 50% lower than that in rodents, and physiological activation of specific modalities increases LCMRglu in discrete areas of the brain that can be visualized with a spatial resolution of a few millimeters. For example, visual stimulations presented to subjects as checkerboard patterns reversing at frequencies ranging from 2 to 10 Hz selectively increase LCMRglu in the primary visual cortex and a few connected cortical areas. With the use of this stimulation paradigm, the combined PET analysis of local cerebral blood flow (LCBF) and local oxygen consumption (LCMRO<sub>2</sub>), in addition to LCMRglu, has revealed a unique and unexpected feature of human brain energy metabolism regulation. The canonical view was that the three metabolic parameters were tightly

coupled, implying that if, for example, CBF increased locally during physiological activation, LCMRglu and LCMRO<sub>2</sub> would increase in parallel. In what is now referred to as the phenomenon of “uncoupling,” physiological stimulation of the visual system increases LCBF and LCMRglu (both by 30–40%) in the primary visual cortex without a commensurate increase in LCMRO<sub>2</sub> (which increases only 6%) (Raichle and Mintun, 2006), indicating that the additional glucose utilized during neuronal activation can be processed through glycolysis rather than through the tricarboxylic acid (TCA) cycle and oxidative phosphorylation. The phenomenon of uncoupling has been confirmed in other cortical areas, although its magnitude may differ depending on the modality, and may actually be absent in certain cases.

A glance at the metabolic pathways reveals that if glucose does not enter the TCA cycle to be oxidized, then lactate will be produced (see Figs. 13.1 and 13.2). Lactate, like several other metabolically relevant molecules, can be determined with the technique of magnetic resonance imaging (MRI) spectroscopy for  $^1\text{H}$ , which provides a means of unequivocally identifying in living tissues the presence of molecules that bear the naturally occurring isotope  $^1\text{H}$ . Consistent with the prediction that if during activation glucose is predominantly processed glycolytically, then lactate should be produced locally in the activated region, a transient increase in the lactate signal is detected with  $^1\text{H}$  MRI spectroscopy in the human primary visual cortex during appropriate visual stimulation (Prichard *et al.*, 1991). These observations support the view that to face the local increases in energy demands linked to neuronal activation, the brain transiently resorts to an integrated sequence of glycolysis and oxidative phosphorylation (Magistretti and Pellerin, 1999). This transient uncoupling may vary in amplitude depending on the modalities of activation (Frackowiak *et al.*, 2001) and is likely to occur in different cellular compartments; that is, astrocytes vs. neurons (Pellerin and Magistretti, 1994; Kasischke *et al.*, 2004).

## Summary

Studies at the whole organ level, based on the A-V differences of metabolic substrates, have revealed a great deal about the global energy metabolism of the brain. They have indicated that, under normal conditions, glucose is virtually the sole energy substrate for the brain and that it is entirely oxidized. New techniques that allow imaging of the three fundamental parameters of brain energy metabolism—namely, blood flow, oxygen consumption, and glucose utilization—provide a more refined level of spatial resolution

and demonstrate that brain energy metabolism is regionally heterogeneous and is coupled tightly to the functional activation of specific neuronal pathways (Magistretti *et al.*, 1999).

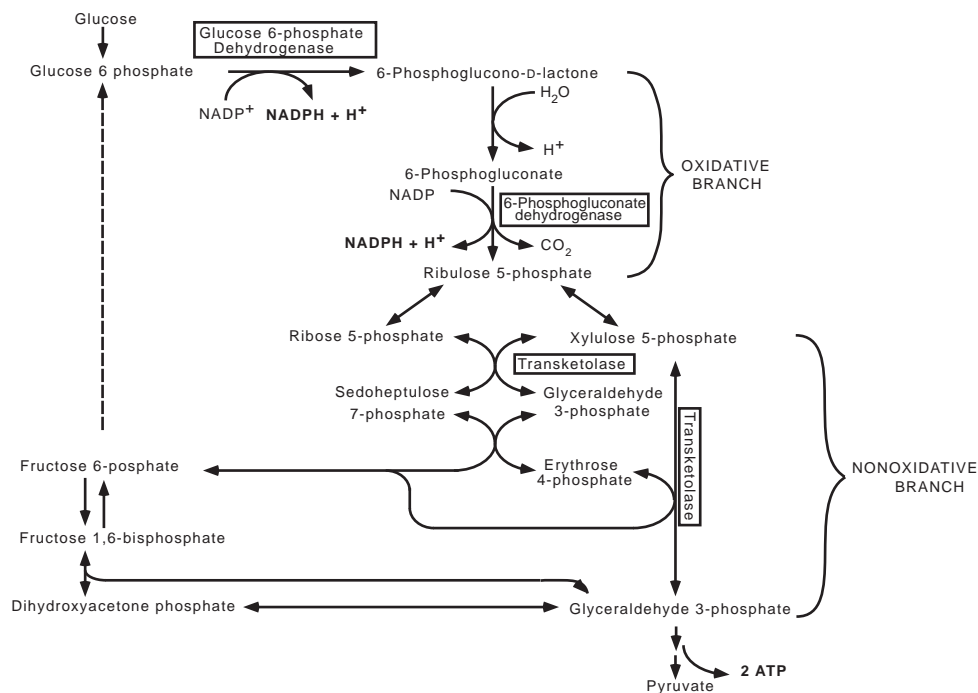

## ENERGY-PRODUCING AND ENERGY-CONSUMING PROCESSES IN THE BRAIN

What are the cellular and molecular mechanisms that underlie the regulation of brain energy metabolism revealed by the foregoing studies at global and regional levels? In particular, what are the metabolic events taking place in the cell types that make up the brain parenchyma? How is it possible to reconcile whole organ studies indicating complete oxidation of glucose with transient activation-induced glycolysis at

the regional level? These and other related questions will be addressed here and in the next sections.

### Glucose Metabolism Produces Energy

Before we move on to an analysis of the cell-specific mechanisms of brain energy metabolism, it seems appropriate to briefly review some basic aspects of the energy balance of the brain. Because glucose, in normal circumstances, is the main energy substrate of the brain, the overview will be restricted to its metabolic pathways. Glucose metabolism in the brain is similar to that in other tissues and includes three principal metabolic pathways: glycolysis, the tri-carboxylic acid cycle, and the pentose phosphate pathway. Because of the global similarities with other tissues, these pathways are simply summarized in Figures 13.1, 13.2, and 13.5, and only a few aspects specific to the nervous tissue will be discussed.

**FIGURE 13.5** The pentose phosphate pathway. In the oxidative branch of the pentose phosphate pathway, two NADPH are generated per glucose 6-phosphate. The first rate-limiting reaction of the pathway is catalyzed by glucose-6-phosphate dehydrogenase; the second NADPH is generated through the oxidative decarboxylation of 6-phosphogluconate, a reaction catalyzed by glucose-6-phosphogluconate dehydrogenase. The nonoxidative branch of the pentose phosphate pathway provides a reversible link with glycolysis by regenerating the two glycolytic intermediates glyceraldehyde 3-phosphate and fructose 6-phosphate. This regeneration is achieved through three sequential reactions. In the first, catalyzed by transketolase, xylulose 5-phosphate and ribose 5-phosphate (which originate from ribulose 5-phosphate, the end product of the oxidative branch) yield glyceraldehyde 3-phosphate and sedoheptulose 7-phosphate. Under the action of transaldolase, these two intermediates yield fructose 6-phosphate and erythrose 4-phosphate. This latter intermediate combines with glyceraldehyde 3-phosphate, in a reaction catalyzed by transketolase, to yield fructose 6-phosphate and glyceraldehyde 3-phosphate. Thus, through the nonoxidative branch of the pentose phosphate pathway, two hexoses (fructose 6-phosphate) and one triose (glyceraldehyde 3-phosphate) of the glycolytic pathway are regenerated from three pentoses (ribulose 5-phosphate).

## Glycolysis

Glycolysis (Embden-Meyerhof pathway) is the metabolism of glucose to pyruvate (Fig. 13.1). It results in the net production of only two molecules of ATP per glucose molecule; indeed, four ATPs are formed in the processing of glucose to pyruvate, whereas two ATPs are consumed to phosphorylate glucose to glucose 6-phosphate and fructose 6-phosphate to fructose 1,6-bisphosphate, respectively (Fig. 13.1). Under anaerobic conditions, pyruvate is converted into lactate, allowing the regeneration of nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ), which is essential to maintain a continued glycolytic flux. Indeed, if  $\text{NAD}^+$  were not regenerated, glycolysis could not proceed beyond glyceraldehyde 3-phosphate (Fig. 13.1). Another situation in which the end product of glycolysis is lactate rather than pyruvate is when oxygen consumption does not match glucose utilization, implying that the rate of pyruvate production through glycolysis exceeds pyruvate oxidation by the TCA cycle (Fig. 13.2). This condition has been well described in skeletal muscle during intense exercise and appears to share similarities with the transient uncoupling observed between glucose utilization and oxygen consumption that has been described in the human cerebral cortex during activation with the use of PET (Raichle and Mintun, 2006).

## Tricarboxylic Acid Cycle

Under aerobic conditions, pyruvate is oxidatively decarboxylated to yield acetyl-CoA in a reaction catalyzed by the enzyme pyruvate dehydrogenase (PDH). Acetyl-coenzyme A condenses with oxaloacetate to produce citrate (Fig. 13.2). This is the first step of the tricarboxylic acid cycle, in which three pairs of electrons are transferred from  $\text{NAD}^+$  to  $\text{NADH}$ —and one pair from flavin adenine dinucleotide (FAD) to its reduced form ( $\text{FADH}_2$ )—through four oxidation-reduction steps (Fig. 13.2).  $\text{NADH}$  and  $\text{FADH}_2$  transfer their electrons to molecular  $\text{O}_2$  through the mitochondrial electron transfer chain to produce ATP in the process of oxidative phosphorylation. Thus, under aerobic conditions (i.e., when glucose is fully oxidized through the TCA cycle to  $\text{CO}_2$  and  $\text{H}_2\text{O}$ ),  $\text{NAD}^+$  is regenerated, and glycolysis proceeds to pyruvate, not lactate. However, as soon as a mismatch, even a transient one, occurs between glucose utilization and oxygen consumption, lactate is produced. As discussed earlier, such a transient production of lactate appears to occur in the human brain during activation. Experiments performed in freely moving rats also have demonstrated a transient increase in lactate content in the

extracellular space of discrete brain regions during physiological sensory stimulation (Hu and Wilson, 1997).

## Pentose Phosphate Pathway

Although glycolysis, the TCA cycle, and oxidative phosphorylation are coordinated pathways that produce ATP, using glucose as a fuel, ATP is not the only form of metabolic energy. Indeed, for several biosynthetic reactions in which the precursors are in a more oxidized state than the products, metabolic energy in the form of reducing power is needed in addition to ATP. This is the case for the reductive synthesis of free fatty acids from acetyl-CoA, which are components of myelin and of other structural elements of neural cells, such as the plasma membrane. In cells of the brain, as in other organs, the reducing power is provided by the reduced form of nicotinamide adenine dinucleotide phosphate ( $\text{NADPH}$ ). The processing of glucose through the pentose phosphate pathway produces  $\text{NADPH}$ . The first reaction in the pentose phosphate pathway is the conversion of glucose 6-phosphate into ribulose 5-phosphate (Fig. 13.5). This dehydrogenation, in which two molecules of  $\text{NADPH}$  are generated per molecule of glucose 6-phosphate, is the rate-limiting step of the pentose phosphate pathway. The  $\text{NADP}/\text{NADPH}$  ratio is the single most important factor regulating the entry of glucose 6-phosphate into the pentose phosphate pathway. Thus, if a high reducing power is needed,  $\text{NADPH}$  levels decrease and the pentose phosphate pathway is activated to generate new reducing equivalents. The pentose phosphate pathway is also tightly connected to glycolysis through two enzymes, transketolase and transaldolase, which recycle ribulose 5-phosphate to fructose 6-phosphate and glyceraldehyde 3-phosphate, two intermediates of glycolysis (Fig. 13.5).

## Glucose Metabolism, Reactive Oxygen Species, and the Protective Role of Glutathione

In addition to reductive biosynthesis,  $\text{NADPH}$  is needed for the scavenging of reactive oxygen species (ROS). The superoxide radical anion ( $\text{O}_2^-$ ), hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), and the hydroxy radical ( $\text{HO}$ ) are three ROS, generated by the transfer of single electrons to molecular oxygen as by-products of several physiological cellular processes. A considerable contribution to the generation of ROS is the oxidative metabolism of glucose taking place in the mitochondrial electron transfer chain associated with oxidative phosphorylation. Other ROS-generating reactions include the

activities of monoamine oxidase, tyrosine hydroxylase, nitric oxide synthase, and the eicosanoid-forming enzymes lipoxygenases and cyclooxygenases. Reactive oxygen species are highly damaging to cells because they can cause DNA disruption and mutations, as well as activation of enzymatic cascades, including proteases and lipases that can eventually lead to cell death.

Thus, oxidative metabolism, which is so essential to cell viability by generating large amounts of the cellular fuel ATP, implies as a by-product a potentially harmful activity such as ROS generation. The coordinated activity of two molecules is essential in protecting cells against ROS-mediated damage, or oxidative stress: NADPH and glutathione. As we have seen, NADPH is produced through a particular arm of glucose metabolism, the pentose phosphate pathway. Interestingly, therefore, glucose metabolism provides two forms of energy, high energy phosphates such as ATP and reducing power such as NAD(P)H, the latter contributing to the neutralization of ROS, the harmful by-products of the process (oxidative phosphorylation) which produces the former. It is, however, through its combined action with glutathione that NADPH contributes to ROS scavenging. Scavenging of ROS is ensured by the sequential action of superoxide dismutase (SOD) and glutathione peroxidase (Fig. 13.6). Thus, two superoxide anions formed by the aforementioned cellular processes are converted by SOD into  $H_2O_2$ , still a ROS. Glutathione peroxidase converts  $H_2O_2$  into  $H_2O$  and  $O_2$  at the expense of reduced glutathione, which is regenerated by glutathione reductase in the presence of NADPH.

The metabolism of glutathione is tightly regulated and implies yet another example of neuron-astrocyte cooperation. Glutathione is a tripeptide (GSH; gamma-L-glutamyl-L-cysteinylglycine) synthesized through the concerted action of two enzymes, gammaGluCys synthase, which combines glutamate and cysteine to yield the dipeptide gammaGlu Cys, and glutathione synthase, which adds a glycine to the dipeptide to yield GSH (Fig. 13.6).

The glutathione content and reducing potential are considerably higher in astrocytes compared to neurons; this fact, combined with the much higher oxidative activity of neurons vs. astrocytes, makes neurons more vulnerable to oxidative stress as well as highly dependent on astrocytes for their protection (Dringen, 2000). Indeed, a cooperativity between astrocytes and neurons appears to exist for glutathione metabolism; astrocytes release GSH, which is cleaved by the ectoenzyme gamma-Glutamyl Transferase (gamma-GT), which releases CysGly. The dipeptide is transported into neurons (note that neurons cannot take up GSH), pro-

viding two precursors for GSH synthesis glutamate, the third precursor of GSH, also is provided by astrocytes to neurons under the form of glutamine, from which glutamate is produced through the action of glutaminase (Fig. 13.6).

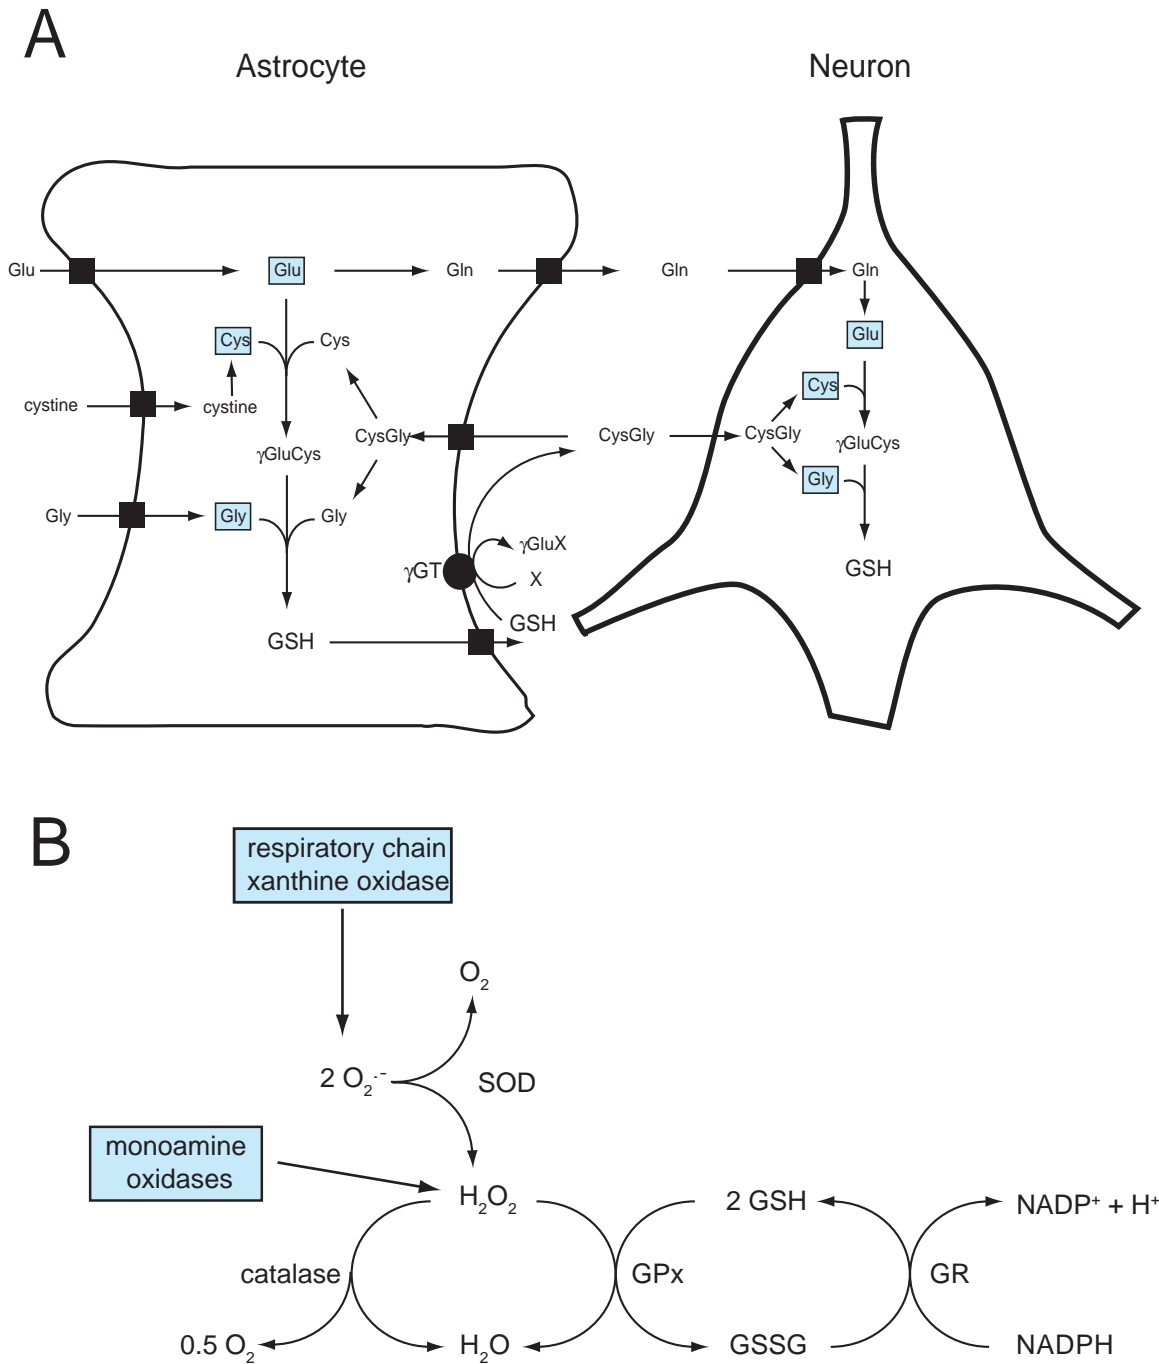

Several neurodegenerative disorders appear to involve a dysfunction in the ability of neural cells to control oxidative stress. For example, a familial form of amyotrophic lateral sclerosis is due to a SOD mutation; evidence for a decrease in GSH content in the substantia nigra has been described in Parkinson's disease (Beal, 2005).

### **The Wernicke-Korsakoff Syndrome: A Neuropsychiatric Disorder Due to a Dysfunction of Energy Metabolism**

A well-characterized neuropsychiatric disorder, the Wernicke-Korsakoff syndrome, is caused by transketolase hypoactivity. The Wernicke-Korsakoff syndrome is characterized by a severe impairment of memory and of other cognitive processes accompanied by balance and gait dysfunction and by paralysis of oculomotor muscles. The syndrome is due to a lack of thiamine (vitamin  $B_1$ ) in the diet; it affects only susceptible persons who are also alcoholics or chronically undernourished. Thiamine pyrophosphate is a thiamine-containing cofactor essential for the activity of transketolase. In patients with the Wernicke-Korsakoff syndrome, thiamine pyrophosphate binds 10 times less avidly to transketolase compared with the enzyme of normal persons. This enzymatic dysfunction renders patients with the Wernicke-Korsakoff syndrome much more vulnerable to thiamine deficiency. This syndrome illustrates how an anomaly in a discrete metabolic pathway of energy metabolism may result in severe alterations in behavior and motor function.

### **Processes Linked to Neuronal Function Consume Energy**

The main energy-consuming process of the brain is the maintenance of ionic gradients across the plasma membrane, a condition that is crucial for excitability. Maintenance of these gradients is achieved predominantly through the activity of ionic pumps fueled by ATP, particularly  $Na^+$ ,  $K^+$ -ATPase, localized in neurons as well as in other cell types such as glia. Activity of these pumps accounts for approximately 50% of basal glucose oxidation in the nervous system. Very recently theoretical calculations of the cost of synaptic transmission have been provided by Attwell and Laughlin (2001). These calculations are based on a number of assumptions and therefore should be taken with some

**FIGURE 13.6** (A) Metabolic interaction between astrocytes and neurons in the synthesis of glutathione. In astrocytes, glutathione (GSH) is synthesized from cysteine (produced from cystine), glycine (Gly) and glutamate (Glu). GSH is released from astrocytes into the extracellular space; the membrane-bound astrocytic ectoenzyme, gamma-glutamyl transpeptidase (gamma-GT) releases the dipeptide CysGly, which along with glutamine (Gln, also released by astrocytes and taken up by neurons to yield glutamate) provides the precursors for neuronal glutathione synthesis. Neurons are highly dependent on astrocytes for GSH synthesis. (B) Enzymatic reactions for scavenging reactive oxygen species (ROS). The toxic superoxide anion ( $O_2^{\cdot -}$ ) formed by a variety of physiological reactions, including respiratory chain and oxidase-mediated reactions (e.g., xanthine and monoamine oxidases), is scavenged by superoxide dismutase (SOD), which converts the superoxide anion into hydrogen peroxide ( $H_2O_2$ ) and molecular oxygen. Glutathione peroxidase (GPx) converts the still toxic hydrogen peroxide into water; reduced glutathione (GSH) is required for this reaction, in which it is converted into its oxidized form (GSSG). GSH is regenerated through the action of glutathione reductase (GR), a reaction requiring NADPH.

caution; they nevertheless provide a valuable framework for further experimental studies on brain's energy budget. The energy budget of an average glutamatergic pyramidal neuron firing at 4Hz was estimated, with the assumption that >80% of cortical neurons are pyramidal cells and that >90% of the synapses release glutamate. First, the cost of the recycling of released glutamate via reuptake and metabolism in astrocytes and the restoration of the postsynaptic ion gradient has been estimated. Glutamate recycling requires 2.67 ATP/glutamate molecule; since one vesicle contains  $4 \times 10^3$  molecules of glutamate, the cost of transmitter recycling is  $\sim 1.1 \times 10^4$  ATP/vesicle. The restoration of postsynaptic ionic gradients disrupted by the activity of NMDA and non-NMDA receptors is  $\sim 1.4 \times 10^5$  ATP/vesicle, giving a total of  $1.51 \times 10^5$  ATP/vesicle. By estimating the total number of synapses formed by a single pyramidal neuron at  $8 \times 10^3$  and a firing rate of 4Hz (implying a 1:4 chance that an active potential releases one vesicle), the figure of  $3.2 \times 10^8$  ATP/action potential/neuron is obtained.

Contrary to previous estimates based on the measurement of heat production in peripheral *unmyelinated* nerves, the cost of action potential propagation is rather elevated. Thus by considering that an action potential actively depolarizes the cell body and axons by 100mV and passively the dendrites by 50mV, the calculation yields a value of  $3.8 \times 10^8$  ATP/neuron. This calculation is based on the estimate of the minimal  $\text{Na}^+$  influx required to depolarize the cell (Attwell and Laughlin, 2001). If calculations also include  $\text{Ca}^{2+}$ -mediated depolarization of dendrites, the cost is increased by 7%. Remember that these energetic costs are due to the activation of ATPases needed to restore ion gradients. Thus, the overall cost of synaptic transmission plus action potential propagation for a pyramidal neuron firing at 4Hz would be  $2.8 \times 10^9$  ATP/neuron/s. The basal energy consumption for maintenance of the resting potential based on the estimates of input resistance, reversal potential, and membrane conductance yields values of  $3.4 \times 10^8$  ATP/cell/s for neurons and  $1 \times 10^8$  ATP/cell/s for glia, thus a combined consumption of  $3.4 \times 10^9$  ATP/cell/s assuming a 1:1 ratio between neurons and glia. On the basis of this calculation, one can conclude that approximately 87% of total energy consumed reflects the activity of glutamate-mediated neurotransmission and 13% reflects the energy requirements of resting potential maintenance (Fig. 13.7). This value is in remarkable agreement with estimates made *in vivo* using MRS. If the total energy consumption per neuron and the associated glia is compounded per gram of tissue per minute (the conventional form for expressing glucose utilisation), the figure obtained is  $30 \mu\text{M}$  ATP/g/min,

FIGURE 13.7 Energy budget for the rodent central cortex (Attwell and Laughlin, 2001). Relative rates of ATP consumption by resting neurons and glia (modified from Frackowiak *et al.*, 2001).

a value that is very close to that determined *in vivo* for brain glucose utilization—that is, 30 to  $50 \mu\text{M}$  ATP/g/min (Sokoloff, 1981).

In addition to the maintenance of ionic gradients that are disrupted during activity, other energy-consuming processes exist in neurons. Thus, the permanent synthesis of molecules needed for communications, such as neurotransmitters, or for general cellular purposes consumes energy. Axonal transport of molecules synthesized in the nucleus to their final destination along the axon or at the axon terminal is yet another process fueled by cellular energy metabolism.

## Summary

Exactly as in other tissues, the metabolism of glucose, the main energy substrate of the brain, produces two forms of energy: ATP and NADPH. Glycolysis and the TCA cycle produce ATP, whereas energy in the form of reducing equivalents stored in the NADPH molecule is produced predominantly through the pentose phosphate pathway. Reduced glutathione provides a major defense against oxidative stress. Maintenance of the electrochemical gradients, particularly for  $\text{Na}^+$  and  $\text{K}^+$ , needed for electrical signaling via the action potential and for chemical signaling through synaptic transmission is the main energy-consuming process of neural cells.

## BRAIN ENERGY METABOLISM AT THE CELLULAR LEVEL

### Glia and Vascular Endothelial Cells, in Addition to Neurons, Contribute to Brain Energy Metabolism

Neurons exist in a variety of sizes and shapes and express a large spectrum of firing properties (Chapter 6). These differences are likely to imply specific energy demands; for example, large pyramidal cells in the primary motor cortex, which must maintain energy-consuming processes such as ion pumping over a large membrane surface or axonal transport along several centimeters, have considerably larger energy requirements than local interneurons. However, it is now clear that other cell types of the nervous system—glia and vascular endothelial cells—not only consume energy but also play a crucial role in the flux of energy substrates to neurons. Arguments for such an active role for nonneuronal cells—in particular, glia—are both quantitative and qualitative. Glial cells make up approximately half the brain volume. A conservative figure is a 1:1 ratio between the number of astrocytes, one of the predominant glial cell types (see Chapters 1 and 2), and neurons. Higher ratios have been described, depending on the regions, developmental ages, or species. Indeed, the astrocyte-to-neuron ratio increases with the size of the brain and is thus high in humans. It is therefore clear that glucose reaching the brain parenchyma provides energy substrates to a variety of cell types, only some of which are neurons.

Even more compelling for the realization of the key role that astrocytes play in providing energy substrates to active neurons are the cytological relations that exist among brain capillaries, astrocytes, and neurons. These relations, which are illustrated in Figure 13.8, are as follows. First, through specialized processes, called end feet, astrocytes surround brain capillaries (Kacem *et al.*, 1998). This implies that astrocytes form the first cellular barrier that glucose entering the brain parenchyma encounters and make them a likely site of prevalent glucose uptake and energy substrate distribution. More than a century ago, the Italian histologist Camillo Golgi and his pupil Luigi Sala sketched such a principle. In addition to perivascular end feet, astrocytes bear processes that ensheath the synaptic contacts. Astrocytes also express receptors and uptake sites with which neurotransmitters released during synaptic activity can interact (Chapters 6 and 7). These features endow astrocytes with an exquisite sensitivity to detect increases in synaptic activity. In summary, because of the foregoing structural and functional characteristics, astrocytes are ideally suited to couple local changes in

**FIGURE 13.8** Schematic representation of cytological relations existing among intraparenchymal capillaries, astrocytes, and the neuropil. Astrocyte processes surround capillaries (end feet) and ensheath the synapses; in addition, receptors and uptake sites for neurotransmitters are present on astrocytes. These features make astrocytes ideally suited to sense synaptic activity (A) and to couple it with uptake and metabolism of energy substrates originating from the circulation (B).

neuronal activity with coordinated adaptations in energy metabolism (Fig. 13.8).

### A Tightly Regulated Glucose Metabolism Occurs in All Cell Types of the Brain, Neuronal and Nonneuronal

Given the high degree of cellular heterogeneity of the brain, understanding the relative role played by each cell type in the flux of energy substrates has depended largely on the availability of purified preparations, such as primary cultures enriched in neurons, astrocytes, or vascular endothelial cells. Such preparations have some drawbacks because they may not nec-

essarily express all the properties of the cells *in situ*. In addition, one of the parameters of energy metabolism *in vivo*—namely, blood flow—cannot be examined in cultures. Despite these limitations, *in vitro* studies in primary cultures have proved very useful in identifying the cellular sites of glucose uptake and its subsequent metabolic fate, particularly, glycolysis and oxidative phosphorylation, thus providing illuminating correlations of two parameters of brain energy metabolism that are monitored *in vivo*: (1) glucose utilization and (2) oxygen consumption.

## Glucose Transporters in the Brain

Glucose is a highly hydrophilic molecule that enters cells through a facilitated transport mediated by specific transporters. Twelve genes, encoding glucose transporter proteins, have been identified and cloned so far; these are designated GLUT1 to GLUT12 (Uldry and Thorens, 2004). Glucose transporters belong to a family of rather homologous glycosylated membrane proteins with 12 transmembrane-spanning domains, and both amino and carboxyl terminals are exposed to the cytoplasmic surface of the membrane. In the brain, seven transporters are expressed predominantly in a cell-specific manner, GLUT1 (two isoforms), GLUT2 through GLUT5, and GLUT8 (McEwen and Reagan, 2004).

Two isoforms of GLUT1 with molecular masses of 55 and 45 kDa, respectively, are detected in the brain, depending on their degree of glycosylation. The 55-kDa form of GLUT1 essentially is localized in brain microvessels, choroid plexus, and ependymal cells. In microvessels, the distribution of GLUT1 is asymmetric, with a higher density on the abluminal (parenchymal) side than on the vascular side. An intracellular pool of GLUT1 also has been identified in vascular endothelial cells. In the brain *in situ*, the 45-kDa form of GLUT1 is localized predominantly in astrocytes. Under culture conditions, all neural cells, including neurons and other glial cells, express GLUT1; however, this phenomenon appears to be due to the capacity of GLUT1 to be induced by cellular stress.

The glucose transporter specific to neurons is GLUT3. Its cellular distribution appears to predominate in the neuropil. This distribution contrasts with that of GLUT 4 and 8, which appears to predominate on the cell body and proximal dendrites.

GLUT5 is localized to microglial cells, the resident macrophages of the brain, taking part in the immune and inflammatory responses of the nervous system. In peripheral tissues, particularly in the small intestine (from which it was cloned), GLUT5 functions as a transporter for fructose, whose concentrations are

very low in the brain. In the nervous system, therefore, GLUT5 may have diverse transport functions.

Another glucose transporter, GLUT2, has been localized selectively in astrocytes of discrete brain areas, such as certain hypothalamic and brain stem nuclei, which participate in the regulation of feeding behavior and in the central control of insulin release.

It is clear that glucose uptake into the brain parenchyma is a highly specified process regulated in a cell-specific manner by glucose transporter subtypes. Figure 13.9 summarizes this process: Glucose enters the brain through 55-kDa GLUT1 transporters localized on endothelial cells of the blood–brain barrier. Uptake into astrocytes is mediated by 45-kDa GLUT1 transporters, whereas GLUT3 transporters mediate this process in neurons. GLUT2 transporters on astrocytes may “sense” glucose, a function of this glucose transporter subtype in pancreatic  $\beta$  cells. Finally, GLUT5 mediates the uptake of an unidentified substrate into microglial cells. Other glucose transporters identified in the brain with cellular and regional distributions not yet clearly defined are GLUT 6 and 10 (McEwen and Reagan, 2004).

## Cell-Specific Glucose Uptake and Metabolism

As we have seen, glucose utilization can be assessed with radioactively labeled 2-DG. To determine the cellular site of basal and activity-related glucose utilization, this technique has been applied to homogeneous cultures of astrocytes or neurons. For quantitative purposes and to allow comparisons with *in vivo* studies, these *in vitro* experiments, in which radioactive 2-DG is used as a tracer, must be conducted in a medium containing a concentration of glucose near that measured *in vivo* in the extracellular space of the brain (0.5 to 2 mM). The basal rate of glucose utilization is higher in astrocytes than in neurons, with values of about 20 and 6 nmol per milligram of protein per minute, respectively (Magistretti and Pellerin, 1999). These values are of the same order as those determined *in vivo* for cortical gray matter (10–20 nmol mg<sup>-1</sup> min<sup>-1</sup>) with the 2-DG autoradiographic technique. In view of this difference and of the quantitative preponderance of astrocytes compared with neurons in the gray matter, these data reveal a significant contribution by astrocytes to basal glucose utilization as determined by 2-DG autoradiography or PET *in vivo*. Recent high-resolution microautoradiographic imaging *ex vivo* has indicated an approximately even distribution of 2-DG in neurons and astrocytes (Nehlig *et al.*, 2004).

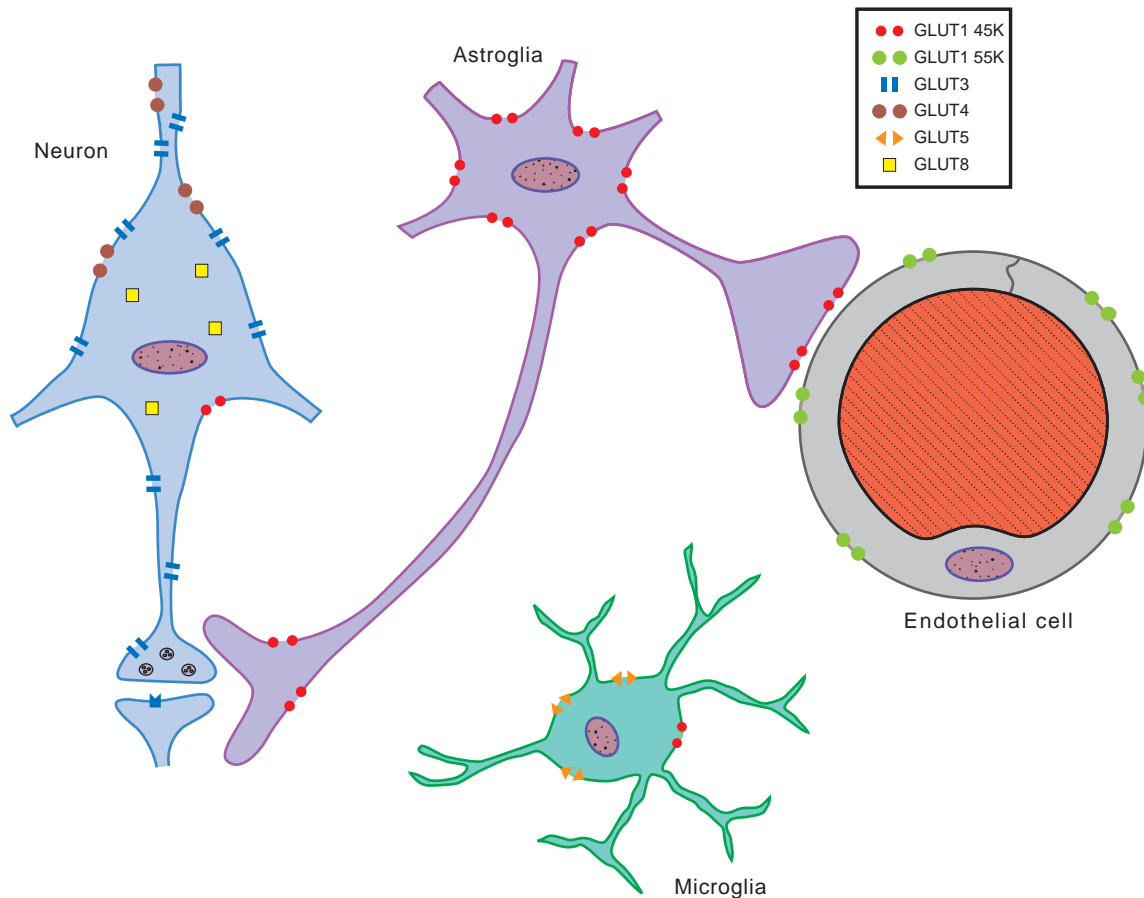

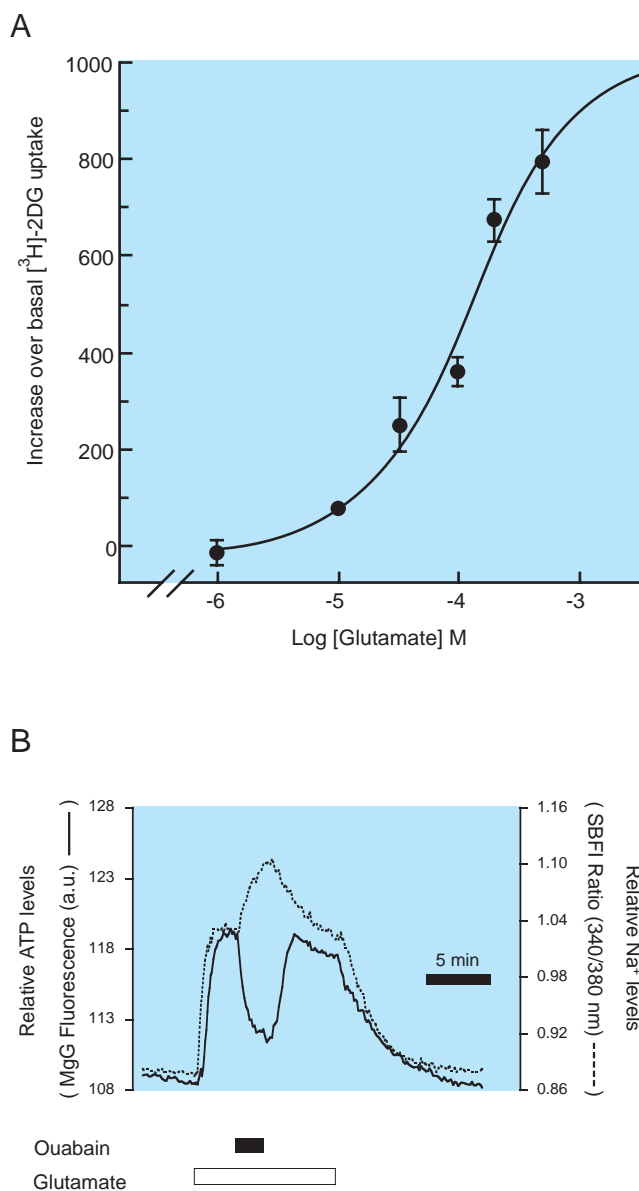

FIGURE 13.9 Cellular distribution of the principle glucose transporters in the nervous system.

The contribution of astrocytes to glucose utilization during activation appears to be even more striking. *In vitro*, activation can be mimicked by exposure of the cells to glutamate, the principal excitatory neurotransmitter (Chapter 7), because, during activation of a given cortical area, the concentration of glutamate in the extracellular space increases considerably due to its release from the axon terminals of activated pathways. As shown in Figure 13.10A, L-glutamate stimulates 2-DG uptake and phosphorylation by astrocytes in a concentration-dependent manner, with an  $EC_{50}$  of 60 to 80 mM (Pellerin and Magistretti, 1994; Takahashi *et al.*, 1995). Unlike other actions of glutamate, stimulation of glucose utilization in astrocytes is mediated not by specific glutamate receptors, but by glutamate transporters. Indeed, in addition to the maintenance of extracellular  $K^+$  homeostasis, one of the well-established functions of astrocytes is to ensure the reuptake of certain neurotransmitters, particularly, that of glutamate at excitatory synapses. Five glutamate transporter subtypes have been cloned in various species,

including humans (Beart and O'Shea, 2007). The EAAT-1 and EAAT-2 subtypes are localized exclusively in astrocytes, whereas the EAAT 3 and 4 are localized predominantly in neurons, with a widespread distribution for EAAT 3 and a localized distribution to Purkinje neurons for EAAT 4. EAAT 5 is localized in rod photoreceptors and in bipolar cells of the retina. The density of EAAT 1 and 2 is particularly high on astrocytes that surround nerve terminals and dendritic spines, consistent with the prominent role of these transporters in the reuptake of synaptically released glutamate. The driving force for glutamate uptake through the specific transporters is the transmembrane  $Na^+$  gradient; indeed, glutamate is cotransported with  $Na^+$  in a ratio of one glutamate for every two or three  $Na^+$  ions. The selective loss of EAAT 2, the astrocyte-selective glutamate transporter, has been demonstrated in the motor cortex and spinal cord of patients who died of amyotrophic lateral sclerosis, a neurodegenerative disease affecting motor neurons.

**FIGURE 13.10** (A) Stimulation by glutamate of glucose uptake and phosphorylation in astrocytes. This effect is concentration-dependent with an  $EC_{50}$  of  $\sim 60$   $\mu$ M. This process is dependent on sodium signaling associated with glutamate uptake and is energy consuming as the increase in sodium activates the sodium-potassium ATPase (see also Fig. 13.11). (B) Temporal coincidence in the increase in sodium concentration and ATP consumption triggered by glutamate in astrocytes. These processes, which are dependent on the activity of the sodium-potassium ATPase as they are ouabain-sensitive, are the effectors of the glutamate-stimulated glycolysis in astrocytes (see also Fig. 13.11). Modified from Magistretti and Chatton (2005).

### Glutamate-Stimulated Uptake of Glucose by Astrocytes Is a Source of Insight into the Cellular Bases of $^{18}\text{F}$ -2-DG PET *in Vivo*

The glutamate-stimulated uptake of glucose by astrocytes is a source of insight into the cellular bases of the activation-induced local increase in glucose utilization visualized with  $^{18}\text{F}$ -2-DG PET *in vivo*. As we have seen, focal physiological activation of specific brain areas is accompanied by increases in glucose utilization; because glutamate is released from excitatory synapses when neuronal pathways subserving specific modalities are activated, the stimulation by glutamate of glucose utilization in astrocytes provides a direct mechanism for coupling neuronal activity to glucose utilization in the brain (Fig. 13.11). The intracellular molecular mechanism of this coupling requires  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase because ouabain completely inhibits the glutamate-evoked 2-DG uptake by astrocytes (Pellerin and Magistretti, 1994). The astrocytic  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase responds predominantly to increases in intracellular  $\text{Na}^+$  ( $\text{Na}_i^+$ ) for which it shows a  $K_m$  of about 10 mM. In astrocytes, the  $\text{Na}_i^+$  concentration ranges between 10 and 20 mM, and so  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase is set to be activated readily when  $\text{Na}_i^+$  rises concomitantly with glutamate uptake (Magistretti and Chatton, 2005) (Figure 13.10B). These observations indicate that a major determinant of glucose utilization is the activity of  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase.

In this context, we should note that, *in vivo*, the main mechanism that accounts for activation-induced 2-DG uptake is the activity of  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase. It is important here to briefly consider the relative participation of the neuronal and astrocytic  $\text{Na}^+$ ,  $\text{K}^+$ -ATPases in glucose utilization. When glutamate is released from depolarized neuronal terminals, it is taken up predominantly into astrocytes. The stoichiometry of glutamate reuptake being one molecule of glutamate cotransported with three  $\text{Na}^+$  ions, the increase in intracellular astrocytic  $\text{Na}^+$  concentration associated with glutamate reuptake massively activates the pump. Thus, although the tonic activity of the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase is needed to maintain the transmembrane neuronal and glial ionic gradients and accounts for basal glucose utilization, on a short-term temporal scale (from milliseconds to seconds), when glutamate is released from depolarized axon terminals of modality-specific afferents, the astrocytic  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase is briskly activated, due to the massive increase (by at least 10  $\mu$ M) in intracellular  $\text{Na}^+$  associated with glutamate reuptake, providing the signal for the activation-dependent glucose utilization. Increases of glutamate as small as 10  $\mu$ M are sufficient to double the activity of  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase.

**FIGURE 13.11** Schematic representation of the mechanism for glutamate-induced glycolysis in astrocytes during physiological activation. At glutamatergic synapses, presynaptically released glutamate depolarizes postsynaptic neurons by acting at specific receptor subtypes. The action of glutamate is terminated by an efficient glutamate uptake system located primarily in astrocytes. Glutamate is cotransported with  $\text{Na}^+$ , resulting in an increase in the intraastrocytic concentration of  $\text{Na}^+$ , leading to an activation of the astrocyte  $\text{Na}^+, \text{K}^+$ -ATPase. Activation of  $\text{Na}^+, \text{K}^+$ -ATPase stimulates glycolysis (i.e., glucose utilization and lactate production). The stoichiometry of this process is such that for one glutamate molecule taken up with three  $\text{Na}^+$  ions, one glucose molecule enters astrocytes, two ATP molecules are produced through glycolysis, and two lactate molecules are released. Within the astrocyte, one ATP fuels one “turn of the pump,” and the other provides the energy needed to convert glutamate to glutamine by glutamine synthase (Fig. 13.13). Once released by astrocytes, lactate can be taken up by neurons and serve as an energy substrate. (For graphic clarity only lactate uptake into presynaptic terminals is indicated. However, this process could also take place at the postsynaptic neuron.) This model, which summarizes *in vitro* experimental evidence indicating glutamate-induced glycolysis, is taken to show cellular and molecular events occurring during activation of a given cortical area (arrow labeled A, activation). Direct glucose uptake into neurons under basal conditions is also shown (arrow labeled B, basal conditions). Pyr, pyruvate; Lac, lactate; Gln, glutamine; G, G protein. Modified from Pellerin and Magistretti (1994).

How does activation of  $\text{Na}^+, \text{K}^+$ -ATPase cause increased glucose utilization? The mechanism was explained by pioneering studies on erythrocytes by Joseph Hoffmann and colleagues at Yale University, which have been confirmed in a number of other cell systems, including brain and vascular smooth muscle. The increase in pump activity consumes ATP (Fig. 13.10B), which is a negative modulator of phosphofructo-kinase, the principal rate-limiting enzyme of glycolysis (Fig. 13.1). Thus, when ATP concentration is low, phosphofructokinase activity is stimulated, resulting in increased glucose utilization. The activity of hexokinase, the enzyme responsible for glucose and 2-DG phosphorylation (Fig. 13.4), is also increased

under these conditions. This explains why the increase in glucose utilization, associated with the stimulation of  $\text{Na}^+, \text{K}^+$ -ATPase, can be monitored with 2-DG, which is not processed beyond the hexokinase step.

A compartmentalization of glucose uptake during activation also has been unequivocally found by Marco Tsacopoulos and colleagues in the honeybee drone retina (Tsacopoulos *et al.*, 1988). In this highly organized, crystal-like nervous tissue preparation, photoreceptor cells form rosette-like structures that are surrounded by glial cells. In addition, mitochondria are exclusively present in the photoreceptor neurons. Light activation reveals an increase in radioactive 2-DG uptake in the glial cells surrounding the

rosettes but not in the photoreceptor neurons. An increase in  $O_2$  consumption nevertheless is measured in photoreceptor neurons. After activation of photoreceptors by light, glucose probably is taken up predominantly by glial cells, which then release a metabolic substrate to be oxidized by photoreceptor neurons.

In summary, as indicated in the operational model described in Figure 13.11, upon activation of a particular brain area, glutamate released from excitatory terminals is taken up by a  $Na^+$ -dependent transporter located on astrocytes. The ensuing local increase in intracellular  $Na^+$  concentration activates  $Na^+$ ,  $K^+$ -ATPase, which in turn stimulates glucose uptake by astrocytes. The key role of glial glutamate transporters in activity-dependent glucose uptake by the brain has been demonstrated *in vivo* (Cholet *et al.*, 2001). This model delineates a simple mechanism for coupling synaptic activity to glucose utilization; in addition, it is consistent with the notion that the signals detected during physiological activation in humans with  $^{18}F$ -2-DG PET and autoradiography in laboratory animals may predominantly reflect uptake of the tracer into astrocytes. This conclusion does not question the validity of the 2-DG-based techniques; rather, it provides a cellular and molecular basis for these functional brain-imaging techniques (Magistretti *et al.*, 1999).

### Lactate Released by Astrocytes May Be a Metabolic Substrate for Neurons

The fact that the increase in glucose uptake during activation can be ascribed predominantly, if not exclusively, to astrocytes indicates that energy substrates must be released by astrocytes to meet the energy demands of neurons. As indicated earlier, lactate and pyruvate are adequate substrates for brain tissue *in vitro* (Schurr 2006). In fact, synaptic activity can be maintained *in vitro* in cerebral cortical slices with only lactate or pyruvate as a substrate. Lactate is quantitatively the main metabolic intermediate released by cultured astrocytes at a rate of 15 to 30 nmol per milligram of protein per minute. Other quantitatively less important intermediates released by astrocytes are pyruvate (approximately 10 times less than lactate) and  $\alpha$ -ketoglutarate, citrate, and malate, which are released in marginal amounts. For lactate (or pyruvate) to be a metabolic substrate for neurons, particularly during activation, two additional conditions must be fulfilled: (1) that indeed during activation lactate release by astrocytes increases and (2) lactate uptake by neurons must be demonstrated. Both mechanisms have been demonstrated. Mimicking activation *in vitro* by exposing cultured astrocytes to glutamate results in a marked release of lactate and, to a lesser degree,

pyruvate (Pellerin and Magistretti, 1994). This glutamate-evoked lactate release shows the same pharmacology and time course as glutamate-evoked glucose utilization and indicates that glutamate stimulates the processing of glucose through glycolysis. *In vivo*  $^1H$  MRI studies in humans that show a transient lactate peak in the primary visual cortex during physiological stimulation (Prichard *et al.*, 1991) are consistent with the notion of activation-induced glycolysis. In addition, lactate levels in the rat hippocampus transiently increase upon stimulation (Hu and Wilson 1997). Finally, monocarboxylate transporters have been demonstrated on neurons and astrocytes in addition to capillaries (Pierre and Pellerin, 2005).

Thus, a metabolic compartmentation whereby glucose taken up by astrocytes and metabolized glycolytically to lactate is then released in the extracellular space to be utilized by neurons is consistent with biochemical and electrophysiological observations (Tsacopoulos and Magistretti, 1996; Magistretti 2006; Hyder *et al.*, 2006). This array of *in vitro* and *in vivo* experimental evidence is summarized in the model of cell-specific metabolic regulation illustrated in Figure 13.11.

Studies of the well-compartmentalized honeybee drone retina and of isolated preparations of guinea pig retina containing photoreceptors attached to Mueller (glial) cells corroborate the existence of such metabolic fluxes between glia and neurons. In addition to the glial localization of glucose uptake during activation, glycolytic products have been shown to be released. In particular, during activation, glial cells in the honeybee drone retina release alanine produced from pyruvate by transamination; the released alanine is taken up by photoreceptor neurons and, after reconversion into pyruvate, can enter the TCA cycle to yield ATP through oxidative phosphorylation (Fig. 13.2). In the guinea pig retina, lactate, formed glycolytically from glucose, is released by Mueller cells to fuel photoreceptor neurons (Tsacopoulos and Magistretti, 1996).

Although plasma lactate, except under particular conditions such as vigorous exercise, contributes only marginally as a metabolic substrate for the brain, lactate formed *within* the brain parenchyma (e.g., through glutamate-activated glycolysis in astrocytes) can fulfill the energetic needs of neurons. Lactate, after conversion into pyruvate by a reaction catalyzed by lactate dehydrogenase (LDH), can provide, on a molar basis, 15–18 ATP through oxidative phosphorylation. Conversion of lactate into pyruvate does not require ATP, and, in this regard, lactate is energetically more favorable than the first obligatory step of glycolysis in which glucose is phosphorylated to glucose 6-phosphate at the expense of one molecule of ATP

(Fig. 13.1). In addition, lactate may contribute to the redox potential of neurons, since through its conversion to pyruvate it generates NADH (Cerdan *et al.*, 2006), hence providing reducing equivalents useful for ROS scavenging (Fig. 13.6). Another metabolic fate for lactate has been shown *in vitro* and *in vivo* by MRS. Thus, once converted to pyruvate in neurons, lactate may enzymatically yield glutamate and hence be a substrate for the replenishment of the neuronal pool of glutamate. Because this reaction is not associated with oxygen consumption, part of the uncoupling between glucose utilization and oxygen consumption described in certain paradigms of activation may be explained by the processing of glucose-derived lactate into the glutamate neuronal pool.

### Glycogen, the Storage Form of Glucose, Is Localized in Astrocytes

Glycogen is the single largest energy reserve of the brain (Magistretti *et al.*, 1993); it is localized mainly in astrocytes, although ependymal and choroid plexus cells, as well as certain large neurons in the brain stem, contain glycogen. When compared to the contents in liver and muscle, the glycogen content of the brain is exceedingly small, about 100 and 10 times inferior, respectively. Thus, the brain can hardly be considered a glycogen storage organ, and here the function of glycogen should be viewed as that of providing a metabolic buffer during physiological activity.

### Glycogen Metabolism Is Coupled to Neuronal Activity

Glycogen turnover in the brain is extremely rapid, and glycogen levels are finely coordinated with synaptic activity (Magistretti *et al.*, 1993). For example, during general anesthesia, a condition in which synaptic activity is markedly attenuated, glycogen levels rise sharply. Interestingly, however, the glycogen content of cultures containing exclusively astrocytes is not increased by general anesthetics; this observation indicates that the *in vivo* action of general anesthetics on astrocyte glycogen is due to the inhibition of neuronal activity, stressing the existence of a tight coupling between synaptic activity and astrocyte glycogen. Accordingly, reactive astrocytes, which develop in areas where neuronal activity is decreased or absent as a consequence of injury, contain high amounts of glycogen.

In addition to glycogen, glucose is incorporated into other macromolecules such as proteins (glycoproteins) and lipids (glycolipids) at rates specific for the turnover of each macromolecule, which can span from a few minutes to a few days.

### Certain Neurotransmitters Regulate Glycogen Metabolism in Astrocytes

Glycogen levels in astrocytes are tightly regulated by various neurotransmitters. Several monoamine neurotransmitters—namely, noradrenaline, serotonin, and histamine—are glycogenolytic in the brain, in addition to certain peptides, such as vasoactive intestinal peptide (VIP) and pituitary adenylylating peptide (PACAP), and adenosine and ATP (Magistretti *et al.*, 1993). The effects of all these neurotransmitters are mediated by their cognate specific receptors coupled to second messenger pathways that are under the control of adenylylating cyclase or phospholipase C. The initial rate of glycogenolysis activated by VIP and noradrenaline is between 5 and 10 nmol per milligram of protein per minute, a value that is remarkably close to glucose utilization of the gray matter, as determined by the 2-DG autoradiographic method. This correlation indicates that glycosyl units mobilized in response to glycogenolytic neurotransmitters can provide quantitatively adequate substrates for the energy demands of the brain parenchyma. At present, whether the glycosyl units mobilized through glycogenolysis are used by astrocytes to meet their energy demands during activation or are metabolized to a substrate such as lactate, which is then released for the use of neurons, is not clear. It appears, however, that glucose is not released by astrocytes after glycogenolysis, supporting the view that the activity of glucose-6-phosphatase (Fig. 13.1) in astrocytes is very low. Lactate may be the metabolic intermediate produced through glycogenolysis and exported from astrocytes (Tekkok *et al.*, 2005).

These observations show that neuronal signals (e.g., certain neurotransmitters) can exert receptor-mediated metabolic effects on astrocytes in a manner similar to peripheral hormones on their target cells. However, the action of this type of neurotransmitter is temporally specified and spatially restricted to activated areas. Indeed, brain glycogenolysis visualized by autoradiography in laboratory animals also has been demonstrated *in vivo* after physiological activation of a modality-specific pathway (Swanson *et al.*, 1992). Repeated stimulation of whiskers resulted in a marked decrease in the density of glycogen-associated autoradiographic grains in the somatosensory cortex of rats (barrel fields), as well as in the relevant thalamic nuclei (Swanson *et al.*, 1992). These observations indicate that the physiological activation of specific neuronal circuits results in the mobilization of glial glycogen stores.

## Summary

Under basal conditions, glucose uptake and metabolism occur in every brain cell type. Glucose uptake is mediated by specific transporters that are distributed in a cell-specific manner. Astrocytes play a critical role in the utilization of glucose coupled to excitatory synaptic transmission. The molecular mechanisms of this coupling are stoichiometrically directed: for each synaptically released glutamate molecule taken up with three  $\text{Na}^+$  ions by an astrocyte, one glucose molecule enters the same astrocyte, two ATP molecules are produced through glycolysis, and two lactate molecules are released and consumed by neurons to yield 15–18 ATPs through oxidative phosphorylation. Neuronal signals (e.g., certain neurotransmitters) can exert receptor-mediated glycogenolysis in astrocytes in a manner similar to peripheral hormones on their target cells. However, this type of effect by neurotransmitters is temporally specified and spatially restricted within activated areas, possibly to provide additional energy substrates in register with local increases in neuronal activity.

## GLUTAMATE AND NITROGEN METABOLISM: A COORDINATED SHUTTLE BETWEEN ASTROCYTES AND NEURONS

As has been shown, synaptically released glutamate is removed rapidly from the extracellular space by a transporter-mediated reuptake system that is particularly efficient in astrocytes (Beart and O'Shea, 2007). This mechanism contributes in a crucial manner to the fidelity of glutamate-mediated neurotransmission. Indeed, glutamate levels in the extracellular space are low ( $<3\ \mu\text{M}$ ), allowing for optimal glutamate-mediated signaling after depolarization while preventing overactivation of glutamate receptors, which eventually could result in excitotoxic neuronal damage.

One may wonder how astrocytes dispose of the glutamate that they take up, because, unlike carbohydrates or lipids, amino acids cannot be stored. The predominant pathway in peripheral tissues for disposing of amino acids is the transfer of their  $\alpha$  amino group to a corresponding  $\alpha$ -keto acid; this reaction is catalyzed by aminotransferases (Fig. 13.12). In astrocytes, the  $\alpha$  amino group of glutamate can be transferred to oxaloacetate to yield  $\alpha$ -ketoglutarate ( $\alpha$ -KG) and aspartate in a reaction catalyzed by aspartate amino transferase (AAT). The  $\alpha$ -KG generated is an intermediate of the TCA cycle and is therefore ox-

FIGURE 13.12 Metabolic fate of glutamate taken up by astrocytes. ALAT, alanine aminotransferase; GDH, glutamate dehydrogenase; GS, glutamine synthase; AAT, aspartate aminotransferase; GPT, glutamate dehydrogenase;  $\alpha$ -KG,  $\alpha$ -ketoglutarate.

dized further. Another transamination reaction catalyzed by alanine amino transferase (ALAT) transfers the  $\alpha$  amino group of glutamate to pyruvate, resulting in the formation of alanine and  $\alpha$ -KG.

Two other pathways exist in astrocytes to metabolize glutamate. First, glutamate can be converted directly into  $\alpha$ -KG through an NAD-requiring oxidative deamination catalyzed by glutamate dehydrogenase (GDH) (Fig. 13.12). Glutamate, by entering the TCA cycle indirectly (through AAT or ALAT) or directly (through GDH), is an energy substrate for astrocytes. Second, the quantitatively predominant metabolic pathway of glutamate in astrocytes is its amidation to glutamine, an ATP-requiring reaction in which an ammonium ion is fixed on glutamate (Fig. 13.12) (Van den Berg and Garfinkel, 1971). This reaction is catalyzed by glutamine synthase (GS), an enzyme almost exclusively localized in astrocytes, and provides an efficient means of disposing not only of glutamate but also of ammonium (Box 13.2). Glutamine is released by astrocytes and is taken up by neurons, where it is hydrolyzed back to glutamate by the phosphate-dependent mitochondrial enzyme glutaminase (Erecinska and Silver, 1990). This metabolic pathway, often referred to as the glutamate-glutamine shuttle, is a clear example of cooperation between astrocytes and neurons (Fig. 13.13). It allows the removal of potentially toxic excess glutamate from the extracellular space, while returning to the neuron a synaptically inert (glutamine does not affect neurotransmission) precursor with which to regenerate the neuronal pool of glutamate.

## BOX 13.1

## HEPATIC ENCEPHALOPATHY IS A DISORDER OF ASTROCYTE FUNCTION RESULTING IN A NEUROPSYCHIATRIC SYNDROME

Hepatic encephalopathy is observed in patients with severe liver failure. The disease can be in one of two forms: an acute form, called fulminant hepatic failure, and a chronic form, portosystemic encephalopathy. The neuropsychiatric symptoms of fulminant hepatic failure are delirium, coma, and seizures associated with acute toxic or viral hepatic failure. Patients having portosystemic encephalopathy may present personality changes, episodic confusion, or stupor and, in the most severe cases, coma. The current view on the pathophysiology of hepatic encephalopathy is that, due to liver failure, "toxic" substances that affect brain function accumulate in the circulation.

One of the substances thought to be responsible for neuropsychiatric "toxicity" is ammonia. The neuropathological findings are rather striking: astrocytes are the brain cells that appear principally affected. In the acute form, astrocyte swelling is prominent and likely to be the cause of the observed acute brain edema. In portosystemic encephalopathy, astrocytes adopt morphological features characteristic of what is defined as an Alzheimer type II astrocyte: in these cells, the nucleus is pale and enlarged, chromatin is marginated, and a prominent

nucleolus often is observed. Lipofuscin deposits may be present, and the amount of the astrocyte-specific protein glial fibrillary acidic protein (Chapter 4) is decreased. Neurons appear structurally normal. All the foregoing histopathological changes have been reproduced *in vitro* by acutely or chronically applying ammonium chloride to primary astrocyte cultures. As mentioned earlier, detoxification of ammonium is an ATP-requiring, astrocyte-specific reaction catalyzed by glutamine synthase (Fig. 13.12). It is therefore not surprising that excess ammonia perturbs energy metabolism; indeed, ammonia stimulates glycolysis whereas it inhibits TCA cycle activity. In addition, ammonia decreases the glycogen content of astrocytes markedly.

In summary, though the precise pathophysiological mechanisms of the neuropsychiatric syndrome in hepatic encephalopathy are still unknown, this clinical condition provides a striking illustration of the fundamental importance of neuron-astrocyte metabolic interactions because structural and functional alterations apparently restricted to astrocytes result in severe behavioral perturbations.

Pierre J. Magistretti

However, not all glutamate is regenerated through the glutamate-glutamine shuttle because some of the glutamate released by neurons enters at the  $\alpha$ -KG level, the TCA cycle in astrocytes; therefore, *de novo* synthesis is required to maintain the neuronal glutamate pool. Glutamate can be synthesized through NADPH-dependent reductive amination of  $\alpha$ -KG catalyzed by GDH (note that here the cofactor is NADPH, whereas, for the opposite reaction also catalyzed by GDH, the oxidant is NAD; see Figs. 13.12 and 13.13) (Erecinska and Silver, 1990). For the synthesis of glutamate, glucose provides the carbon backbone as  $\alpha$ -KG through the TCA cycle, whereas an exogenous source of nitrogen is necessary (Fig. 13.13). Convincing evidence, obtained by using  $^{15}\text{N}$ -labeled amino acids whose metabolic fate was determined by gas chromatography and mass spectrometry, indicates that plasma leucine provides the nitrogen required for net glutamate synthesis from  $\alpha$ -KG. Thus, leucine taken up from the circulation at astrocytic end feet provides the amino group to  $\alpha$ -KG in a reaction catalyzed by leucine transaminase (LT), resulting in the formation of glutamate and  $\alpha$ -ketoisocaproate ( $\alpha$ -KIC) (Fig. 13.13). Because this reaction takes place in astrocytes, to replenish the neuronal glutamate pool, the astrocytes export glutamate as glutamine. As noted earlier, the neuronal glutamate pool could also be replenished by lactate released by astrocytes.

Finally, another potential pathway described by Arne Schousboe and colleagues exists for the *de novo* synthesis of glutamate in neurons from substrates provided by astrocytes. With the use of uniformly labeled  $^{13}\text{C}$  compounds in combination with magnetic resonance spectroscopy, astrocytes have been shown to release significant amounts of alanine and  $\alpha$ -KG. Both metabolic intermediates are taken up by neurons and can be converted into glutamate and pyruvate in a transamination reaction catalyzed by ALAT (Fig. 13.12). In this case, as for the glutamate-glutamine shuttle (Fig. 13.13), astrocytes provide the substrate(s) necessary for glutamate synthesis in neurons.

Note that because  $\alpha$ -KG is used for glutamate synthesis, metabolic intermediates downstream of  $\alpha$ -KG

must be available to maintain a sustained flux through the TCA cycle in astrocytes (Fig. 13.13). This need is met by the activity of the enzyme pyruvate carboxylase (PC), which fixes  $\text{CO}_2$  on pyruvate to generate oxaloacetate, which, by condensing with acetyl-CoA, maintains the flux through the TCA cycle. The carboxylation of pyruvate to oxaloacetate is referred to as an anaplerotic (Greek for "fill up") reaction. Interestingly, like glutamine synthase, PC is selectively localized in astrocytes. The fact that these two enzymes are localized in astrocytes in conjunction with the existence of a glutamate-glutamine shuttle stresses that astrocytes are essential for maintaining the neuronal glutamate pool used for neurotransmission (Fig. 13.13).

As noted earlier, the metabolic intermediate  $\alpha$ -KG lies at the branching point of glucose and glutamate metabolism (Fig. 13.12). Any change in the activities of the enzymes that convert  $\alpha$ -KG into glutamate or into succinyl-CoA, the next intermediate in the TCA cycle, may affect the efficacy of the TCA cycle or glutamate levels. Interestingly, a marked decrease in the activity of  $\alpha$ -ketoglutarate dehydrogenase ( $\alpha$ -KGDH), the enzyme catalyzing the conversion of  $\alpha$ -KG into succinyl-CoA, was found in a very high proportion of postmortem brains from patients with Alzheimer disease; in addition, a similar decrease in  $\alpha$ -KGDH activity has been demonstrated in the fibroblasts of patients affected by the familial form of Alzheimer disease.

## Summary

A key function of astrocytes is to remove synaptically released glutamate. A large proportion of glutamate is transformed to glutamine through an energy-requiring process that also allows for the detoxification of ammonium. Glutamine released by astrocytes regenerates the neuronal glutamate pool. Some of the glutamate also is regenerated from lactate and through fixation of the amino group of leucine onto the TCA intermediate  $\alpha$ -KG, providing another indication of the tight link existing between glutamate

**FIGURE 13.13** Metabolic intermediates are released by astrocytes to regenerate the glutamate neurotransmitter pool in neurons. Glutamine, formed from glutamate in a reaction catalyzed by glutamine synthase (GS), is released by astrocytes and taken up by neurons, which convert it into glutamate under the action of glutaminase. GS is an enzyme selectively localized in astrocytes. This metabolic cycle is referred to as the glutamate-glutamine shuttle. Other quantitatively less important sources of neuronal glutamate are lactate, alanine, and  $\alpha$ -ketoglutarate ( $\alpha$ -KG). In astrocytes, glutamate is synthesized *de novo* from  $\alpha$ -KG in a reaction catalyzed by glutamate dehydrogenase (GDH). The carbon backbone of glutamate is exported by astrocytes after conversion into glutamine under the action of GS; the conversion of leucine into  $\alpha$ -ketoisocaproate ( $\alpha$ -KIC), catalyzed by leucine transaminase (LT), provides the amino group for the synthesis of glutamine from glutamate. Carbons "lost" from the TCA cycle as  $\alpha$ -KG is converted into glutamate are replenished by oxaloacetate (OxA) formed from pyruvate in a reaction catalyzed by pyruvate carboxylase, another astrocyte-specific enzyme.

and nitrogen metabolism and of the crucial function that astrocytes play in maintaining the neuronal glutamate pool at levels that ensure the maintenance of synaptic transmission.

### THE ASTROCYTE-NEURON METABOLIC UNIT

From a strictly energetic viewpoint, the brain can be seen as an almost exclusive glucose-processing machine producing  $H_2O$  and  $CO_2$ . However, the metabolism of glucose in the brain is specified temporally, spatially, and functionally. Thus, glucose metabolism increases with exquisite spatiotemporal precision in register with neuronal activity. The site of this increase is not the neuronal cell body; rather, it is the neuropil, where presynaptic terminals, postsynaptic elements, and astrocytes ensheathing synaptic contacts are localized (Sokoloff, 1981). This cytological relation between astrocytes and neurons also is manifested by a functional metabolic partnership: in response to a neuronal signal (glutamate), astrocytes release a glucose-derived metabolic substrate for neurons (lactate). Glucose also provides the carbon backbone for regeneration of the neuronal pool of glutamate. This process results from a close astrocyte-neuron cooperation. Indeed, the selective localization of pyruvate carboxylase in astrocytes, indicating the need to replenish the TCA cycle with carbon backbones, strongly suggests that glucose-derived metabolic intermediates are used for glutamate (and other amino acid) synthesis. The newly synthesized glutamate is not provided as such by astrocytes to neurons; rather, it is converted into glutamine by glutamine synthase, another enzyme localized selectively in astrocytes. Glutamate, taken up by astrocytes during synaptic activity, undergoes the same metabolic process, also being released as glutamine (the glutamate-glutamine shuttle).

#### Summary

In conclusion, the axon terminal of glutamatergic neurons, which are the main communication lines in the nervous system, and the astrocytic processes that surround them should be viewed as a metabolic unit in which the neuron furnishes the activation signal (glutamate) to the astrocyte and the astrocyte provides not only the precursors needed to maintain the neurotransmitter pool (glutamine and, in part, lactate and alanine), but also the energy substrate (lactate) (Fig. 13.14). The efficacy of the predominant excitatory synapse in the brain, the glutamatergic synapse, cannot

**FIGURE 13.14** The astrocyte-neuron metabolic unit. Glutamatergic terminals and the astrocytic processes that surround them can be viewed as a highly specialized metabolic unit in which the activation signal (glutamate) is furnished by the neuron to the astrocyte, whereas the astrocyte provides the precursors needed to maintain the neurotransmitter pool (glutamine, lactate, alanine), as well as the energy substrate (lactate). AP, astrocyte process.

be maintained without a close astrocyte-neuron interaction.

# Neural Induction and Pattern Formation

This chapter covers some of the key events that take place in the early stages of development of the vertebrate nervous system, a period during which structures such as the neural tube, placodes, and neural crest are formed, setting in place the foundations on which a functioning nervous system is subsequently built. The first part of the chapter describes how these embryonic structures first are specified by inductive tissue interactions and how they form by the process of morphogenesis. The second part of the chapter describes the extensive early developmental events required for regionalizing the nervous system along its different axes. Regionalization requires the complex processes of neural patterning that endow neural precursor cells with the ability to give rise to correct types of neuron in appropriate locations in the adult nervous system. These processes are gradual, continuous, and begin when neural tissue first forms. We describe some of the processes underlying neural patterning, beginning with how polarity along each of the neuraxes is first established, and progressing to more fine levels of regional organization.

## NEURAL INDUCTION

### Embryonic Origins of the Nervous System

The progenitor cells that form the vertebrate nervous system can be traced back in development to an epithelial cell layer, called the ectoderm, that covers the outside of the embryo during gastrulation (Fig. 14.1). Ectodermal cells give rise to different tissue derivatives depending on axial position. The dorsal-most ectoderm thickens to form the *neural plate*, a structure in the shape of a key-hole with the broad end located

anteriorly. During a complex morphogenetic process called *neurulation*, cells in the neural plate give rise to the neural tube and, subsequently, the central nervous system (CNS). Ectodermal cells lying more ventrally at the edges of the neural plate, the neural folds, come to lie at the dorsal surface of the neural tube during neurulation, form the *neural crest* and emigrate, subsequently giving rise to most of the peripheral nervous system. The ectodermal cells lying even more ventral around the edge of the cranial neural plate constitute a domain where various sensory structures such as the ear, nose, and cranial sensory ganglia will arise from isolated ectodermal areas called placodes. Finally, ectodermal cells on the extreme ventral side of the embryo give rise to the skin or epidermis. The first step in forming the nervous system, therefore, is to establish these different regions of ectoderm along the dorsoventral (DV) axis of the embryo soon after gastrulation is complete. The key mechanism that establishes these different subregions of ectoderm involves inductive interactions that were discovered in the early part of the last century. More recently, the molecules that underlie embryonic induction have been defined and their action understood.

### Neural Induction and the Organizer

In the 1930's, Mangold and Spemann discovered neural induction during experiments in which they transplanted small pieces of tissues from one amphibian embryo to another at pregastrulae stages. The key observation was made when they transplanted a small piece of tissue from a region called the dorsal blastopore lip (DBL), and the host embryo responded to the grafted tissue by forming a complete secondary dorsal axis (Fig. 14.2). Importantly, most of the tissues

**FIGURE 14.1** Ectoderm is subdivided into different fates during gastrulation. Shown is a cross-sectional side view, and top view of an amphibian embryo before (blastula-stage) and after gastrulation (neural plate-stage). During gastrulation, the grey and green (dorsal mesoderm) regions of the blastula involute inward, and the ectoderm (blue/red) at the top spreads over the outside of the embryo, and extends along anterior-posterior axis. As this process occurs, signals emanating from the dorsal and ventral sides of the embryo specify different fates, so that dorsal ectoderm (red) becomes neural tissue while ventral ectoderm (blue) becomes epidermis.

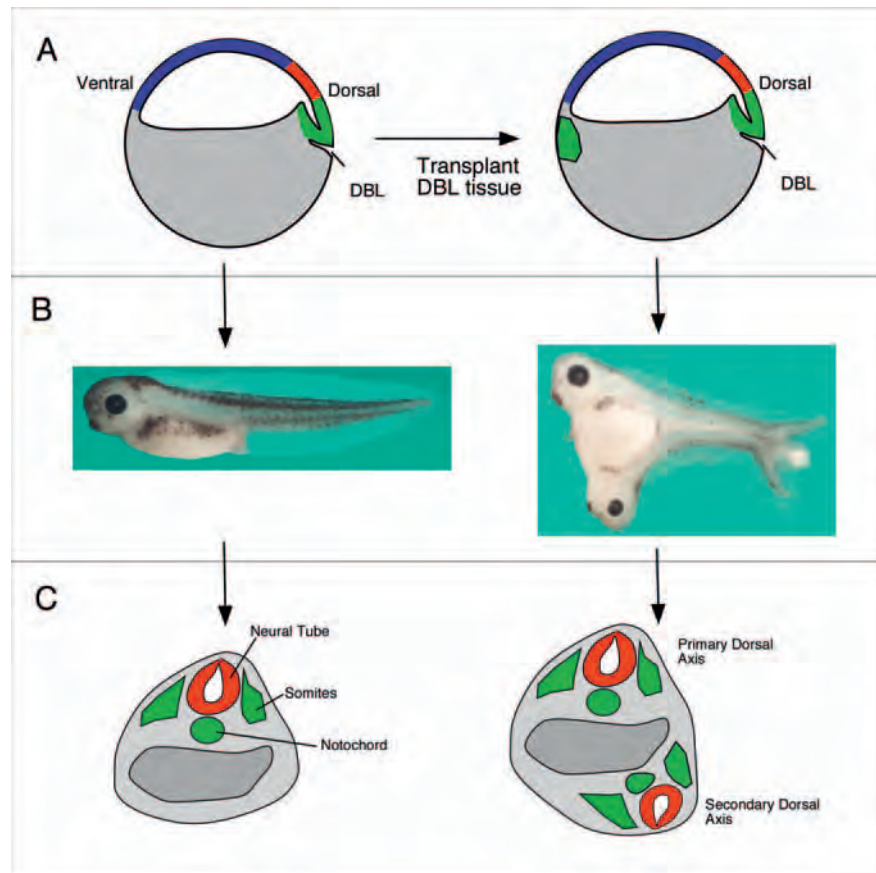

in the secondary dorsal axes were not derived from the transplanted tissue but rather from the tissue in the host embryo. In particular, the secondary dorsal axis contained a complete nervous system that was derived entirely from the ventral ectoderm of the host embryo, a tissue that would have differentiated into skin in the absence of a graft. The implication of this observation was that the transplanted tissue can act as a source of inducing signals that can cause ventral ectoderm to form neural tissue, and that this inductive interaction normally occurs on the dorsal side of the embryo. Tissue in the DBL was later termed the organizer because of its ability, when transplanted, to reprogram the ventral side of the embryo to form dorsal tissues, not only in the ectoderm but also in the internal mesodermal tissues. Following Mangold and Spemann's lead, it was subsequently found all vertebrate embryos appear to contain a region, called *Spemann's organizer*, which can induce ectoderm to form neural tissue.

Organizer transplantation experiments also gave the first indication that signals produced by Spemann's organizer were responsible for inducing different regions of the CNS. In these experiments, smaller regions of the DBL were used, and taken from embryos

at different stages. The DBL of **younger** embryos contains the first involuting tissue and, when transplanted, induces head structures that contained neural tissue from the anterior portions of the neuraxis. Conversely, the DBL from **older** embryos involutes later and, when transplanted, induces tail structures that contained neural tissue from just the posterior portions of the neuraxis. The organizer, therefore, can be subdivided into two parts, a head and trunk/tail organizer, which specify different regions of the CNS along the AP axis. The role of the organizer tissue in the regionalization of the CNS is discussed further in a later section.

### The Molecular Nature of Neural Inducers

The molecular nature of the inducers produced by organizer tissue remained elusive until the 1990's, when key biochemical pathways that mediate cell-cell signaling in animal development were identified using the tools of molecular genetics. One such pathway is a subfamily of TGF $\beta$ -like factors, called the bone morphogenetic proteins (BMPs), which has proven to be remarkably conserved in action across the animal kingdom, from flies to humans (Bier, 1997). The core components of this pathway are the BMP

**FIGURE 14.2** Organizer transplant experiment of Mangold and Spemann. (A) Tissue around the DBL was removed from one embryo and placed into the ventral side of another. (B) The transplanted DBL, if large enough, will cause a complete second dorsal axis to form on the host embryo, resulting in twinning. (C) Cross-section through the tadpoles shows that the second dorsal axis contains a complete nervous system. Importantly, by using tracers, one can show that the nervous system in this new dorsal axis is not derived from the transplanted tissue, but rather from host tissue, fated to give rise to ventral tissues in the absence of a graft.

ligands, secreted extracellular proteins that bind and activate a small family of heterodimeric cell surface receptors, which in turn transduce a signal by intracellular phosphorylation events that ultimately lead to changes in the activities of transcription factors, the SMAD proteins (Fig. 14.3). Importantly, the core activity of this signaling pathway is subjected to complex layers of regulation, both positive and negative (Fig. 14.3). This complex regulation is required to induce neural tissue by creating a gradient of BMP signaling activity across the DV axis of the ectoderm, although for a purpose not envisioned by the early embryologists (Weinstein and Hemmati-Brivanlou, 1999).

### The Default Model

The current view of neural induction, the default model, stems from experiments using the amphibian *Xenopus laevis*, mainly because of an assay where

the ectoderm can be explanted into culture before gastrulation into a simple salt solution. Ectoderm isolated before gastrulation differentiates into ventral epidermal tissue in culture. However, if BMP signaling is inhibited experimentally in these ectodermal explants, epidermal differentiation is suppressed, and neural tissue forms instead, presumably as a default pathway. The converse result can also be obtained using the fact that when isolated ectodermal cells are dissociated into single cells, they form nerve cells. However, if BMP4 is added to these cells, they revert back to epidermis. These early experiments were instrumental in showing that BMPs are potent epidermalizing agents and that blocking BMP signaling was sufficient to induce the ectoderm to form neural tissue as a default pathway. The ventral ectoderm of *Xenopus* and other vertebrate embryos was subsequently shown to express several BMPs ligands, consistent with their epidermalizing effects (Fig. 14.3).

**FIGURE 14.3** The BMP signalling pathway and its role in DV patterning of the ectoderm (A) At blastula-stages embryos, have a ventralizing center that promotes BMP signalling, and a dorsalizing center that induces neural tissue by inhibiting BMP signalling. (B) Schematic showing the various components of the BMP signalling pathway. The core components are the ligands (BMP2,4,7) that activate a signal transduction pathway (large green arrows), by binding transmembrane receptors. The BMP receptors signal by activating Smad1, allowing it to dimerize with Smad4 and activate gene expression. Transcriptional targets are genes involved in epidermal differentiation, but also components in the pathway as indicated by the green arrows. Also shown are various molecules that regulate the activity of the pathway, through complex interactions that allow self-regulation, as indicated by positive (green) and red (negative) arrows. The key negative regulators are BMP antagonists, such as chordin, noggin, follistatin and cereberus, which bind to ligand and inhibit their activity (large red arrow). Chordin activity on the ventral side is negatively regulated by a metalloprotease, Tolloid, which in turn is negatively regulated by Sizzled. ADMP is a BMP ligand that is expressed on the dorsal side, and show cross-inhibitory interactions with Chordin. BAMBI is an inhibitory receptor expressed on the ventral side to dampen BMP signalling. Finally Smurf1, Ectodermin, and Dullard target Smad1, Smad4, and the receptors, respectively, to degradation.

The default model gained further support from the discovery that Spemann's organizer is a rich source of BMP antagonists (Fig. 14.3A). At least four secreted polypeptide—follistatin, noggin, chordin, and Cerberus—are expressed in the organizer region of *Xenopus*. All four can bind tightly to the BMP ligands and prevent activation of the receptors, and all four act as potent neural inducers when expressed in the iso-

lated ectoderm assay (Lamb *et al.*, 1993). At first, genetic tests of these putative neural inducers in other species were unimpressive since mutations that eliminate only one of these inhibitors tend to have relatively mild phenotypes on their own. For example, a loss-of-function mutation in Zebrafish chordin (the *chordino* mutant) causes only a reduction in the size of the neural plate. Similarly, mouse embryos that lack just

one the BMP antagonists, chordin or noggin, by knock-out mutations (Box 14.1) have a relatively normal nervous system. However, the full potential of these antagonists has only become apparent when multiple antagonists are removed at the same time, mainly by using an approach where embryos are injected with small, stable oligonucleotides, called morpholinos, which bind to and inhibit the expression of target mRNAs. A complete loss of neural tissue is then observed when all three BMP antagonists, Chordin, Follastatin and Noggin, are simultaneously targeted using morpholinos, both in *Xenopus* and in Zebrafish. Thus, the production of multiple BMP antagonists within Spemann's organizer creates a dorsalizing center on one side of the embryo that inhibits the epidermalizing effects of BMPs produced in a ventralizing center on the other (Fig. 14.3A).

Why does Spemann's organizer express multiple BMP antagonists that apparently compensate for each other, when in principle one would do? Spemann coined the phrase "double-assurance" to emphasize the importance of redundancy in developmental mechanism as a way to reliably pattern the early embryo. Redundancy in the BMP pathway, moreover, is used as a mechanism to self-regulate, thus ensuring the appropriate gradient of BMP signaling is established across the DV axis of the ectoderm reliably, time after time (De Robertis, 2006). For example, targeting three BMPs, BMP2/4/7, with morpholinos in *Xenopus* embryos results in marked expansion of neural tissue, but some ventral, epidermal tissue remains. The surprising result is that ubiquitous neural tissue along the entire DV axis is only observed when a fourth ligand, ADMP, is also targeted, except that ADMP is not expressed in the ventralizing center with BMP2/4/7 but on the dorsal side where neural tissue forms. This paradox is resolved by the observation that BMP signaling promotes the expression of BMP ligands ventrally but represses the expression of ADMP dorsally. Thus, dorsal expression of ADMP is strongly upregulated when BMP2/4/7 are targeted by morpholinos, thereby compensating for the decrease in the source of BMPs ventrally, and reestablishing ventral fates. This is one of several such regulatory interactions that enables the BMP patterning system to self-regulate, thus ensuring that embryos consistently form proper amounts of neural and epidermal tissue.

### Additional Pathways Involved in Neural Induction

While the basic tenets of the default model have stood up over time, the current picture of neural induction has increasingly become more complicated as

additional neural inducers have been identified. One of the most important of these is fibroblast growth factor (FGF), a ligand that binds to its receptors and signals via the MAP kinase cascade. FGF has been proposed to have several potential roles during neural induction, as a "priming" signal and as an inducer of posterior neural tissue, which forms from a region of the blastula that lie at some distance from the organizer region. How FGF induces neural tissue remains somewhat controversial. One model is that FGF signaling acts by suppressing BMP signaling by targeting Smad1, either directly by phosphorylating a critical linker region, or indirectly by inducing the expression of a protein called SIP1, a zinc-finger, homeodomain protein, that binds to and represses the transcriptional activity of the Smad proteins. Alternatively, FGF signaling is likely to induce neural tissue independent of its effects on BMP signaling, although the exact details of this mechanism remain unexplored. Currently it remains unclear whether there are other signaling pathways such as FGF that induce neural tissue by novel mechanisms or whether all inducers ultimately act by somehow inhibiting BMP signaling.

The default model correctly underscores the importance of inhibiting BMP activity in neural induction, but unfortunately de-emphasizes other changes that are required for neural tissue to form (Stern, 2006). Experiments in the chick embryo for example have shown that inhibiting BMP signaling in some regions of the ectoderm is not sufficient to induce a neural fate, suggesting that additional signals may act earlier in embryogenesis to create the potential for forming neural tissue. In addition, the ectodermal cells that form the neural plate activate the expression of genes that mark the formation of neural precursors, such as those encoding the Sox family of the HMG transcription factors. The transcriptional activation of these and other neural precursor genes requires a complex constellation of transcriptional regulators that need to be deployed when ectodermal cells take on a neural fate as a "default" pathway.

### Summary

The nervous system first arises in the vertebrate embryo from a region of ectoderm that is induced to form the neuroepithelium of the neural plate and tube rather than differentiating into epidermis. Classical transplantation studies have shown that dorsal ectoderm forms neural tissue in response to signals from the organizer. More recent studies have shown that ventral ectoderm undergoes epidermal differentiation in response to multiple, endogenously produced BMP ligands. Spemann's organizer expresses multiple BMP antagonists that act redundantly to induce neural

tissue. This redundancy is the bases for the complex mechanisms of self-regulation ensuring that the BMP signaling pathway is activated stably and correctly along the DV axis. Additional pathways are likely required during neural induction, including ones that establish gene expression required for neural precursor formation.

### Early Neural Morphogenesis

Among the earliest changes that occur during the formation of the vertebrate nervous system are ones associated with morphological changes in cellular and tissue structure. At the cellular level, ectoderm cells lose their cuboidal shape and elongate into the pseudostratified, neuroepithelial cells that characterizes the morphology of neural precursors cells along the entire axis of the embryo. At a tissue level, the neuroepithelium of the neural plate undergoes the complex morphogenetic movements of *neurulation* to form the neural tube, which invaginates into the embryo, pinches off from the surrounding ectoderm and forms a separate tissue anlage. Neurulation is an exceedingly complex process and prone to failure for multiple reasons. Indeed, a failure to close the neural tube has devastating downstream consequences on neural development and the cause of neural tube defects (NTDs), a relatively common class of human birth defects.

In higher vertebrates, neurulation can be divided into two phases which differ in their morphological movements: a primary phase involving the brain and most of the spinal cord and a secondary phase involving more posterior regions of the spinal cord. While we are still quite far from understanding the complex tissue mechanics that underlie primary neurulation, some progress has been made in breaking down aspects of neurulation into cellular behaviors that occurs within subregions of the neuroepithelium. One of the earliest acting of these is convergent-extension (C-E), which occurs during gastrulation and neurulation and extends the neuroepithelium along the AP axis (Fig. 14.4). C-E is driven by organized cell intercalation much like the behavior of movie-goers when they exit a theater using only a central aisle (Keller, 2002). In a similar manner, neural plate cells intercalate pass each other to narrow the neural anlage medio-laterally by about ten-fold, while extending it at least as much along the AP axis of the embryo. C-E is known to require the planar cell polarity (PCP) pathway, a conserved group of proteins that were originally identified in the fly, *Drosophila*, as mutations that cause a defect in the planar organization of hairs on the wing (Wang and Nathans, 2007). These

proteins localize asymmetrically to opposite sides of epithelial cells along the planar polar axis, where they influence the planar orientation of the cytoskeleton. In a similar manner, vertebrate homologs of these proteins are required during C-E to organize the cytoskeleton of migrating cells along the medial-lateral axis of the neural plate in a manner that orients polarized cell rearrangements. Consequentially, mutations of genes in the PCP pathway in *Xenopus*, Zebrafish or the Mouse disable C-E, resulting in an abnormally wide neural plate, a subsequent failure to elevate the neural folds at the edges, and an open neural tube.

As C-E extends the neural plate along the AP axis, other localized cell behaviors along the DV axis contribute to the buckling of the plate into a tube. A hinge point forms at the midline of the neural plate as well as at more dorsal positions (Fig. 14.4), by apical constriction of actin microfilaments in neuroepithelial cells to produce a wedge-shaped morphology. Accordingly, mutations in various proteins that regulate microfilament dynamics are commonly associated with NTDs in the mouse. Shaping of the neural tube also requires localized regions of apoptosis, which if blocked, leads to NTDs. Finally, neural tube closure culminates with the fusion of the neural folds, which also give rise to a population of migrating neural progenitors, the neural crest. Mutations in the mouse that alter neural crest formation and emigration are also capable of producing NTDs. Even with this short summary one can appreciate that integrating these various aspects of cell behavior into a unifying mechanical model of neurulation is a formidable task although one required for a better understanding of this common source of human birth defects.

In the next section, we will discuss the various mechanisms that subdivide the neuroepithelium into different regions along the neuraxis during neural patterning. At this point, we emphasize that among the earliest readouts of this patterning are regional differences in morphogenetic behavior. For instance, the neural tube is wider at its anterior end where the brain forms than at the posterior end, which forms the spinal cord. This difference in shape arises in part because C-E is much more pronounced in posterior regions, presumably as a result of early patterning events along the AP axis. Another obvious example is the early steps in eye formation. The eye anlagen are first apparent during neurulation, when the neuroepithelium at the level of the prospective diencephalon evaginates to form the bilaterally paired eye vesicles. At the point where the neural tube and eye vesicle join, the neuroepithelium eventually pinches together to form the optic stalk while the eye vesicle forms a cup and

**FIGURE 14.4** Morphogenesis of the neural plate and tube. (A) The formation of the neural plate and tube requires an organized intercalation of cells along the medial-lateral axis (convergence) which extends the neural anlage along the anterior-posterior axis (extension). The polarized cell behaviours that drive this process require the PCP pathway. (B) Neurulation of the neural plate into a tube requires several hinge points along the DV axis, including one at the forming ventral midline (MHP) which becomes the floor plate, (comma) as well as more dorsal ones (LHP). These hinge points allow the neural plate to buckle and the neural folds to elevate and fuse at the dorsal midline. At the same time, the neural crest forms (red cells) and emigrate.

divides further into an inner layer that gives rise to the retina and an outer layer that will form the pigmented epithelium. Again, these regionalized morphogenetic processes are downstream consequences of the early patterning of the neural plate into different regions although how patterning controls morphogenesis remains largely unexplored.

### Summary

Formation of the vertebrate nervous system begins with a series of striking changes in cell and tissue morphology as the ectoderm forms the neural plate and tube. Neural tube formation involves the complex morphogenetic process of neurulation that requires coordinated changes in cell shape, cell division, cell migration, cell death, and cell-cell contacts. One prominent cell behavior during neural plate and tube formation is required for CE, which narrows the neural anlage and extends it along the AP axis.

CE requires the PCP pathway to orient cell movement and intercalation behavior. Much remains to be learned, however, about how changes at the molecular, cellular, and tissue level combine to produce the complex morphological changes that occur during neural plate and tube formation.

## EARLY NEURAL PATTERNING

As discussed earlier, the neural plate is a morphologically homogeneous sheet of epithelial cells derived from dorsal ectoderm, which acquires its neural potential and fate as a result of inductive signaling. As the neural plate rolls up and closes into a tube, a series of constrictions appear in its wall, subdividing the anterior end of the tube into a series of vesicles representing the anlagen of fore-, mid-, and hindbrain

(Fig. 14.8). Further subdivision ensues, most conspicuously in the hindbrain region (rhombencephalon), where a series of segment-like swellings, rhombomeres, are formed. Caudal to the hindbrain, the neural tube forms a long narrow cylinder that is the precursor of the spinal cord. These early morphological features of the neural tube dictate the overall plan of the CNS and predict its later regional specializations. The neuroepithelium then commences with the production of a huge diversity of region-specific cell types, each having a distinct identity in terms of morphology, axonal trajectory, synaptic specificity, neurotransmitter content, and so on. Different neuronal cell types also carry distinctive surface labels that may ensure accuracy of axonal navigation and the formation of appropriate connections with other cells.

Perhaps most strikingly, individual neurons or groups of similar neurons originate at predictable times and at precise positions within the various regions of the neural tube. In some cases, neurons remain in their position of origin during and following differentiation; in other cases, young neurons or their precursors are directed to migrate along stereotypic paths to settle in locations distant from their position of origin. Correct specification of this intricate spatial ordering, or *pattern*, of cells is crucial to later events in CNS development when neurons establish complex arrays of specific interconnection that constitute functional networks. Activity-dependent processes and regressive events, such as the pruning of axons and cell death, later reinforce and refine initial patterns of connectivity, but a high degree of precision is achieved from the outset, dependent on, and as a direct result of, appropriate cell patterning. How the different regions of the CNS, and the individual cell types they each contain, are assigned their identity in early development remains an outstanding problem in neurobiology.

Until recently, studies of the earliest developmental stages have been hampered severely by our inability to detect nascent pattern. However, discovery of a multitude of molecular markers that reveal subregions of the neuroepithelium has made it possible to visualize emergent heterogeneity in what was previously seen only as a "white sheet" of cells.

From its inception, the central nervous system is organized along orthogonal axes: longitudinal (anteroposterior or AP) and transverse. Neural tube folding and closure deflect the transverse axis from its original lateromedial orientation so that it becomes dorsoventral (DV) with respect to the body. The third axis is radial (apical-basal) and has little involvement in early patterning, as the radial organization of the tube is largely uniform throughout (with the principal excep-

tion of the cerebral and cerebellar cortices). In contrast, both the AP and DV axes are nonuniform. Different neuronal types appear at different positions in these two dimensions as if reading their grid references on a map. Indeed, a Cartesian coordinate system of *positional information* is a useful framework with which to visualize neural pattern. As shown later, various morphogens act as *positional signals* on one or other of the two main axes, usually by establishing gradients of activity as their concentration falls with distance from a localized source. Uncommitted neural precursor cells respond to the local morphogen concentration by expressing specific transcriptional mediator genes (e. g., *homeobox* genes) that encode the *positional value* of the region. In effect, cells measure their position by reading the strength of signals and finally adopt a specific fate that is appropriate for their AP/DV grid reference in the neuroepithelium. An assigned positional value not only directs differentiation but also, for migrating neurons, translocation away from the site of origin to a new location. As we will see in the following sections, the patterning mechanisms used to regionalize the DV axis are remarkably uniform along the length of the neural tube, but those that operate on the AP axis vary considerably between telencephalon and spinal cord.

### Establishment of the AP Axis

The initial establishment of AP polarity along the neuraxis is coupled intimately to the establishment of the main body axis during early embryonic development. Although AP axis formation in the vertebrate embryo remains poorly understood, it may have conceptual similarities with the strategies used for axis determination in the *Drosophila* embryo, where genetic studies have produced a detailed understanding. In *Drosophila*, AP polarity is first established by a gradient of positional information produced by the maternal morphogen Bicoid emanating from the anterior pole of the egg. The gradient of the Bicoid transcription factor initiates a cascade of transcription factor activation that progressively subdivides the body axes further into smaller segmental units. As these repeat units are established, genes of the *Antennapedia/Bithorax* homeotic complex (HOM-C) act in a well-ordered manner to define unique segment identities. Similarly, formation of the AP body axis in vertebrates is likely to involve the imposition of a crude polarity of transcription factor expression, which is then refined at later stages into smaller domains of gene expression. Despite these conceptual similarities, the vertebrate embryo differs markedly from *Drosophila* where the AP axis is laid down essentially at the same time

along the entire cylindrical-shaped embryo. In higher vertebrates, those parts of the neuraxis lying posterior to the hindbrain are “added-on” by dividing cells that extend the axis in an anterior to posterior direction in a progressive manner during gastrulation. As a consequence, AP patterning of the vertebrate nervous system is temporally more asynchronous and protracted, and spatially more complex (Stern *et al.*, 2006).

### Embryology of Early AP Patterning

As discussed in an earlier section, the transplant experiments of Mangold and Spemann also revealed the role of organizer tissues in imparting AP polarity on the developing CNS. Specifically, organizer tissue can be subdivided into two parts: a head organizer that induces anterior structures (i.e., brain) and a trunk/tail organizer that induces posterior structures (i.e., spinal cord). The two types of organizer tissue differ in their position within blastula stage embryos, their time of involution during gastrulation, where they come to lie after gastrulation is complete, and what tissue derivatives they form (Fig. 14.5). In amphibian and fish embryos, head organizer tissue lies adjacent to the prospective anterior neural plate on the dorsal most side of the blastula (Niehrs, 2004). During gastrulation, this tissue moves internally in an anterior direction to form the prechordal mesendoderm (PME), lying underneath the ectoderm that is induced to form the *prechordal* neural plate and give rise to the most anterior end of the brain (forebrain) (Fig. 14.5A). In contrast, trunk/tail organizer tissue lies more superficially and laterally on the blastula fate map, involutes later during gastrulation, forms derivatives of the chordal mesoderm, such as the notochord and somites, and underlies the posterior neural plate, referred to as the *epichordal* neural plate (Fig. 14.5A). In the mouse and chick embryo, the prospective prechordal neural plate receives anteriorizing signals before the onset of gastrulation from underlying anterior visceral endoderm (AVE), or the hypoblast, respectively (Fig. 14.5B). These early anteriorizing signals along with later signals from involuting PME cells and/or from an organizer region called Hensen’s node are required to induce the anterior neural plate. Much of the trunk/tail organizer in mouse and chick embryos resides in Hensen’s node when it extends posteriorly during gastrulation, inducing epichordal neural plate in an anterior to posterior progression (Fig. 14.5B). Finally, another important source of anteriorizing signals in Zebrafish at later stages of neural patterning is the anterior edge of the forming neural plate (Wilson and Houart, 2004). Thus, depending on the vertebrate

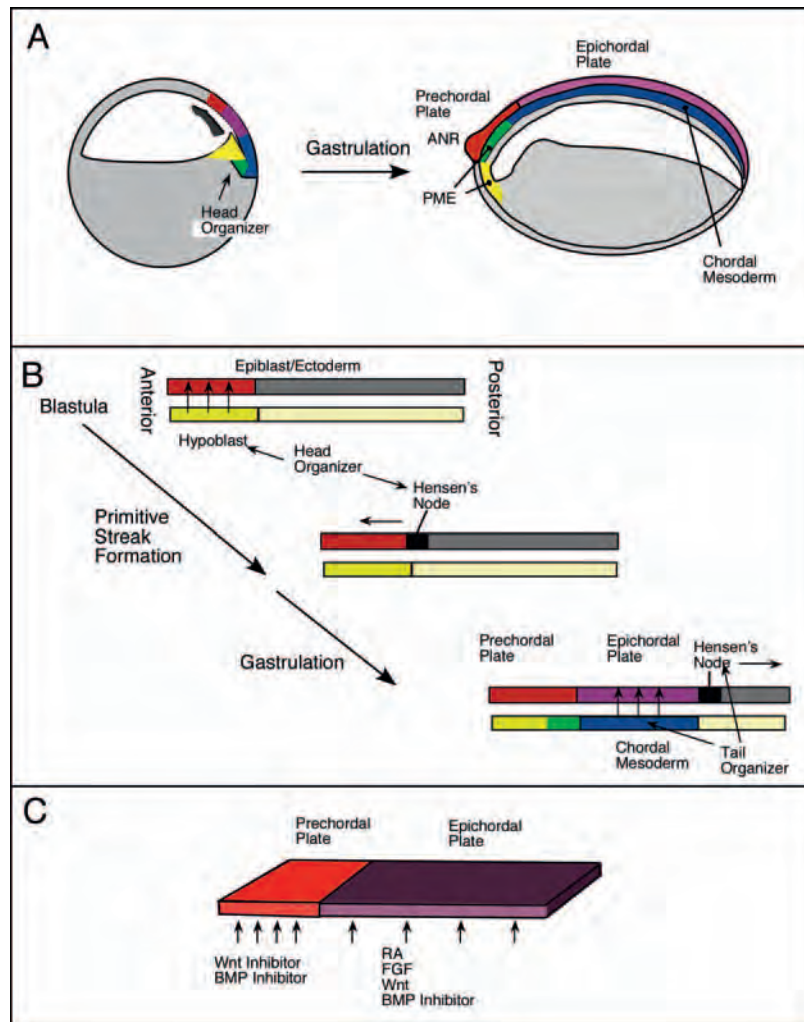

species, head and trunk/tail organizer capabilities may reside in multiple tissues that act at different times to influence the initial division of the neural plate along the AP axis into pre- and epichordal domains.

### Molecular Basis of Early AP Patterning

As described above for neural induction, the study of early neural patterning has been aided by molecular tools to manipulate various signaling pathways in embryos, as well as the ability to reveal the formation of a nascent pattern based on the expression of genes that mark different regions of neural tissue. One major insight from these recent studies is that members of the secreted Wnt family act in combination with the anti-BMP neuralizing agents to induce posterior neural (Niehrs, 2004). The added twist is that head organizer tissues are a rich source of antagonists that inhibit the activity of the Wnt pathway, and play an important role in protecting the anterior neural plate from posteriorization.

The identification of signaling molecules that could posteriorize neural tissue was aided by assays using explants of isolated ectoderm from *Xenopus* embryos neuralized by BMP inhibitors, or explants of the early, anterior chick neural plate dissected from embryos. These explants typically express anterior neural markers, such as the homeobox gene, *Otx2*, but not more posterior neural markers indicative of the hindbrain or spinal cord. Treating these explants with members of the Wnt family however, suppresses anterior neural marker expression and upregulates the expression of posterior markers. The WNTs are expressed by trunk/tail organizer tissue, making them strong candidates as signals required for posteriorizing the central nervous system when it first forms (Fig. 14.5C).

A role for Wnt signaling in posteriorizing the nervous system is also supported by mutations that deregulate Wnt activity in Zebrafish embryos, thereby causing a loss of prechordal neural plate and expansion of the epichordal neural plate. This phenotype is observed in Zebrafish *masterblind* and in *headless*, both of which encode molecules that act to keep the Wnt pathway off in the anterior neural plate (Wilson and Houart, 2004). In addition, a number of secreted proteins have been identified that act as molecular sinks for the Wnt signaling pathway and are produced by various inducing tissues involved in anteriorizing the neural plate (Niehrs, 2004). Dickkopf is a secreted protein produced by the head organizer tissue in the frog, blocks Wnt signaling at the level of the receptors,

**FIGURE 14.5** Early AP patterning of the vertebrate nervous system. (A) Early AP patterning of the amphibian nervous system involves signals emanating from different organizer tissues. The head organizer consists of anterior endoderm and head mesoderm that involutes underneath the prechordal neural plate during gastrulation. The epichordal neural plate is patterning by the chordal mesoderm that involutes later. (B) Similar mechanisms pattern the chick embryo. Early anteriorizing signals from the hypoblast begin to induce the prechordal neural plate, which are reinforced by signals from Hensen's node during primitive streak formation. During gastrulation, the regressing Hensen's node patterns the epichordal plate, along with the underlying chordal mesoderm. (C) Schematic representing the signals that are thought to divide the forming nervous system into a prechordal and epichordal neural plate.

and when mutant causes a loss of anterior neural tissue in the mouse. In Zebrafish, the anterior ridge of the neural plate has anteriorizing properties that can be attributed to the production of a secreted Wnt inhibitor (Wilson and Houart, 2004). The picture from these studies is that Wnt signaling needs to be suppressed during neural plate formation at the extreme anterior end in order for the prechordal neural plate to form (Fig. 14.5C).

In addition to the WNTs, the trunk/tail organizer produces other secreted molecules that may impart initial AP polarity on the neural plate as it first forms. One of these, FGF8, is required for extending the posterior axis, by maintaining a population of stem cells

in Hensen's node that progressively emerge to form posterior neural tissue (Diez del Corral and Storey, 2004). One model is that exposure time to FGF8 defines AP axial position in the spinal cord, based on when stem cells leave the node and form the neural plate. Another molecule produced by the trunk/tail organizer is retinoic acid (RA) which signals through nuclear hormone receptors, has potent posteriorizing activity, and may have several roles in AP patterning of the hindbrain and spinal cord.

### Summary

AP patterning of the CNS begins during the process of neural induction as dorsal ectoderm takes on a

neural fate. This process divides nascent neural tissue into prechordal (anterior) and epichordal (posterior) neural plate regions based on signals that come from adjacent head and tail organizing tissues. Formation of the prechordal plate requires two inhibitory signals produced by the head organizer: one that inhibits BMP and the other WNT signaling. Tail organizer tissue produces potent posteriorizing agents, including WNTs, FGFs, and RA. The extent of signals required for generating AP polarity, however, is not fully known and the details of their action remain to be explored. Interestingly, both neural and anterior-neural are default states, requiring specific molecular activity to become nonneural (BMP) or posterior-neural (WNT).

## REGIONALIZATION OF THE CENTRAL NERVOUS SYSTEM

Following the establishment of polarity along the AP axis of the embryo and the delineation of prechordal and epichordal regions of the neural plate, the AP axis becomes further regionalized into smaller and smaller domains, as revealed by the expression of developmental control genes. This process of progressive regional refinement involves two general classes of mechanism—the establishment of local organizers as sources of diffusible factors (morphogens) that inform neighboring cells about their position and fate, and the partitioning of the neuroepithelium into small modules or segments in which development can proceed with a degree of autonomy. In both cases, a conspicuous and important feature is the setting up of boundaries, which position a local organizer, contain cells within a compartment, or both. We will illustrate these patterning mechanisms by reference to selected examples. Our intention is to outline general principles rather than to provide a comprehensive review of nervous system patterning.

### Definition of AP Pattern by Differential Homeobox Gene Expression

Central to the illumination of vertebrate CNS pattern formation has been the discovery that developmental control genes related to genes with a known patterning role in the *Drosophila* embryo are expressed in spatially restricted domains of the neural plate and tube. These regulatory genes, many of which encode homeodomain proteins, include the *Hox* genes, which specify positional value along the AP body axis of the fly embryo. In both flies and vertebrates the *Hox*

genes have a clustered chromosomal organization in which the relative position of a gene in the cluster reflects its boundary of expression along the AP axis. In vertebrates, the *Hox* genes are expressed in overlapping, or nested, domains along the AP axis of the early embryo, with those at the 3' ends of the cluster being expressed most anteriorly, in the hindbrain, where there is a precise correspondence between their anterior expression borders and the boundaries between the rhombomeres of the hindbrain neuroepithelium (Fig. 14.6).

Accumulating evidence supports the view that, by encoding positional value, *Hox* genes control the identity and phenotypic specializations of subregions of the epichordal neural tube in which they are expressed. Loss-of-function mutations of anteriorly expressed *Hox* genes result in malformations that represent a transformation of rhombomere identity. In the *Hoxb1* mutant mouse, for example, rhombomere (r) 4 (where the gene is normally expressed at a high level) loses its r4-specific character and takes on that of r2, where the gene is not normally expressed (Studer *et al.*, 1996). Similarly, overexpression of *Hoxb1* in r2 causes it to adopt phenotypic characters of r4 (Bell *et al.*, 1999).

Anterior to r2, the brain does not express *Hox* genes but displays spatially restricted expression of other transcriptional control genes whose homeoboxes are divergent from the *Hox* type. These genes are also highly conserved between flies and vertebrates. Two homologues of the *Drosophila* segmentation gene, *engrailed* (*en*), are expressed in a broad region either side of the midbrain–hindbrain boundary (MHB), which later forms the cerebellum and the optic tectum (Fig. 14.7). Expression of the *En* genes is graded, being strongest at the MHB and declining both anteriorly and posteriorly. Morphological derivatives of the entire domain of *En* expression are deleted in *En1* knockout mice, showing that *En* function is crucially involved in the morphogenetic specification of the region (Wurst *et al.*, 1994).

The gap genes *orthodenticle* and *empty spiracles*, which function as homeotic selectors in the specification of particular head segments in *Drosophila*, have vertebrate homologues that are expressed in overlapping domains that encompass the entire rostral extremity of the AP axis with the exception of the ventral forebrain. The two *empty spiracles* homologues, *Emx*, are forebrain specific, whereas the two orthodenticle homologues, *Otx*, have wider expression, encompassing both forebrain and midbrain. The *Otx2* knockout mouse has an extreme phenotype that shows the importance of the gene but betrays little about its function—the entire head rostral to r3 is deleted. This is

**FIGURE 14.6** *Hox* gene expression domains in the CNS of fly and mouse. Nested domains of *Hox* genes along the AP axis of the *Drosophila* CNS closely parallel those of their homologues in mouse. Compare, for example, the fly gene *labial* (*lab*) with its mouse homologue *Hoxb1*. *Hox* genes specify a positional value along the AP axis, which is interpreted differently in fly and mouse in terms of downstream gene activation, resulting in neural structure; shared between the two organisms is the means of encoding the position of a cell along the AP axis. After Hirth *et al.*, (1998).

explained by the fact that *Otx2* is also expressed in the visceral endoderm that lies beneath the anterior ectoderm, where it is required for the induction of anterior neural structure during gastrulation (Simeone *et al.*, 2002). However, the gastrulation phenotype can be rescued by expressing *Otx* in the visceral endoderm while the ectoderm remains functionally null for *Otx2*. This reveals the brain-specific function of the gene, which is to maintain anterior neural identity; in the absence of neuroectodermal *Otx2*, the anterior brain becomes converted into hindbrain, with an enlarged cerebellum rather than forebrain forming the anterior end of the CNS.

An important later function of *Otx2* is to set the position of the midbrain–hindbrain boundary, whose local organizer functions are discussed later. The sharp posterior border of *Otx2* expression coincides with the anterior expression border of another homeobox gene, *Gbx2*, in the anterior hindbrain. Mutual or cross-repression between the two genes stabilizes the interface, forming a boundary where specialized signaling cells are generated. Experimentally extending the expression domain of *Otx2* into hindbrain territory causes the *Gbx2* border and MHB differentiation to retreat posteriorly, whereas extending the *Gbx2* domain into midbrain territory results in a corresponding anterior shift of the *Otx2* border (Rhinn and Brand, 2001).

### Summary

Gene expression patterns have illuminated the time course and mechanisms underlying neural patterning. Functional studies show that homeobox genes direct AP pattern formation, establishing head-to-tail

regionalization. In the hindbrain, *Hox* genes encode subregional (rhombomere) identity. At the midbrain–hindbrain boundary, *Otx* and *Gbx* genes set up and position the MHB organizer, and *En* genes induced at the MHB confer AP polarity on the optic tectum, crucial to formation of the retinotopic map.

### Local Organizers of AP Pattern

Homeobox genes and other classes of transcriptional mediator regulate position-specific development. How is the expression of these genes, or their upstream regulators, directed to specific domains of the AP axis? In many cases, it appears that long-range signals from local organizers are involved, directly or indirectly, in activating specific regional control elements of these genes at appropriate levels of the axis. In the case of *Hox* genes, a gradient of retinoic acid (RA) signaling has this role of positional signal (Glover *et al.*, 2006).

RA exerts its effects via multiple types of RA receptors (RARs and RXRs), members of the nuclear receptor superfamily. RA receptors are ligand-dependent transcription factors that bind as hetero-dimers (RAR+RXR) to RA response elements in the promoters of target genes, including *Hox* genes. In the early embryo, RA is produced by the somites that lie alongside the caudal hindbrain (r7, r8) and spinal cord, through the activity of a synthetic enzyme *Raldh2*. Expressed anterior to the hindbrain is another enzyme, *Cyp26*, which degrades RA. These appear to act as source and sink for a gradient of RA activity that traverses the AP length of the hindbrain. Thus, targeted mutation of *Raldh2* in mice and treatment of

**FIGURE 14.7** Role of FGF8 in mid/hindbrain patterning. (A) Implanting a bead that releases FGF8 protein (red) in the posterior diencephalon of an early chick embryo results in the induction of *En* (blue) and the transformation of normal posterior diencephalic territory (B) into midbrain (C). In the treated embryo (C), the posterior diencephalon forms a set of midbrain structures laid out in reverse AP polarity to the normal midbrain. This is thought to be due to the induced anterior-to-posterior gradient of EN protein that is the mirror image of the endogenous EN gradient. Also shown in (A) is the expression domain of the prepattern gene *Irx2* (green hatched), which establishes cerebellar competence in rhombomere 1. chick embryos with an antagonist that specifically blocks all RARs both cause anteriorization of the hindbrain.

Immediately anterior to the expression domain of *Hox* genes is a territory, r1 and midbrain, that forms the cerebellum and optic tectum. A unitary process of specification for these adjacent regions is reflected both at the molecular level and by aspects of their developmental potential: the *Drosophila engrailed* homologues, *En1* and *En2* (as mentioned previously) and the *paired* homologues, *Pax2*, *Pax5*, and *Pax8*, are expressed in this domain. The development of midbrain and r1 is coordinated by the MHB: heterotopic grafts of MHB cells locally induce *En* expression in the host and change the fate of the host neuroepithelium such that it ultimately forms tectal structures (when grafted to the posterior diencephalon) or cerebellar structures (when grafted to the posterior hindbrain). These findings provide compelling evidence that a signal emanating from the MHB is involved in local AP patterning.

There are two prominent components of this organizing activity: WNT1, expressed in a transverse ring just anterior to the MHB, acts as a mitogen and to maintain the expression of *En* but is unable to mimic the activity of MHB grafts. FGF8, expressed immediately posterior to the *Wnt1* domain, has midbrain-inducing and polarizing abilities (Fig. 14.7). When a bead coated with recombinant FGF8 is implanted in the posterior diencephalon of chick embryos, *Fgf8*, *Wnt1*, and *En2* expression is induced in the surrounding cells. The posterior diencephalon then becomes completely transformed into the midbrain, whose AP polarity is reversed with respect to that of the normal host midbrain in accord with the gradient of induced *En* expression (Crossley *et al.*, 1996). Loss of FGF8 function in the zebrafish mutant *Ace* results in loss of the MHB, cerebellum, and part of the tectum. Thus, *Fgf8* expression at the MHB is necessary and sufficient to establish the polarized pattern of adjoining regions. The different responses of midbrain and hindbrain to the FGF8 signal is at least partially due to the prior expression of competence factors: expression of *Irx2* (a homologue of *Drosophila Iroquois*) in r1 is necessary and sufficient to direct the tissue to respond to FGF8 by making cerebellum. Ectopic expression of IRX2 in the midbrain transforms presumptive optic tectum into cerebellum on reception of the FGF8 signal, whereas expressing a constitutively repressive form of IRX2 in r1 transforms presumptive cerebellum into optic tectum. Interestingly, the role of FGF8 in this mechanism is to convert IRX2 protein from a repressor into an activator, which it does by phosphorylation via the MAP kinase pathway (Matsumoto *et al.*, 2004).

Diffusion of FGF8 away from the MHB (Scholpp and Brand, 2004) can be seen to act as an on-switch, setting the timing and extent of development of regions whose final identity has already been established by prepattern gene expression. An important feature of the FGF8-secreting cells is that they are positionally stabilized in the neuroepithelium by lineage restriction (Langenberg and Brand, 2005). Positional stabilization may be seen generally as a requirement for local signalling centers, ensuring that they can produce stereotypic and predictable molecular gradients in adjacent tissues (Irvine and Rauskolb, 2001).

Two further local organizers operate in more rostral regions of the neural tube where a number of early expressed developmental control genes are expressed in a patchwork quilt of small domains, subdividing the diencephalon and telencephalon (the main posterior and anterior subdivisions of the forebrain) into a

number of transverse and longitudinal domains. Signaling at the anterior end of the axis involves FGF secretion from a region known as the anterior neural ridge (ANR), which is responsible for inducing and/or maintaining telencephalic (e.g., *Foxg1*) gene expression and for maintaining telencephalic identity (Rubenstein and Beachy, 1998). The ANR is probably a derivative of those early cells (identified as Row 1 in zebrafish, Houart *et al.*, 1998) that secrete antagonists to WNTs, whose posteriorizing activity must be reduced in order to establish anterior neural identity.

A second local organizer of forebrain pattern, the zona limitans intrathalamica (ZLI), lies at the middle of the prospective diencephalon, roughly midway between the ANR and MHB (Fig. 14.8). The ZLI secretes the signal molecule Sonic Hedgehog (SHH), which is responsible for inducing the expression of regional determinant genes both anteriorly (e.g., *Dlx2* in the

**FIGURE 14.8** Boundaries and compartments in the avian embryo brain. (A) At an early stage cell lineage restriction exists on either side of the presumptive zona limitans intrathalamica (PrZLI), at the midbrain-hindbrain boundary (MHB) and between rhombomeres (r1-r7). Dark blue arrows represent FGF8 signaling to both the presumptive optic tectum (anterior) and presumptive cerebellum (r1, posterior). The presumptive ZLI is a wedge-shaped area devoid of Lunatic Fringe expression (blue) and lineage-restricted at its A and P borders. The pattern gene *lrx3* is expressed posterior to the presumptive ZLI (green hatched). (B) At a later stage, the wedge-shaped pr-ZLI has narrowed to form the definite ZLI, which now expresses Sonic hedgehog (red), inducing the expression of regional determinants in the prethalamus (Pth, anterior, light blue) and thalamus (Th, posterior, dark blue). DMB, diencephalic-mesencephalic boundary; Hth, hypothalamus; PSPB, pallial-subpallial boundary; Ptec, preectum; Tel, telencephalon. After Kiecker and Lumsden (2005).

prethalamus) and posteriorly. (e.g., *Gbx2* in the thalamus). Like the MHB, the ZLI is positionally stabilized by cell lineage restriction and like the action of FGF8 at the MHB, the different inductive responses to SHH signaling from the ZLI are due, at least in part, to pre-patterned differences in competence of the flanking regions: the *Iroquois* gene *Irx3* is expressed only posterior to the ZLI and directs thalamic differentiation via *Gbx2* on receipt of the Shh signal (Kiecker and Lumsden, 2005).

### Summary

Local signaling mechanisms direct the spatial expression of homeobox genes, which appear to be crucial to the delineation and subsequent development of specific anteroposterior subregions of the CNS. Retinoic acid, diffusing from the cervical somites, is in part responsible for establishing the nested expression domains of the *Hox* homeobox genes in the hindbrain. FGF8, produced by cells at the midbrain/hindbrain boundary (MHB), is involved in the elaboration of midbrain and cerebellar structure. SHH, produced by cells at the Zona Limitans Intrathalamica (ZLI), is responsible for elaborating prethalamal and thalamic structure. For both the MHB and the ZLI, tissues lying anterior and posterior to the signaling center respond differently to the secreted morphogen because they have different competences, endowed by the expression of *Irx* prepatterning genes.

## Hindbrain Segmentation

Shortly after closure, a series of seven varicosities appear in the hindbrain neural tube. Although transient, these *rhombomeres* are true segments that play a crucial role in patterning (Lumsden and Keynes, 1989). Thus, the earliest formed neurons are laid out in stripes that match the morphological repeat pattern, with neurogenesis starting within the confines of alternate, even-numbered rhombomeres, and only appearing later in odd-numbered rhombomeres—a ‘two-segment repeat’ pattern (Fig. 14.9). Later in development, these segmental origins become obscured as the motor nuclei condense and migrate bodily to new positions. Segmentation is a developmental mechanism for specifying the pattern of developing structures, not necessarily for deploying those structures in the adult. Subdivision of a tissue or large region by axial segmentation (metamerism) involves the allocation of defined sets of precursor cells into an axially repeated set of similar modules. A developmental strategy adopted independently by many animal phyla, segmentation offers the advantages that organizational fields remain small and specializations of cell

type and pattern can be generated as individual segmental variations on the repetitive theme. In a segmented system, precise boundaries can be set for both cellular assemblies and realms of gene action.

Segmentation of the neural tube cannot proceed in the same way as for the mesoderm, where physically separate somites are formed, because the tube has to retain epithelial continuity, not least as a conduit for extending axons. Rather, the process must involve some mechanism that restricts cell mingling. Vital dye-marking experiments have revealed such a lineage restriction mechanism in the hindbrain: clonal descendants of single marked cells disperse widely within the neuroepithelium, but the spreading cell clone always remains within a single rhombomere, confined at its boundaries (Fraser *et al.*, 1990). The vertebrate hindbrain thus shares with insects the phenomenon of modular construction using cell-tight developmental compartments, where lineage restriction prevents cells wandering from one rhombomere to another and blurring the resulting pattern. As we saw above, lineage restriction acts to stabilize the position of morphogen gradients emanating from local signaling centers; emerging evidence suggests that rhombomere boundaries also act as local signal centers, influencing neurogenesis within the rhombomere bodies (Amoyel *et al.* 2005).

What mechanism is responsible for segregating hindbrain cells into compartments? One possibility is that cells of adjacent rhombomeres have a different specification state, involving the expression of surface molecules that would favor affinity between the cells within a rhombomere but reduce affinity for cells in adjacent rhombomeres. Consistent with this, cultured cell aggregate experiments have shown that cells from even-numbered rhombomeres mix evenly with cells from other evens (as do odds with odds), whereas odd and even cells segregate from each other. Thus, rhombomeres may partition according to an adhesion differential, obeying a two-segment repeat rule. Candidate molecules for mediating reduced intercellular affinity or adhesion at rhombomere boundaries include the Eph family of receptor tyrosine kinases and their ephrin ligands (Xu *et al.*, 1999). The receptors are expressed in odd-numbered prerhombomeres, whereas the ligands are expressed in evens. This mutually exclusive pattern means that ligand-receptor interaction can only occur at forming boundaries, where it results in sharpening of the initially fuzzy interface between the adjacent domains (Fig. 14.10). Little is known about how the segmental pattern of the hindbrain is initially set out. Among the few known candidate regulators of segmental pattern is zinc finger protein Krox20, an upstream transcriptional regulator

**FIGURE 14.9** Distribution of motor neuronal types in the chick embryo hindbrain in relation to rhombomeres. Shown on the right side are branchiomotor neurons, forming in r2 + r3 (Vth cranial nerve, trigeminal), r4 + r5 (VIIth nerve, facial), and r6 + r7 (IXth nerve, glossopharyngeal), and contralaterally migrating efferent neurons of the VIIIth nerve (vestibuloacoustic), which are in the floor plate (FP) of r4 at the stage shown. Shown on the left side are somatic motor neurons, forming in r1 (IVth nerve, trochlear), r5 + r6 (VIth nerve, abducens), and r8 (XIIth nerve, hypoglossal). Cranial nerve entry/exit points and sensory ganglia associated with r2 (trigeminal), r4 (geniculate, vestibuloacoustic), r6 (superior), and r7 (jugular) are shown, as is the otic vesicle (ov). Colored bars represent the AP extent of *Hox* gene expression domains; note that one of these, *Hoxb1*, is expressed at a high level only in r4. Modified from Lumsden and Keynes (1989).

of Eph receptors, which is expressed in two stripes in the neural plate that later become r3 and r5.

### Summary

Shortly after closure, the hindbrain neural tube becomes subdivided by transverse boundaries to form rhombomeres, a series of repetitive elements or metameres that have compartment properties. The existence of compartmental organization in the hindbrain suggests that cells become specified in segmental groups during their confinement in the ventricular zone and that they initially share a common identity, or ground state. First a row of similar boxes is formed and then the boxes are assigned individual identities according to their positional value, encoded by *Hox*

genes. The lineage-restricted boundaries between rhombomeres may also act as local signaling centers, influencing neurogenesis.

### AP Pattern of Spinal Nerves

Spinal nerves form a ladder-like array on either side of the spinal cord, an obvious manifestation of segmentation, but here, in contrast to the intrinsic patterning mechanism that operates in the hindbrain, spinal segmentation is imposed extrinsically by somatic mesoderm that lies alongside. A serially reiterated asymmetry in the sclerotomal component of the somites allows axon to grow, and neural crest cells to migrate, only within the anterior half of each somite,

**FIGURE 14.10** Model for neural boundary formation. 1. An initially uniform sheet of cells is polarized by a global signalling gradient (yellow), e.g., by WNT from the posterior pole of the neuraxis. 2. This results in a coarse prepattern of transcription factor expression, with blue induced at low signal level and red at a higher level. 3. Cross-repression between blue and red establishes two distinct populations of cells separated by a fuzzy interface. 4. Cell sorting processes depending on affinity molecules regulated by the red and blue transcription factors then sharpen the interface, generating a sharp interface and reducing adhesion red and blue cells. 5. Boundary cell phenotype involves expression of boundary-specific markers (shaded area). 6. The boundary cells then express signal molecules (green) that spread laterally and induce prepattern-dependent cell fates (yellow, violet). Later (7), postmitotic cells may migrate to new positions in the non-lineage restricted mantle layer. After Kiecker and Lumsden (2005).

where neural crest cells then condense to form dorsal root ganglia (DRG). The posterior half of each somite expresses glycoproteins that inhibit cell migration and cause growth cone repulsion or collapse. Thus, microsurgically substituting posterior halves for anterior halves results in the local absence of peripheral nerves, whereas the converse experiment results in enlarged DRG and motor nerves. Subdivision of the paraxial mesoderm into AP-polarized somites thus ensures a positional correspondence between the segmented dermomyotome on the one hand and its sensorimotor innervation on the other (Fig. 14.11).

Although it lacks intrinsic segmentation and has a superficial uniformity of organization, the developing spinal cord does manifest distinct AP variations in cellular subtype composition, particularly with respect to motor neurons arranged in discontinuous longitudinal columns. Posterior Hox genes have domains of expression in the spinal region that underlie this regional cellular diversity.

### Local Organizers of DV Pattern

The entire neural tube has a characteristic dorsoventral zonation where different cell types differentiate

stereotypically at different DV positions. The ventral midline of the spinal cord, hindbrain, midbrain and diencephalon, is formed by a palisade of specialized glia, the floor plate. Above the floor plate are five zones containing, in ventral to dorsal sequence, V3 interneurons, motor neurons, and three other types of interneuron, V2, V1, and V0 (Fig. 14.13A). Further subtypes of interneuron differentiate in the dorsal half, whereas the dorsal-most region, represented early on by neural folds that mark the transition between cells with neural and epidermal fates, forms the migratory neural crest cells that give rise to the glia and the majority of neurons in the peripheral nervous system. Later, after the neural crest has departed, the dorsal midline is populated by nonneurogenic roof plate cells.

The patterning of neuronal cell types has been studied intensively in the spinal neural tube, but the same molecules appear to be involved in regionalizing the DV axis of more anterior regions of the neuraxis. Unlike the AP axis, where local organizers signal position and fate to neighboring cells through single morphogen gradients, the DV axis has organizers at both dorsal and ventral poles and their respective morphogen gradients appear to counteract one another.

### Ventral Organizers

Crucially involved in patterning the ventral neural tube is the notochord, a mesodermal skeletal structure that occupies the midline of the embryo directly beneath the neuroectoderm. Grafting experiments in avian embryos have shown that both floor plate and motor neuron differentiation depend on notochord signals. Early removal of the notochord results in a normal-sized spinal cord in which both of these ventral cell types are absent, with dorsal cell types and dorsal-specific markers appearing in their place. Similarly, implanting a supernumerary notochord alongside and in contact with the lateral neural plate results in formation of an additional group of floor plate cells at the point of contact, with clusters of motor neurons on either side (Fig. 14.12A). These experiments show not only the power of the ventral midline signal to influence fate choice, but also the multipotent competence of responding neural tube cells at different DV positions. At a slightly later developmental stage, the floor plate itself acquires the same inductive capabilities—it can also induce motor neurons and will induce itself homeogenetically. The floor plate thus becomes an organizing center for a ventral pattern that is built into the neural tube itself.

Although it first appeared that motor neuron and floor plate induction would require different signals, one diffusible and the other contact dependent, a

**FIGURE 14.11** Segmented pathways for motor axon growth and neural crest migration in the trunk region. The AP positions at which motor axons collect to form a ventral root motor nerve and crest cell aggregate to form a dorsal root ganglion (DRG) are determined by somites. By the stage at which these constituents of the peripheral nervous system appear, the medial (sclerotomal) region of somites has dispersed and surrounds the notochord and ventral neural tube. The sclerotome is divided into anterior (light gray) and posterior (dark gray) halves, which are distinct from each other according to cell density and molecular markers. All components of the peripheral nervous system are confined to the anterior half sclerotome of each somite, which is permissive for the migration of neural crest cells (arrows), some of which condense to form DRG, and the ingrowth of motor neuron growth cones.

single molecule can account for both processes (for a review, see Briscoe and Ericson, 2001). *Sonic hedgehog* (*Shh*) is expressed first in the notochord and then in the floor plate and can elicit ectopic floor plate and motor neuron differentiation when misexpressed in the dorsal neural tube. Similarly, an activated form of Smoothened, the signal-transducing component of the SHH receptor, acts in cell autonomous fashion to produce ventral cell types ectopically. Explant studies have shown that the choice of cell fate by progenitor cells is influenced by the concentration of the diffusible Shh protein to which they are exposed: threefold incremental change in Shh concentration can result in the generation of five distinct classes of ventral neural tube cell types in vitro, including, at the higher end of the range, motor neurons, V3 interneurons, and floor plate cells (Fig. 14.13B). Midventral neural plate cells that are contacted by the notochord are thus likely to be exposed to a high local concentration of SHH, exceeding the threshold for floor plate induction, whereas the lower levels of SHH that diffuse from floor plate are sufficient to induce motor neuron and ventral interneuron differentiation, but insufficient to induce the floor plate. Antibodies that block SHH activity abolish the induction of ventral cell types showing that SHH is necessary as well as sufficient for establishing the ventral polarity of the neural tube.

The ability of midline signals to influence development of the ventral neural tube is not restricted to the spinal cord. In addition to inducing motor neurons and floor plate in the hindbrain and midbrain, midline signals also are involved in the development of AP region-specific neuronal subpopulations. Serotonergic neurons of the hindbrain raphé nucleus and dopaminergic neurons of the midbrain substantia nigra both develop close to the floor plate and can be induced to form in competent neuroepithelium by the notochord, floor plate, or SHH protein. The issue of how ventral midline signaling can elicit different responses at different AP positions is considered later.

### Dorsal Organizers

In genetically or surgically notochordless animals, dorsal markers are expressed in the ventral spinal cord, showing that cell pattern in the dorsal half of the spinal cord does not require notochord signals. However, dorsal cell types such as neural crest and roof plate, do not develop by default, but are induced by an interaction that initially takes place between the neuroectoderm and the flanking epidermal ectoderm when the two epithelia are still contiguous (Fig. 14.12B). This dorsalizing activity appears to be mediated by multiple types of BMP protein, which are expressed in

**FIGURE 14.12** (A) Influence of ventral midline signals on spinal cord pattern. Cross sections through the developing chick spinal cord at the neural plate stage and resulting spinal cord, showing the effect of adding or removing notochord. (Left) Normal development: the floor plate (red) develops above the notochord (n) and motor neurons (yellow) differentiate in the adjacent ventrolateral region of the neural tube; *Pax6* (blue) is expressed in more dorsal regions. (Center) Grafting a donor notochord (n') alongside the folding neural plate results in formation of an additional floor plate and a third column of motor neurons. *Pax6* expression retreats from the transformed region. (Right) Removing the notochord from beneath the neural plate results in the permanent absence of both floor plate and motor neurons in the region of the extirpation. *Pax6* expression extends through the ventral region of the cord. (B) Sequence of stages in the formation of DV pattern in the spinal cord and hindbrain. Notochord-derived Shh protein (red) induces differentiation of the floor plate, which also expresses *Shh*. BMPs (dark blue) are expressed in epidermal ectoderm adjoining the neural plate. As the neural plate closes, neural crest cells individuate (light blue) at the junction between neural and epidermal ectoderm. At the early neural tube stage, *Isl1*-expressing motor neuron precursors (yellow) appear close to the floor plate and neural crest cells leave the dorsal tube and midline ectoderm through breaks in the basal lamina. *BMP* expression transfers to the dorsal neural tube. Finally, motor neurons differentiate in the ventral cord. White and yellow arrows denote Shh signaling; black and purple arrows denote Bmp signaling.

the dorsal ectoderm and can mimic the ability of epidermal ectoderm to induce neural crest cells and roof plate differentiation. As for the ventral neural tube, where initial SHH activation is passed on to the floor plate by homeogenetic induction, so for the dorsal neural tube where BMPs are subsequently expressed in the roof plate and dorsal neural tube itself. BMP signaling is then responsible for inducing the several types of interneuron that differentiate at progressively more ventral positions in the dorsal half of the cord (Fig. 14.13A; Helms and Johnson, 2003; Liu and Niswander, 2005).

The DV axis is thus patterned by two counteracting gradients, emanating from the ventral and dorsal poles. At either pole, the transfer of signal molecule expression from notochord or epidermal ectoderm to the neuroepithelium attends the physical separation of the neural tube from the initial source, presumably ensuring a more precise control of concentration within the tube.

### Definition of DV Pattern by Differential Homeobox Gene Expression

At the time of neuronal differentiation, each of the five zones of neuronal cell types in the ventral neural

**FIGURE 14.13** (A) Formation of different cell types at different DV positions in the spinal cord. Sonic hedgehog (SHH) is responsible for generating interneuron (V0 – V3) and motor neuron (MN) diversity in the ventral half of the spinal cord whereas BMPs are responsible for interneuron (D1-D6) diversity in the dorsal half. SHH protein (red), produced by the floor plate, and BMP protein (blue) by the roof plate act as counteracting graded signals, inducing different cell types at different DV positions *in vivo*. (B) Recombinant SHH protein has been shown to induce a similar range of responses and at different concentrations *in vitro*.

tube is defined by the combinatorial expression of homeobox genes. These genes are either induced (*Nkx2.2*, *Nkx6.1*) or repressed (*Pax6*, *Pax7*, *Dbx1*, *Dbx2*) at defined concentrations of SHH protein (Fig. 14.14). The differential responses to a graded SHH signal is thought to set up a pattern of fuzzy zones in the ventral half of the cord, which is later refined and sharpened by cross-repressive interactions between the homeobox genes themselves (see Briscoe and Ericson, 2001): the expression borders of complementary genes are seen to move following gain and loss of function of the opposing gene, as for *Otx2/Gbx2* at the MHB. Such shifts in the expression domains of these and other homeobox genes result in corresponding and predictable changes in neuronal identity, demonstrating the critical role of these homeobox genes as determinants of cell fate.

As for the AP axis, where positional determinants of identity are conserved with *Drosophila*, there are also striking similarities for the DV axis. For example, the homologue of *Nkx2.2*, *vnd*, is expressed close to the ventral midline of the fly embryo and is required for establishing the identity of its ventral-most neuroblasts (Cornell and von Ohlen, 2000).

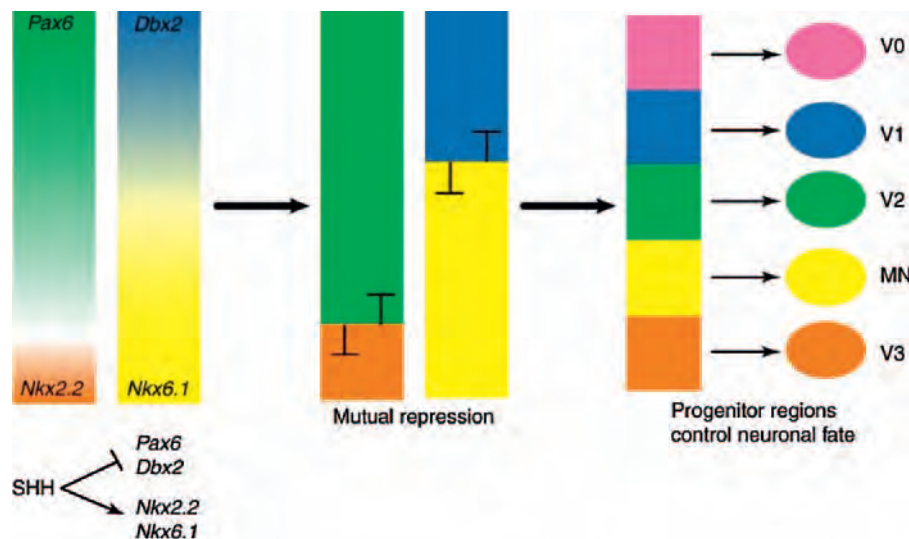

### Summary

Patterned cell differentiation along the DV axis of the neural tube involves the initial medial–lateral polarization of the neural plate and the later generation of distinct cell types at different DV positions

under the spatial control and coordinate actions of an SHH-mediated ventralizing signal from the notochord (later from the floor plate) and BMP-mediated dorsalizing signals from the epidermal ectoderm (later from the roof plate). SHH is both necessary and sufficient for inducing a range of ventral cell types, including floor plate cells, motor neurons and interneurons, at different concentrations—it therefore has the prime characteristic of a morphogen. Patterning along the entire DV axis involves the intersection of opposing signals emanating from the two poles: BMPs act to limit the ventralizing activity of SHH, whereas SHH acts to limit the dorsalizing activity of BMPs.

### Intersection of AP and DV Patterning Mechanisms

The early inductive signals that establish DV cell fate appear to be similar along the entire epichordal neuraxis. However, at a same DV position, there are marked differences in the identity of neurons at different AP positions, such as between oculomotor neurons and dopaminergic neurons of the midbrain and branchiomotor neurons of the hindbrain. That these distinct cell types arise in response to apparently similar levels of SHH signaling suggests that the choice of fate depends on the competence of the responding tissue—SHH must act within the context of previously established AP positional cues and previously specified AP positional values (Simon *et al.*, 1995).

**FIGURE 14.14** Model for ventral neural patterning. (Left) Graded SHH signaling from the ventral pole induces new expression of some homeobox genes (e.g., *Nkx2.2*, *Nkx6.1*) and represses the existing expression of others (e.g., *Pax6*, *Dbx2*). (Center) Cross-repressive interactions between pairs of transcription factors sharpen mutually exclusive expression domains. (Right) Profiles of homeobox gene expression define progenitor zones and control neuronal fate. After Briscoe and Ericson (2001).

## DV Pattern in the Telencephalon

The DV axis of the telencephalon is conspicuously subdivided into a dorsal pallial region, which becomes the neocortex and archicortex (hippocampus) in mammals, and a ventral subpallial region that forms the basal ganglia. While the pallium remains a sheet-like roof over the lateral ventricles, proliferation in the subpallial region thickens the wall considerably, forming two swellings from which the basal ganglia arise: the lateral ganglionic eminence (LGE), which gives rise to the striatum, and the medial ganglionic eminence (MGE), which produces the globus pallidus. The pallial and subpallial moieties of the telencephalic vesicle are segregated by a longitudinal boundary, which marks the domain border of several dorsoventrally expressed developmental control genes and which may also act as a lineage restriction, at least during early stages of development (Fig. 14.15; Schuurmans and Guillemot, 2002; Campbell, 2003).

The telencephalon is devoid of motor neurons, has no floor plate, and is not underlain by notochord. The absence of these midline structures raises the question of how the bilateral organization of the forebrain and the differentiation of its ventral cell types are controlled. It appears, however, that even in this terminal expansion of the central nervous system a common mechanism is used for ventral patterning. SHH expression spreads rostrally in planar fashion from the diencephalic floor region into the ventral tel-

**FIGURE 14.15** Cross section of the telencephalon of an early mouse embryo, with signalling on the left and DV regionalization on the right. Ventromedial patterning of medial and lateral ganglionic eminences (MGE, LGE) is influenced by SHH signalling from the ventral midline. BMPs and WNTs, produced by dorsomedial regions (roof plate, and medial pallium) and later from the cortical hem (CH), are implicated in pallium (P) specification. POA, preoptic area.

encephalon where it induces expression of the transcriptional mediator *Nkx2.1*, characteristic of the MGE (Fuccillo *et al.*, 2006). SHH from the MGE is subsequently required for generation of the more lateral region, the LGE, though some LGE markers, such as *Gsh* are still expressed in *Shh* null mutants. The different responses of medial versus lateral regions appear to reflect a change in the competence of telencephalic cells with time, with the resulting DV pattern reflecting the delay in reception of the SHH signal rather than a difference in SHH concentration. BMP and WNT signals emanating from the roof plate and medial pallium regulate tissue growth and the expression of dorsal telencephalic markers such as *Lhx2*, *Emx1* and *Emx2* (Campbell, 2003).

## Patterning the Cortex

The adult mammalian neocortex, developing from the telencephalic pallium, comprises a very large number of anatomically and functionally discrete areas—more than 50 in human. One difficulty in addressing the question of how the elaborate areal pattern of the neocortex develops is that it is virtually uniform in structure and cytoarchitecture from one end to the other, at least in lower mammals such as mouse and rat. Furthermore, few known developmental control genes are expressed early enough to be candidate area determinants, and none of these is unique to a single prospective area. Thus, it has long been thought that the areal pattern is imposed on the neocortex by extrinsic elements, principally via the thalamic afferents that penetrate the cortex in an area-specific manner. However, it now appears that the cortical neuroepithelium acquires regional pattern prior to afferent innervation and in a manner not unlike other regions of the neural tube, with transcriptional mediators being expressed in a graded fashion in response to a local concentration of morphogens diffusing from focal sources. Putative signaling centers include the ANR, which secretes FGFs, and the posteromedial cortical hem region, which secretes WNTs and BMPs. In the absence of area-specific transcription factors it is likely that areal specification involves threshold levels of transcriptional control genes such as *Emx2* and *Pax6*, which are expressed in opposing gradients along the AP extent of the cortex (Fig. 14.16), and others such as *Lef1* (a mediator of Wnt signaling) that display graded expression from medial to lateral. In support of this, loss of *Emx2* function shrinks visual cortex (posterior) and expands sensory (mid) and motor (anterior) areas, whereas loss of *Pax6* function results in the opposite alteration. Thus, in contradiction to longstanding ideas, the cortical pattern is prob-

## BOX 14.1

## TRANSGENIC MICE AND ENGINEERED MUTATIONS

Rapid and complementary advances in the fields of molecular biology and experimental embryology have combined to offer neuroscience researchers unprecedented power to manipulate the mammalian genome. The technologies used for these manipulations have been worked out primarily in the laboratory mouse and fall into two basic classes: those used for transgenic mice and those used for embryonic stem cell chimeric mice.

Transgenic mice are created by the injection of a cloned DNA fragment into the male pronucleus of a recently fertilized mouse embryo. The fragment will integrate into the host genome and be passed through subsequent mitoses to all the cells of the adult, including the gametes. The integrated DNA fragment, now known as a "transgene," usually is engineered to contain a promoter and associated regulatory sequences, a structural gene, and a 3' polyadenylation signal. Transgenes add to the genome. As a genetic element, the chromosomal site of integration is random, and there is no wild-type allele on the sister chromosome. As an expressed locus, the transgene message is made over and above the endogenous gene expression pattern. This technique can be used as both an analytical and an experimental tool. Used as an analytical tool, the potency of a certain genetic element to direct cell- or tissue-specific gene expression can be determined by using the element to regulate marker genes such as  $\beta$ -galactosidase or green fluorescent protein. The genetic elements that regulate the temporal and spatial expression pattern of *Hox* genes in hindbrain, tyrosine hydroxylase in adrenergic neurons, and L7 in Purkinje cells have all been explored by this means. Used as an experimental tool, transgenes can exploit a genetic element with known specificity to deliver a gene product to an ectopic cell site or developmental time. Thus, the PDGF promoter has been used to drive the expression of human  $\beta$ -amyloid precursor protein, the L7 promoter has been used to deliver diphtheria toxin to differentiating Purkinje cells, and the  $\beta$ -actin promoter has been used to

deliver *Hox-A1* to inappropriate sites in the developing embryo.

Embryonic stem cells (ES cells) are stable cell lines derived from the inner cell mass of the preimplantation embryo. They are totipotent, which means that if they are introduced into a host embryo, they can contribute to all cell types in the resulting chimera (including gametes). The use of homologous recombination in ES cells allows changes to be engineered in specific genetic loci in culture. By using modified cells to create chimeras, changes can be introduced into the mouse germline and propagated as new mutations. The mutations can be insertions, deletions, modifications, or any combination of the three. When the engineered insertion/deletion disables the normal allele, the resulting mutation often is referred to by the slang term "knockout." These techniques alter the genome. As a genetic element, the engineered locus replaces a specific gene locus, and there is a normal wild-type allele on the sister chromosome. Used in this way, a knockout mutation can be used to model an inherited disease. Lesch-Nyhan (HPRT-null), ataxia-telangiectasia (ATM-null), and fragile-X mental retardation syndrome (FMR1-null) have all been modeled in this way. As an expressed locus, the knockout transcript is made instead of the wild-type gene product. This technique can thus be used to create a modified locus such that the targeted gene is mutated rather than destroyed, in the same way an endogenous transcript of one gene can be replaced with that of a different one. Thus, sequences encoding *Engrailed-2* have been inserted into the *Engrailed-1* locus in such a way that the *Engrailed-1* transcript is lost (a null mutation) and *Engrailed-2* is made in its place.

These are only some of the ways in which the powerful new technologies of transgenic and knockout mice are providing powerful genetic tools for use in neuroscience research.

Karl Herrup

ably set up early within the parent neuroepithelium and the role of thalamic innervation is secondary reinforcing, refining, or modifying this initial pattern (Ragsdale and Grove, 2001; O'Leary and Nakagawa, 2002).

## CONCLUSIONS

Neural-inducing factors and modifiers produced during gastrulation have a basic role in establishing an initial crude AP regional identity in the neural plate

**FIGURE 14.16** (A) Regulation of neocortical pattern by local signals: FGF8 (green) from the anterior neural ridge (ANR), WNTs and Bmps (blue) from the cortical hem; and SHH (red) from the medial ganglionic eminence. (B) These and other signals are thought to induce expression of the transcriptional factors *Emx2* and *Pax6* in opposed gradients, that control regional identity. (C) Loss of function of either of these genes results a specific shift of area identity from wild type (left), implying that visual cortex (V1) is specified by *Emx2* [high], *Pax6* [low] and that of motor cortex is specified by *Emx2* [low], *Pax6* [high]. After O'Leary and Nakagawa (2002).

that emerges from the dorsal surface of the embryo toward the end of this period. Abrogation of Wnt signaling, by depletion of ligand or blockade of signal transduction pathways, is important in conferring anterior neural identity. Wnts, Fgfs and RA cooperate to posteriorize the neuraxis. The resulting coarse-grained AP pattern is subsequently refined by the action of local organizers. Acting on both the AP and DV axes local organizers exert regional growth control and either induce or repress transcriptional mediators of regional fate. These mediators, in turn, may also interact among themselves, sharpening domains of action by cross-repression. The combined processes of segmentation and compartmentation provide an alternative or perhaps additional mechanism for sharpening gene expression borders and cellular domains. These events result in the precise delineation of regions and subregions. Although we tend to think of neuraxial patterning as a series of discrete steps leading to greater refinement, it is a continuous process that extends over a protracted period of development and involves a continuity of signaling systems (e.g., RA, FGFs, SHH, BMPs). We have also presented this subject as if pattern is acquired separately on AP and DV axes, whereas it is clear that cell specification on the DV axis must intersect with and act on already existing AP positional values. It is also clear that patterning mechanisms must be integrated with those that control neurogenesis, a topic that is considered in Chapter 15.

## Cellular Determination

In order to make a functional nervous system, the progenitor cells that proliferate throughout the induction and patterning of the neural primordium must eventually exit the cell cycle and differentiate into mature neurons of different types. There are a huge variety of cells types in the nervous system. Differences can be dramatic, such as neurons and glia, or even between types of neurons. Compare, for example, a cone cell in the retina and a cerebellar Purkinje cell. They have completely different shapes, patterns of connectivity, neurochemistry, and physiological characteristics. Differences can also be subtle, such as between types of motor neurons, which may differ only with regard to their axonal projection to different muscles and the synaptic inputs they receive.

The distribution of different types of neuron follows a highly invariant pattern in a given species. Neurons located at a given position within the nervous system are always the same type. In vertebrates, this is true on the level of populations of neurons (e.g., cells of layer III of the cortical area 17 are glutaminergic pyramidal cells projecting to cortical areas 18 and 19); in many invertebrates, it is true even on the level of individual, uniquely identifiable cells. Experimental studies carried out over the last few decades have provided substantial progress in understanding how the right types of neuron develop in the right place in the brain. This chapter attempts to summarize some of the main insights gained into the mechanisms controlling neuronal fate.

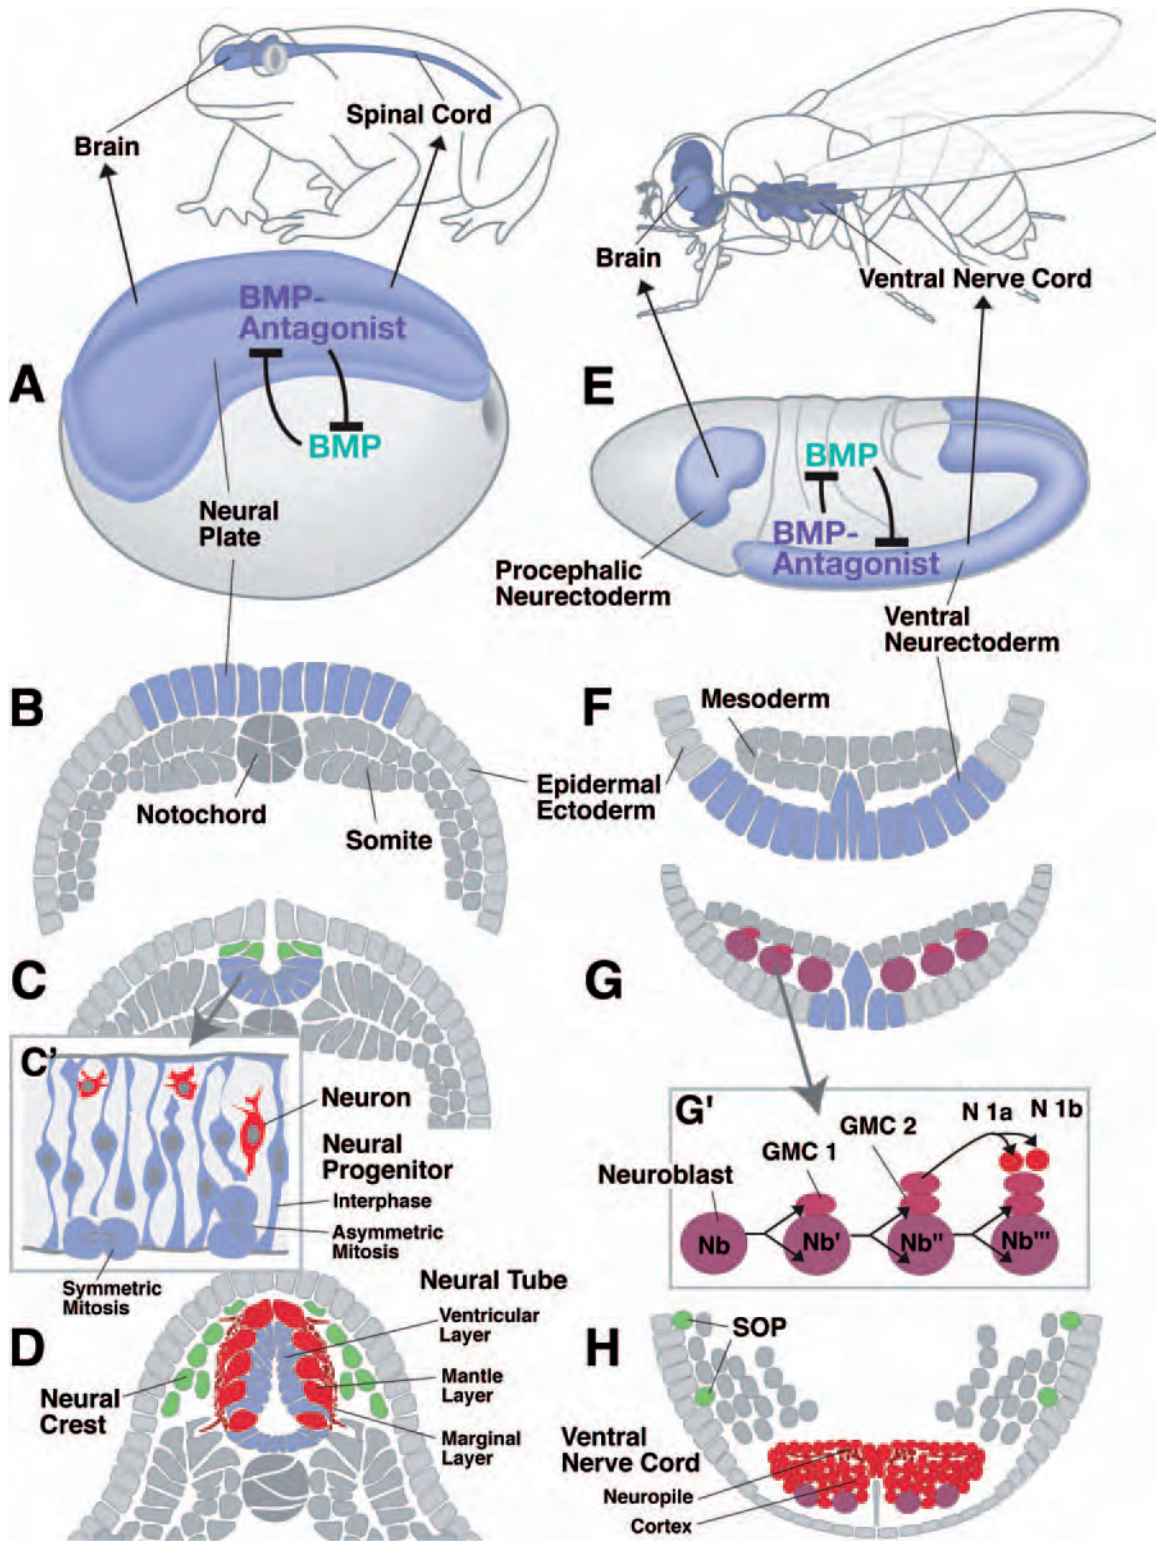

### ORIGINS AND GENERATION OF NEURONAL PROGENITORS

Neurons are specified gradually by a series of fate choices that begin with their distant progenitors who make the first decision between neural and ectodermal

fates. Progenitors of the nervous system arise from specialized regions of the ectoderm called the neurectoderm (Fig. 15.1A). A highly conserved molecular network, which includes the localized expression of BMP signaling molecules and their antagonists, specifies the size and position of these regions (Stern, 2006). In vertebrates, BMP is expressed in the ectoderm of the gastrulating embryo (Fig. 15.1A). Target genes of BMP signaling promote the differentiation of epidermis, one of the two major organ systems that develop from the ectoderm. BMP signaling is inhibited by BMP-antagonists, notably chordin and noggin, which are secreted from the dorsal part of the mesoderm, the so-called organizer. Ectoderm cells within reach of BMP antagonists do not embark on the epidermal pathway of differentiation. They instead develop as neurectoderm. In vertebrates, the determined neurectoderm, called the neural plate, invaginates to become the elongated, dorsally located neural tube from which brain and spinal cord develop (Fig. 15.1A–D).

In many invertebrates, including the fruit fly, *Drosophila*, most of the neurectoderm is located on the ventral side of the ectoderm (Fig. 15.1E) and gives rise to a ventral chain of segmental ganglia, called the ventral nerve cord, which is comparable to the vertebrate spinal cord, and the posterior part of the brain, which is comparable to the vertebrate hindbrain. The anterior brain of the fly, which is comparable to the mid/forebrain of vertebrates, is derived from the procephalic neurectoderm (Fig. 15.1E).

The neural tube of a vertebrate embryo forms a continuous epithelium that lines an inner lumen (ventricle; Fig. 15.1C,D). Cells of the neural tube first divide symmetrically in the plane of the epithelium (Fig. 15.1C'). After variable periods of time, they spin off postmitotic daughters that differentiate into neurons and glia. The generation of postmitotic neurons in some parts of the vertebrate neuroepithelium, such as

**FIGURE 15.1** Synopsis of early neural development in vertebrates (example: the amphibian *Xenopus laevis*; A–D) and insects (example: the fruit fly *Drosophila melanogaster*; E–H). (A and E) Dorso-lateral views of embryos at the onset of neurulation. The neurectoderm is shaded light blue. The expression of the signal bone morphogenetic protein (BMP) and its antagonists is indicated. (B and F) Schematic cross-sections of embryos depicted in A and E. (C and G) Cross-sections at a later stage when neurulation is well under way. In vertebrates, the neural plate folds in to become the neural tube. Cells at the junction between the neural tube and the epidermal ectoderm (green) form the neural crest, which gives rise to the peripheral and autonomic nervous systems. The neural tube is a proliferating neuroepithelium (C'); symmetric mitoses increase the number of epithelial neural progenitor cells, asymmetric mitoses result in daughter cells that delaminate from the epithelium and become neurons (red). In insects, individual neural progenitors (neuroblasts; purple) delaminate from the neurectoderm. They divide in a stem cell mode (G'), producing stacks of daughter cells called ganglion mother cells (GMC). Each ganglion mother cell divides into two neurons (e.g., N1a and N1b). (D and H) Cross-sections of late embryos in which some neurons (red) have differentiated. In vertebrates, these neurons form the mantle layer that surrounds the neuroepithelium, now called ventricular layer. Neurites gather at the outside of the neural tube (marginal layer). In insects neuronal cell bodies form an outer layer (cortex); neurites gather in the center, forming the neuropile. Progenitors of the peripheral nervous system (sensory organ progenitors (SOPs); green) segregate from different locations in the epidermis.

the cortex, has been seen to be associated with asymmetric cleavages. The cell that remains next to the ventricle continues to divide as a neuroepithelial progenitor cell, while its sibling exits the cell cycle and migrates toward the outer surface of the neural tube (Fig. 15.1C'). Here young neurons form dendrites and axons. At this stage, the nervous system has reached a three-layered configuration of a ventricular layer, mantle layer, and marginal layer (Fig. 15.1D).

Progenitors of the central nervous system of *Drosophila*, called neuroblasts, separate from the neurectoderm and move inside the embryo as individual cells (Fig. 15.1G). Other ectodermal cells, which stay behind after the neuroblasts have migrated, are called dermoblasts and give rise to the epidermis. Mitotic divisions of *Drosophila* neuroblasts are asymmetric throughout development. Thus, each neuroblast divides unequally into one large and one small daughter cell. The large cell remains as a neuroblast and continues to divide asymmetrically for a number of rounds (Fig. 15.1G'). The small cell, called the ganglion mother cell (GMC), typically divides one more time and both of its daughter cells differentiate into mature neurons. Often, GMCs and immature neurons form a stack on top of the neuroblast from which they originated. Postmitotic neurons generally do not migrate, so the progeny of a neuroblast remain spatially close to one another, with the position of each neuron dependent on the position of the neuroblast and the time at which it was born. Thereby, a two-layered cortex-neuropil architecture typical of the mature ganglion is generated (Fig. 15.1H).

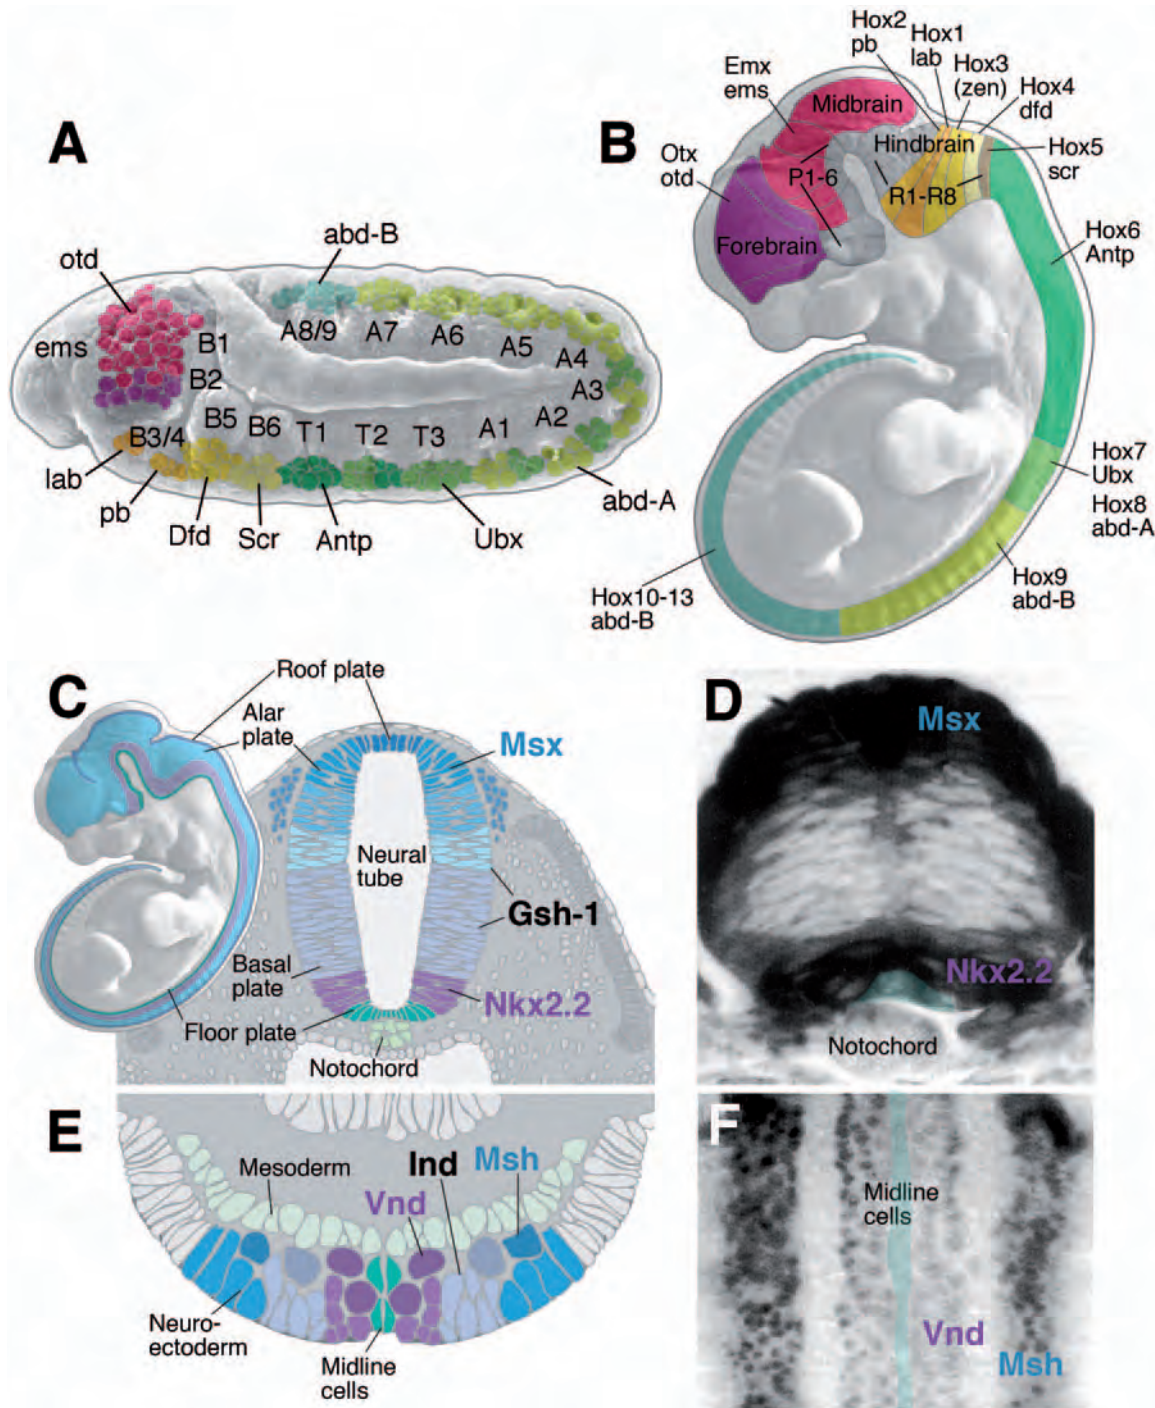

## SPATIAL AND TEMPORAL COORDINATES OF NEURONAL SPECIFICATION

Neurogenesis proceeds quite differently in different parts of the neural primordium. For example, neuro-

epithelial cells in the anterior part of the vertebrate neural tube (which includes the forebrain) undergo many more rounds of division than those of the posterior part (spinal cord). In addition, the maturing neurons have distinct phenotypes and establish different types of connections depending on where they are located. When pieces of neural tube are transplanted to new positions, features such as proliferative potential and cellular phenotype often are carried to the new position, implying that, in the neural primordium, intrinsic determinants profoundly influence the fate of neural progenitors. These determinants subdivide the neural primordium into a “geographic map” with many different domains, each one characterized by a unique identity. The mechanisms underlying the spatial regionalization, discussed in more detail in Chapter 14, are intricately involved in neural fate specification.

Along its anterior-posterior axis the neural tube is subdivided into transverse domains that give rise to morphologically defined partitions of the CNS, including the spinal cord, hindbrain, midbrain, and forebrain (Fig. 15.2B). Each of these major sections of the neural tube becomes further partitioned into neuromeres, each neuromere delineated by its own peripheral nerve. In the spinal cord of mammals, one distinguishes seven cervical (neck) neuromeres whose neurons innervate the upper extremity, 12 thoracic neuromeres, five lumbar neuromeres belonging to the lower extremity, and a variable number of sacral neuromeres. Seven or eight neuromeres are present in the hindbrain, where they are called rhombomeres. Similar to spinal neuromeres, rhombomeres are characterized by the pattern of peripheral nerves they emit. The midbrain is thought to represent a single neuromere. The forebrain possesses no peripheral nerves; however, based upon other morphological landmarks, as well as the expression of molecular markers, it is subdivided into six prosomeres. The posterior three prosomeres (P4, P5, and P6) give rise to the diencephalon and prosomeres 1, 2, and 3 form the telencephalon.

Along this anterior-posterior axis, Hox genes, which code for Homeobox transcription factors, and segment polarity genes (Chapter 14) are expressed in sharply demarcated domains in the neural primordia of both vertebrates and invertebrates. These genes provide neural progenitors with intrinsic “spatial information” that reflects their location along this axis (Fig. 15.2A,B).

Each neuromere is characterized by the expression of a distinct set of homeobox genes (a “Hox code”) and thereby acquires its unique anterior posterior identity. Thus, knock out of a Hox gene in posterior segment of the nervous systems transforms the neurons there into more anterior types, whereas ectopic activation of these genes has the opposite effect. The Hox genes are

**FIGURE 15.2** Specification of regional identity of the neural primordium. (A and B) Homeobox genes control regional identity along the antero-posterior axis. (A) *Drosophila*. The neuroectoderm and neuroblast layer is subdivided into a series of neuromeres, each of which gives rise to a segmental ganglion. Transcription factors of the Hox family are expressed in blocks of neuromeres and provide neuroblasts with a segment-specific identity. In the segments of the abdomen (A1–A9), thorax (T1–T3), and posterior head (B3–B6) genes of the Hox complex are expressed (*lab, pb, Dfd, Scr, Antp, Ubx, AbdA, AbdB*); head gap genes (*otd, ems*) are found in the anterior head (B1–2). B: Mouse. Homologous Hox genes and Head gap genes are expressed in sets of vertebrate neuromeres in the same antero-posterior sequence (P1–P6: prosomeres of forebrain; R1–7: rhombomeres of hindbrain). *Otx* is expressed in the dorsal telencephalon (P1–3) that gives rise to cerebral cortex. *Emx* defines alar plate of prosomeres 4–6, that will form the dorsal thalamus and ventral thalamus, as well as the dorsal midbrain. Hox genes are expressed in hindbrain and spinal cord. Note that for the Hox genes, the level indicated represents the anterior boundary of a wider domain that extends posteriorly for an unspecified distance. (C–F) Regional identity along the dorso-ventral axis. (C and D): Vertebrate. The neural tube (shown in C for mouse) is subdivided into four domains, the floor plate, basal plate, alar plate, and roof plate. Floor plate and roof plate do not give rise to neurons. The basal plate produces motoneurons and interneurons. Interneurons formed by the alar plate are the target of sensory input to the spinal cord and brain. The Homeobox gene *Nkx2.2* is expressed in the ventral part of the basal plate; *Msx* is expressed in the dorsal part of the alar plate. The expression of these two genes in a cross-section of the zebrafish spinal cord are shown in (D). A third homeobox gene, *Gsh-1*, is expressed at a lateral level in between *Msx* and *Nkx2.2*. (E and F) Homologs of these genes are expressed in the same dorso-ventral succession in *Drosophila*. The schematic cross-section of the fly neuroectoderm (E) shows that the *Nkx2.2* homolog *Vnd* forms a medial stripe adjacent to the midline cells; *Ind* (homolog of *Gsh-1*) and *Msh* (homolog of *Msx*) are expressed at an intermediate and lateral level, respectively. Panel F shows a ventral view of a wholemount *in situ* preparation demonstrating the expression of *Vnd* and *Msh*.

arranged in evolutionarily conserved genetic complexes, such that the more anterior and more posterior parts of the nervous system are specified by homologous Hox transcription factors. This is dramatically evident in animals where the patterning of the nervous system has been studied in detail such as *Drosophila* and mice (Fig. 15.2).

The dorsal-ventral axis of the neuroectoderm in both vertebrates and *Drosophila* is divided up by the expression of three conserved homeodomain transcription factors, called, *vnd*, *ind*, and *msh* in flies, which are expressed in longitudinal stripes along the extent of the neural primordium (Cornell and Ohlen, 2000). In *Drosophila*, *vnd* gene expression specifies the neuroblasts close to the ventral midline, *msh* specifies the neuroblasts in the most dorsal domain and *ind* neuroblasts in an intermediate stripe (Fig. 15.2E,F). These dorsal-ventral genes are, like the Hox genes, functionally conserved in evolution such that in the vertebrate neural tube, the more ventral regions are specified by the *vnd*, *msh*, and *ind* homologues *Nkx2.2*, *msx1/2*, and *Gsh-1*, respectively (Fig. 15.2C,D). The expression of dorsal-ventral genes subdivides the vertebrate neural tube into four longitudinal domains, called the floor plate, basal plate, alar plate, and roof plate. The floor plate is characterized by expression of the Sonic hedgehog (Shh). The basal plate next to the floor plate includes all motor neurons. In the lateral wall of the neural tube, a furrow called sulcus limitans separates the basal plate ventrally from the alar plate dorsally. The alar plate later gives rise to the dorsal sensory column.

Although the mechanisms that originally set up the polarity of the Hox gene expression in flies and vertebrates are quite distinct, it appears that high dorsal

concentrations of the signaling molecule BMP in vertebrates, or its equivalent *Dpp* in *Drosophila*, is key to establishing the relative domains of these dorsal-ventral specifying transcription factors (Mizutani *et al.*, 2006), although in vertebrate the ventral gradient of Shh also has an important role in specifying particular fates (see section on motor neuron determination, later). In addition, in both vertebrates and invertebrates, these spatially arrayed transcription factors of the anterior-posterior and the dorsal-ventral axes collaborate to divide the developing nervous system into a grid of molecular coordinates that specify the positional identity of neural progenitors down to the level of small groups or, in some invertebrates, even single cells.

Neurogenesis is patterned in time as well as space. This is exemplified in *Drosophila* neuroblasts, which go through a program of proliferation where each neuroblast gives rise to a series of distinct GMCs. The first GMCs of a neuroblast lineage tend to lie deeper in the CNS and usually generate neurons with long axons, whereas the later arising GMCs stay closer to the edge of the CNS and produce neurons with short axons. In the stages when the first GMCs are generated, most neuroblasts express *hunchback* (*hb*), and GMCs that arise at this time inherit this *hb* expression. Later, the same neuroblasts turn off *hb* and express *Krüppel* (*Kr*) instead, and GMCs generated at this stage inherit *Kr* expression. Experiments in which *hb* or *Kr* is eliminated or expressed at the wrong time lead to predictable switches in the fates of early and later born descendants of these neuroblasts (Isshiki *et al.*, 2001). Another gene that contributes to temporal patterning is called *Chinmo*, named for *chronologically inappropriate morphogenesis*. The identity of neurons issuing from a particular neuroblast can be advanced or retarded by

reducing or increasing the expression of *Chinmo* (Doe, 2006). It is likely that a temporal succession of transcription factors like those in *Drosophila* also pattern neurogenesis in vertebrates.

The expression of both spatially and temporally coordinated transcription factors in neuroblasts, preserved in their progeny, forms part of the rich intrinsic inheritance that influences the phenotype of each developing neuron.

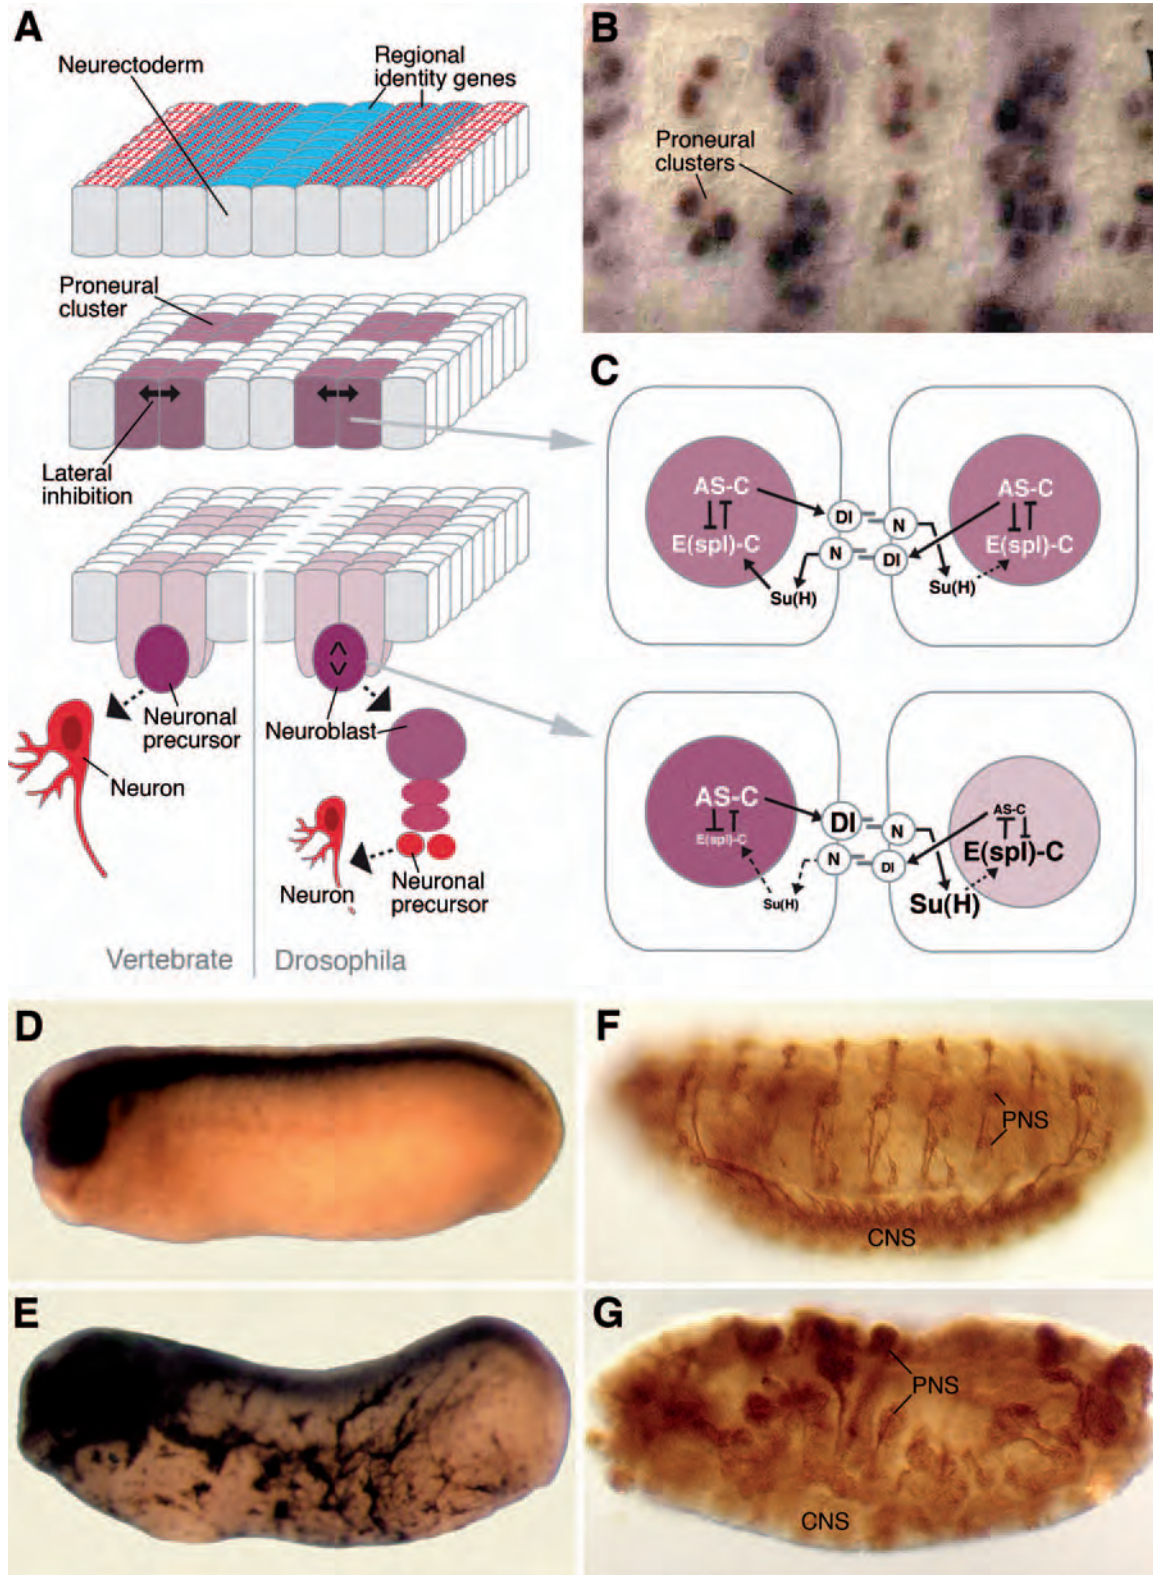

## THE PRONEURAL AND NEUROGENIC GENES

The neurectoderm of *Drosophila* is a mixed population of cells. Only some of these cells become neuroblasts; others develop as dermoblasts. Cell–cell interactions that take place within the neurectoderm define the number and pattern of neuroblasts. Experimental and genetic studies suggest a two-step mechanism for this process (Campos-Ortega, 1995). First, discrete groups of neurectodermal cells are made competent to become neuroblasts. These groups of cells, called proneural clusters, represent “equivalence groups” in which all cells initiate a neural rather than an epidermal fate (Fig. 15.3A,B). In *Drosophila*, a group of proneural genes expressed in the proneural clusters is responsible for making these cells competent to

become neural progenitors. In a second step, cells of the proneural cluster interact to sort out which of them will become neurons and which will fall back to become dermoblasts (Fig. 15.3A). As the first cell in each cluster begins to differentiate as a neuroblast, it sends out inhibitory signals to its neighbors, inhibiting them from also becoming neuroblasts. If the delaminating neuroblasts are ablated by a laser microbeam, then neighboring cells of the equivalence group, which would otherwise have developed into dermoblasts, replace the lost neuroblast. Genetic studies in *Drosophila* led to the discovery of a group of genes, called neurogenic genes, which mediate this inhibitory cell–cell interaction.

Most proneural genes are transcription factors of the basic helix-loop-helix (bHLH) family. In *Drosophila*, four of these genes form a complex called the achaete-scute complex (AS-C). Loss of proneural gene function leads to a reduction of neuroblasts. The neurogenic genes encode a cell communication mechanism that is activated within the proneural clusters and that acts to restrict the number of neural progenitors developing from each cluster to one or a few cells. The neurogenic genes *Notch* and *Delta* encode membrane proteins that function as signal and receptor, respectively. Activation of Notch by Delta sets in motion a signal transduction cascade (Fig. 15.3C) that involves another neurogenic gene called *suppressor of hairless* (Su(H)). Su(H) forms a complex with the intracellular domain

**FIGURE 15.3** Function of proneural and neurogenic genes in neural development. (A) The sequence of events that leads to the segregation of individual neural progenitors (in insects) or neurons (in vertebrates). First, proneural genes are turned on in discrete cell populations, called proneural clusters (purple). In *Drosophila*, a number of genes (called “regional identity genes” in the diagram) have been identified. They are expressed in distinct pattern of transverse and longitudinal stripes before proneural genes appear and are proven or likely factors to control the expression of proneural genes. Proneural genes in turn trigger different events in the proneural clusters. One outcome of their expression is a cell–cell interaction process, mediated by the neurogenic genes, that selects a single cell (or a smaller group of cells) from each proneural cluster. Only this cell continues along the neural pathway and segregates from the neurectoderm as a neuroblast (right side of panel; intense purple), which divides and produces a neural lineage (red); the other cells of the proneural cluster remain within the neurectoderm. In vertebrates (left side of panel), the entire neurectoderm (i.e., the neural plate/neural tube) is formed by neural progenitors. Here, the proneural/neurogenic gene cassette seems to select cells that become postmitotic and differentiate from other (neural progenitor) cells, which remain in the neuroepithelium and continue to proliferate. (B) Detail of proneural gene expression in the neurectoderm of the *Drosophila* embryo (from Skeath and Carroll, 1992). (C) Interaction between proneural and neurogenic genes in the *Drosophila* neurectoderm. The upper panel shows two cells of a proneural cluster in which proneural genes of the *achaete-scute* complex (AS-C) are expressed. Genes of the AS-C activate the expression of the signaling molecule Delta (Dl). Dl activates the receptor Notch (N) in neighboring cells; this leads to cleavage of the N molecule and the translocation of the cytoplasmic domain of N along with the transcription factor Suppressor of Hairless (Su(H)) to the nucleus, where they upregulate the expression of proteins of the Enhancer of split complex (E(spl)-C). E(spl) initiates or maintains the development of an undifferentiated neurectodermal cell; at the same time, it directly inhibits the expression of AS-C genes, which promote differentiation of a cell as a neural progenitor or neuron. Imbalances introduced by an unknown mechanism into the levels of AS-C or E(spl)-C expression, respectively, are rapidly amplified (lower half of C) and lead to the segregation of a single neural progenitor (high levels of AS-C) from other cells that stay epithelial (high levels of E(spl)-C). (D-G) The proneural gene turns epidermal cells into neurons. (D) A normal *Xenopus* embryo stained for the neural marker NCAM shows no staining in the epidermis. (E) A neuroD-injected embryo has NCA-stained cells with neuronal morphology in the entire epidermis (F) Wild-type *Drosophila* embryo labeled with the neuronal marker 22C10 contains discrete clusters of neurons forming the central nervous system (CNS) and peripheral nervous system (PNS). (G) Loss of the signaling molecule Dl causes a massive increase in neurons at the expense of epidermis.

of Notch, which is released from the membrane when the pathway is activated. This complex moves into the nucleus and activates the *E(spl)-C* genes. E(spl)-C proteins are bHLH transcription factors that antagonize and repress the proneural bHLH genes, completing an inhibitory feedback loop. Loss of function of any of the neurogenic genes results in a higher number of neural progenitors, at the expense of dermoblasts (Fig. 15.3F,G).

Several AS-C homologues (*ASH* genes) have been identified in vertebrates. Likewise, multiple homologs of the *Drosophila* proneural gene *atonal* (*ato*) exist in vertebrates. In *Xenopus*, injection of *XASH-3* mRNA into blastomeres leads to an increased number of neural progenitor cells in the neural tube. In similar experiments, an *atonal* bHLH proneural homologue, called *neuroD*, powerfully transforms epidermal cells into neurons (Fig. 15.3D,E). Conversely, knockout of *ASH* genes in mouse or zebrafish leads to the absence of populations of neural cells. Homologues of the neurogenic genes *Notch*, *Delta*, *Su(H)*, and *E(spl)-C* also have been identified in all vertebrates. In *Xenopus*, injection of active forms of *Notch* or *Delta* mRNAs resulted in decreased formation of primary neurons. Lack of *Delta* function has the opposite effect, increasing the formation of primary neurons at the expense of neuroepithelial cells.

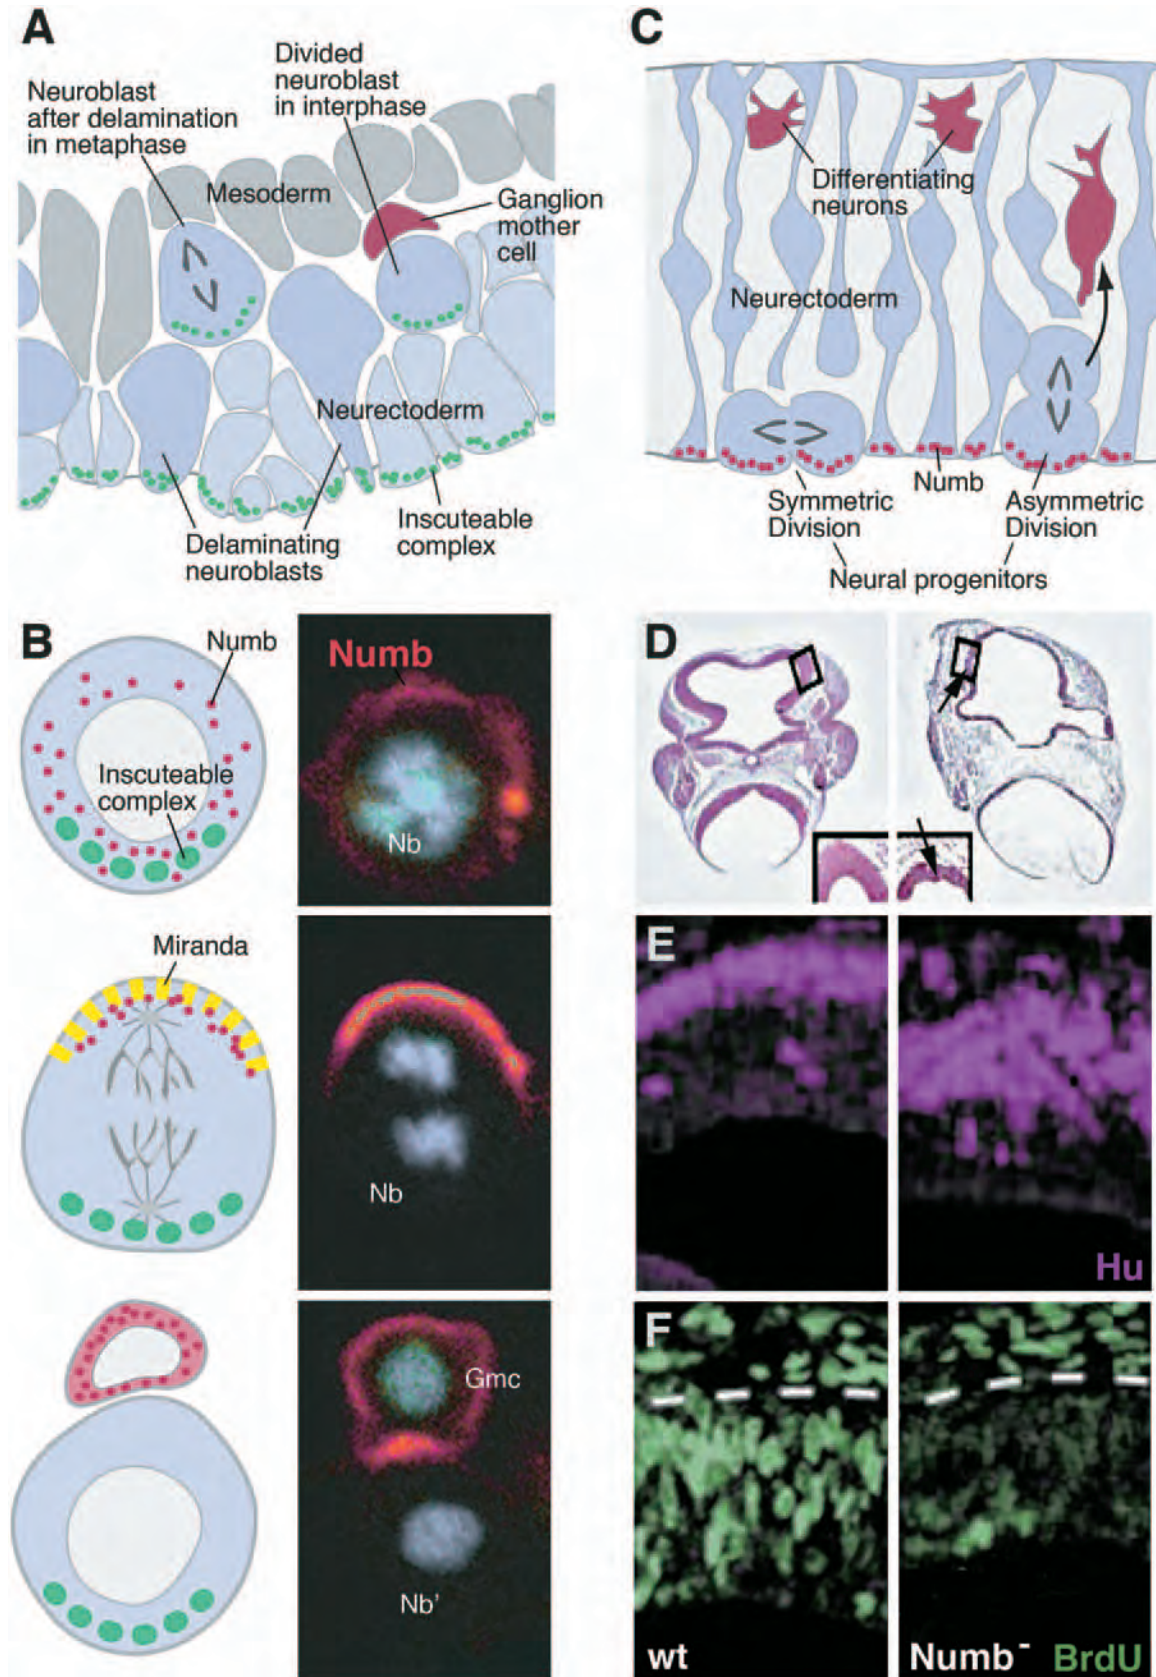

### ASYMMETRIC CELL DIVISION AND CELL FATE

Neuroblasts divide asymmetrically and differentially distribute intrinsic determinants to their two daughter cells to produce distinct fates, a large neuroblast that remains in the neuroectoderm to divide again and again, and a small GMC that moves further anteriorly and divides just once more to produce post-mitotic neurons.

The initial positions of the two different daughters give a clue to the way in which asymmetric divisions happen. The machinery involved in asymmetric cell division (Betschinger and Knoblich, 2004) involves a number of proteins at the apical cortex of the neuroblast (Fig. 15.4A). One of the key proteins is the membrane-associated Inscuteable (*Insc*) protein, and so the whole complex of proteins, which includes a protein called Partner of Inscuteable (aka Pins), is called the Insc complex. Pins locally activates a G-protein-coupled pathway that attracts one of the centrioles toward this complex. The result of this is that the axis of the division plane is apicobasal. The different fates of the apical neuroblast and the basal GMC are due to the differential inheritance of cytoplasmic determinants, Numb and Prospero, which move to the basal pole of the parent neuroblast just before cytokinesis (Fig. 15.4B). As Numb is a negative regulator of the Notch pathway (discussed earlier), and Prospero is a homeodomain transcription factor that specifies GMC fate, the fact that these proteins end up in the GMC and not the neuroblast make the fates of these two cells very different.

In the vertebrate CNS, neuroepithelial cells first tend to divide symmetrically, giving rise to two dividing progenitor cells, but as neurogenesis proceeds, some neuroepithelial cells, like *Drosophila* neuroblasts, begin to divide asymmetrically, in this case giving rise to one neuroepithelial progenitor and one differentiated neuron. Time-lapse observations of neuroepithelial cells in organotypic slices of the developing mammalian cortex show that divisions along the horizontal plane produce two cells that stay in contact with the ventricular (apical) surface, whereas more apicobasal divisions produce a basal daughter that migrates away from the ventricular surface while the other daughter remains in contact, consistent with it retaining a neuroepithelial fate (Fig. 15.4C) (Chenn and McConnell, 1995). Homologues of the *Drosophila* genes

**FIGURE 15.4** Control of asymmetric cell division in neural progenitors. (A) Schematic section of *Drosophila* neuroectoderm at the stage of neuroblast delamination. The Inscuteable protein complex (green) is expressed apically in the neuroectoderm and is carried interiorly by delaminating neuroblasts. (B) Schematic (left) and microphotograph (right) of neuroblast before (top), during (middle), and after (bottom) mitosis. The Inscuteable complex controls asymmetric distribution of intrinsic fate determinants, such as Numb (red), by orienting the mitotic spindle vertically and by localizing the Miranda protein (yellow) basally. Miranda traps Numb at the basal pole of the dividing neuroblast (middle panel) and thereby channels it into the ganglion mother cell (bottom panel). (C) Schematic cross-section of the mouse neuroepithelium. The mouse Numb homolog, mNumb, is expressed apically in neural progenitors (red). In asymmetric divisions, mNumb is maintained only in the epithelial daughter cell and not the delaminating neural precursor (right). D–F: Loss of mNumb (right panels) results in loss of progenitors compared to wild type control (left panels). All panels show part of cross-sections of the neural tube. (D) Histological section shows overall thinning of the ventricular layer (compare insets in the two photographs). (E) The differentiation marker Hu reveals that most neuroepithelial cells of the mutant have started to differentiate, as opposed to wild type where only cells of the mantle layer express this molecule. (F) BrdU incorporation visualizes dividing progenitors, which are strongly reduced in the mutant compared to wild type (from Petersen *et al.*, 2002).

involved in asymmetric cell divisions work similarly in vertebrates. mInsc is the mammalian homologue of Insc and ASG3 is the mammalian homolog of Pins. Interfering with the expression or function of these homologues leads to the loss of apicobasal spindle orientation in the mammalian nervous system, resulting in too many cells dividing in the horizontal plane. In the mouse retina this causes the production of large clones arising from neuroepithelial cells, which can be explained if these cells divide symmetrically to produce two progenitors rather than one. The mammalian homologue of Numb may also play a key role in the distinct fates of daughter cells, as knockout mice suggest that mNumb is essential for cortical neuroepithelial cells to remain in a progenitor state (Fig. 15.4D,E, F) (Petersen *et al.*, 2002).

The orientation of division can thus have an important role in determining cell fate, though which specific fates, of course, depend on where and when these cells arise. Interestingly the environment plays a role in the orientation of cell division lineages, and recent studies in both insects and vertebrates have shown that extrinsic signals, perhaps coming from recently postmitotic cells, can influence the plane of cleavage of a neighboring progenitor. This is one mechanism by which the specific types of neuron may work through a feedback control mechanism to control the appropriate number of neurons of a particular type.

## CENTRAL NEURONS AND GLIA

The nervous system is composed of two main classes of cells: neurons and glia. In both vertebrates and invertebrates, the application of lineage tracers to individual progenitors often yields clones that contain both neurons and glia, suggesting that these two quite distinct cell types often are produced from a common progenitor, a “neuroglioblast.”

In *Drosophila*, intrinsic determinants of glial fate are expressed at an early stage in neuroglioblasts (Jones, 2005). Two genes encoding transcriptional regulators, *glial cells missing* (*gcm*) and *reversed polarity* (*repo*), are expressed in most glial precursors in insects. Their crucial involvement in glial fate is attested to by the fact that ectopic expression of these genes converts neurons into glial cells and that loss-of-function mutants lack glial cells. *Gcm* is expressed first and activates *Repo* by direct binding to the *repo* promoter. The directed expression of *gcm* in glial precursors has been studied in a neuroglioblast called NB6-4 (Akiyama-Oda *et al.*, 2000) (Fig. 15.5A). Following delamination from the neuroectoderm, this neuroglio-

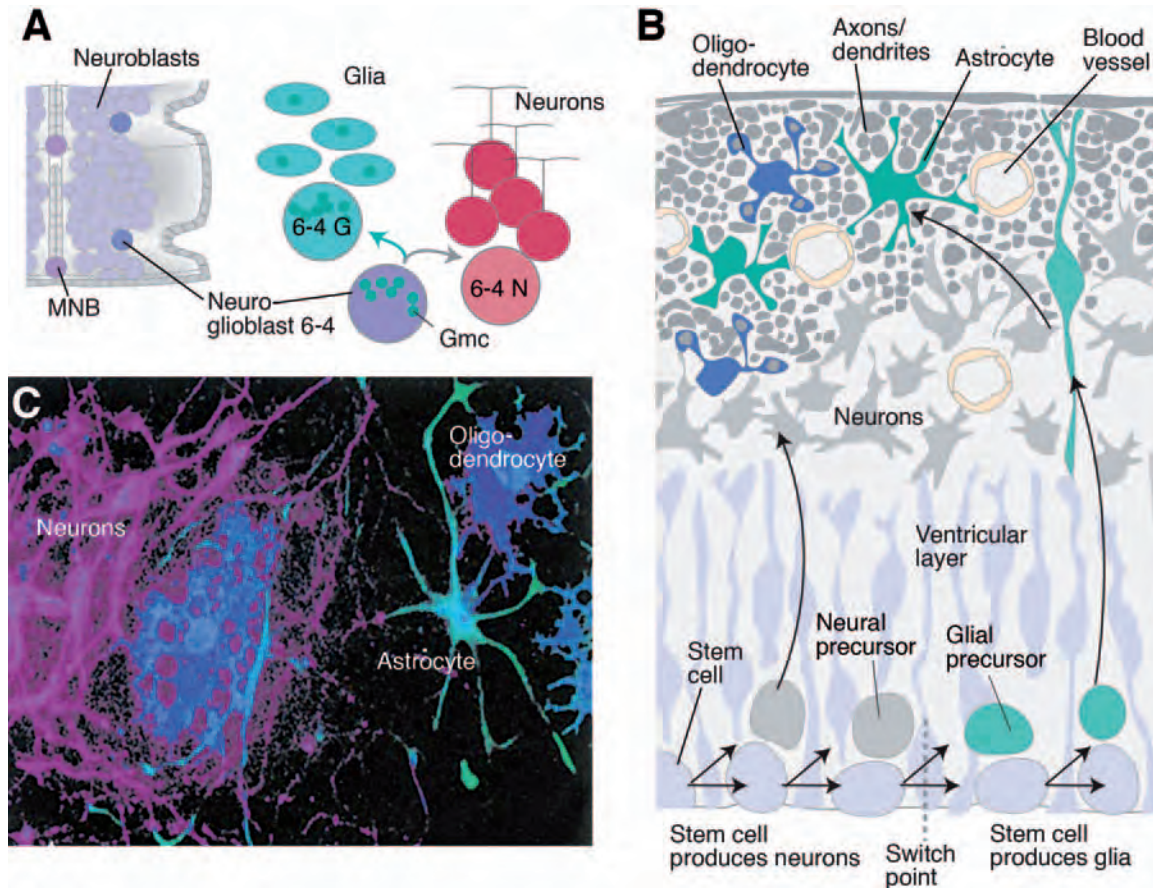

blast cell divides asymmetrically using the Insc complex to localize the *Gcm* protein to the medial side of NB6-4. The medial daughter of this division “inherits” this glial determinant and develops as a pure glioblast, NB6-4G. The other daughter, NB6-4N, which does not receive *Gcm* protein at this division, acts as a “pure” neuroblast.

In the central nervous system of vertebrates, multipotent stem cells often give rise to glia such as oligodendrocytes, as well as neurons (Fig. 15.5B,C). It is usually the case that neurons arise first and glia latter. Time-lapse studies of these stem cells in culture show that they tend to go through several rounds of division that give rise to neuroblasts, and then they suddenly make a transition to divisions that generate glioblasts (Qian *et al.*, 2000) (Fig. 15.5B). PDGF is a mitogen for the oligodendrocyte precursors in the spinal cord and the receptor for this mitogen is specifically expressed in a restricted ventral domain of the neural tube that gives rise to the oligodendrocytes. The oligodendrocyte specific transcription factors, *Olig1* and *Olig2*, are expressed in this same ventral domain. Interestingly, however, motoneurons also arise from this domain suggesting that the same progenitors make both motoneurons and oligodendrocytes. Indeed, cells that express *Olig1* initially also express *Neurogenin2*, a proneural bHLH transcription factor (Kessar *et al.*, 2001; Zhou *et al.*, 2001). These progenitors that express both *Neurogenin 2* and *Olig1* generate motoneurons. Later in development, the expression domain of *Neurogenin 2* moves dorsally and no longer overlaps with the *Olig1/2* expression domain. When this happens, the neuroepithelial cells in this region express *Olig1/2* and not *Neurogenin 2* and thus start producing glia.

The Notch signaling pathway also plays an important role in gliogenesis. Transient activation of Notch promotes the differentiation of glia in the CNS. Activation of the Notch pathway suppresses the transcription of proneural bHLH transcription factors like *Neurogenin 2*, and unblocks the transcription of factors that are necessary for gliogenesis.

## SENSORY NEURONS OF THE PERIPHERAL NERVOUS SYSTEM

Sensory neurons, which are by and large peripheral, do not arise from neuroectodermal regions that generate the CNS. With the exception of the eye, all sensory organs of the vertebrate are derived from sensory placodes and neural crest. A placode is a morphologically visible thickening of an epithelium that often subse-

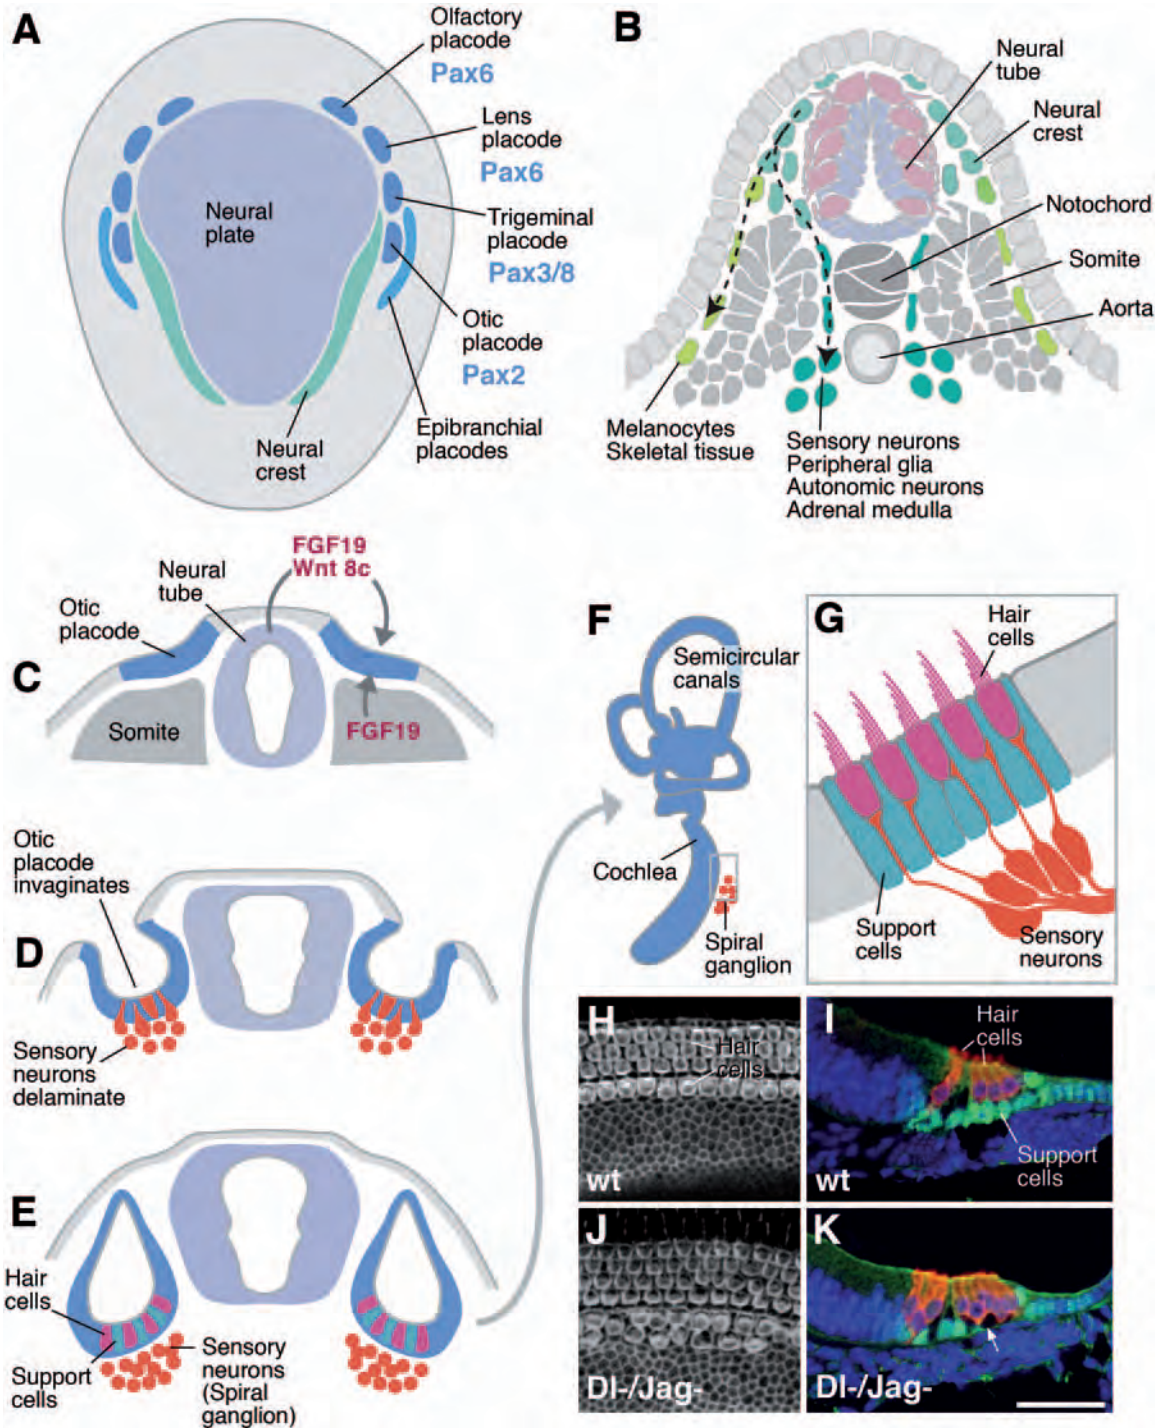

**FIGURE 15.5** Specification of glial lineages. (A) Position of two identified neuroglioblasts, Nb6-4 and MNB, in the *Drosophila* neuroblast map (left). Nb6-4 expresses the glial regulatory protein, Gmc (green). When this cell divides into two daughter cells, 6-4 G and 6-4 N, the In-scuteable complex and Miranda segregate Gmc into 6-4 G, which thereby becomes specified as glioblast. 6-4 N generates neurons. (B) Glial cell development in vertebrates. Diagram shows cross-section of neural tube containing neurons and two main types of glial cells, astrocytes and oligodendrocytes. Oligodendrocytes form processes that wrap around axons and give rise to the myelin sheath. Astrocyte processes connect to capillaries and neurites. Glial progenitors and neural progenitors are derived from the same pool of stem cells that divide in the ventricular layer of the neural tube (bottom of B). At early stages, a stem cell generates neural precursors. Later it undergoes a specific asymmetric division (the “switch point”) at which it changes from making neurons to making glia. (C) Photograph of cell lineage obtained by injecting an individual neuroepithelial cell from mouse cortical progenitor cultured in a dish. Neural and glial-specific antibodies reveal the presence of both neurons (purple) and glia (astrocytes: green; oligodendrocytes: blue) in the lineage (from Qian *et al.*, 2000).

quently invaginates into the interior and transforms into a distinct tissue or organ (Schlosser, 2006). Sensory placodes appear during the late stages of neurulation in the dorsal ectoderm that flanks the invaginating neural tube (Fig. 15.6A). The most anterior placode is the olfactory placode that gives rise to the olfactory sensory neurons of the nose. Further posterior is the otic placode that forms the inner ear. Slightly more laterally is the placode of the trigeminal system that produces the sensory neurons innervating the receptors of the skin and muscles of the face and the head. Developing later and at a more lateral level in contact with the pharyngeal clefts (the gill slits in fish and

amphibians) are the epibranchial placodes. They give rise to sensory neurons that innervate the taste receptors of the mouth, and receptors in the inner organs, such as the heart, large blood vessels, and digestive tract.

Sensory neurons of the trunk are derived from the neural crest (Fig. 15.6B). The neural crest is a transient population of cells that arises along the lateral edges of the neural plate (Chapter 14). Crest cells become localized to the dorsal part of the neural tube as it folds up, and then leave the neural tube and migrate along several well-defined pathways. Neural crest stem cells give rise to a large variety of cell types, among them

skeletal tissue, melanocytes, sensory neurons, and glial cells (Schwann cells) of the peripheral nervous system, adrenergic and cholinergic neurons of the autonomic nervous system, and the endocrine chromaffin cells of the adrenal medulla. Sensory neurons stay close to the neural tube where they aggregate in segmentally reit-

erated dorsal root ganglia. Long peripheral processes extend from the dorsal root ganglia toward the skin, muscles, and skeleton. Here, dendritic endings of sensory neurons interact with specialized, mesodermally derived support cells, forming small “corpuscles” that are tuned to a specific type of stimulus,

**FIGURE 15.6** Sensory organ development in vertebrates. (A) Schematic view of neurula stage embryo, showing neural plate (light blue) flanked by sensory placodes (dark blue; anteriorly) and neural crest (green; posteriorly). Placodes express specific transcription factors of the Pax family. (B) Schematic cross-section of vertebrate embryo in which migrating neural crest cells (green) are indicated. These cells follow two different pathways: a dorsal one (light green), giving rise to melanocytes, connective tissue and skeletal tissue, and a ventral one (dark green), giving rise to sensory and autonomic ganglia, as well as the adrenal medulla. (C–F) Schematic cross-sections of vertebrate embryo at successive stages, showing development of the otic placode. (C) Otic placode is induced from dorsal ectoderm by inductive signals (e.g., *FDG19*, *Wnt8c*) from neural tube and somites. (D) Otic placode invaginates. Precursors of sensory neurons (red) delaminate from placodal epithelium. (E) Cells of the placodal epithelium differentiate. Precursors of hair cells (sensory receptors; magenta) and support cells (green) appear. (F) Otic placode grows and forms cochlea and semicircular canals. (G) Magnified view of cross-section of part of cochlea. Dendrites of sensory neurons (spiral ganglion) form synaptic contacts with sensory hair cells. These specialized, ciliated cells are surrounded by support cells. (H and I) Surface view (H) and section (I) of mouse cochlea, showing normal number and pattern of hair cells and support cells. (J and K) In *Dl1/Jag* double mutants, hair cells are increased in number, and support cells are decreased (from Kiernan *et al.*, 2005).

including touch, vibration, stretch, temperature, and pain. Peripheral sensory neurons of placodal origin also are associated with specialized nonneuronal support cells that mechanically anchor the sensory apparatus, provide the proper ionic environment for sensory transduction, and “tune” the receptor cell to a special stimulus.

Classical embryological experiments in which parts of donor embryos were transplanted to different sites in host embryos indicated that as they invaginate, placodes come in contact with the neural tube, the archenteron, the mesoderm, and the epidermal ectoderm. These structures all have inductive capacities and influence the fate of the placodal cells. In some instances, specific signaling molecules have been identified. For example, *BMP4* and *BMP7*, secreted by the pharyngeal endoderm, are involved in the induction of the epibranchial placodes; and *FGF3* and *Wnt8c* from the hindbrain and *FGF19* from the axial mesoderm work together to induce the otic placode (Fig. 15.6C). A number of transcription factors are expressed under the control of these signaling proteins. These factors, like those in the CNS involved in regional identity, act in specifying sensory organ fate. The regional identity genes expressed in sensory placodes are members of several families: the *distalless* family (*dlx3/5*), the pax family (*pax2*, 3, 5, 6, 8), the *eyes absent* (*eya*) family (*eya1/2*), and the *six* family (*six1*, 3, 6). Initially, many of these genes are expressed in widespread domains surrounding the neural plate (a.k.a. the preplacodal ectoderm). Later, the genes become restricted to specific sensory placodes. Notably, *pax2* expression is strongly correlated with the otic placode; *pax6* appears in the olfactory and lens placode, and *pax3* and *pax8* in the trigeminal placode (Fig. 15.6A). Absence or downregulation of these genes results in loss of the corresponding sensory organ.

Let us follow the determination of sensory cells of the inner ear. Following invagination from the dorsal ectoderm, the otic placode forms a hollow vesicle, the otocyst (Fig. 15.6C–E). The lumen of the otocyst ulti-

mately becomes the endolymph filled cavity of the inner ear. Initially, the wall of the otocyst is formed by a homogenous epithelial layer. Subsequently, the otocyst folds in a complex manner to give rise to the cochlea for sensing sound, the utricle for sensing gravity, and the semicircular canals for sensing rotational head movements in the three dimensions (Fig. 15.6F).

As the inner ear takes shape, the cells that form the otocyst wall diversify. In the same way that we learned about for the neural tube, different cell types delaminate from the epithelium and form additional layers basally adjacent to the epithelium (Fig. 15.6D). These cells become sensory neurons (forming the spiral ganglion), whereas the neural cells that remain epithelial form sensory hair cells and support cells (Fig. 15.6G). Hair cells, the receptor cells of the inner ear, have specialized cilia and microvilli (“stereocilia”) that sense movement of the endolymph. Deflection of stereocilia generates a receptor potential that is transmitted to the sensory neuron connected to the hair cell.

The domain of the otocyst that produces sensory neurons expresses the proneural gene *Ath1*, as well as signals of the Notch pathway, which suggests that a lateral inhibition mechanism is active to control the number of neural precursors that form at any given time. Notch activity is also required in the epithelial layer of the otocyst to distinguish between hair cells and support cells. Thus, precursors of hair cells appear at regular intervals, separated by support cell precursors (Fig. 15.6G). A Notch dependent lateral inhibition mechanism operates to determine the spacing of hair cells. Thus, at an early stage, the Notch receptor and the Delta ligand are expressed in all cells of the otic epithelium. Subsequently, Delta becomes restricted to the developing hair cells, which thereby inhibit their neighbors from choosing the same fate; these neighbors become the support cells. Genetic studies, using mouse and zebrafish, show that loss of Delta in the developing inner ear results in an increased number of hair cells (Fig. 15.6H–K)

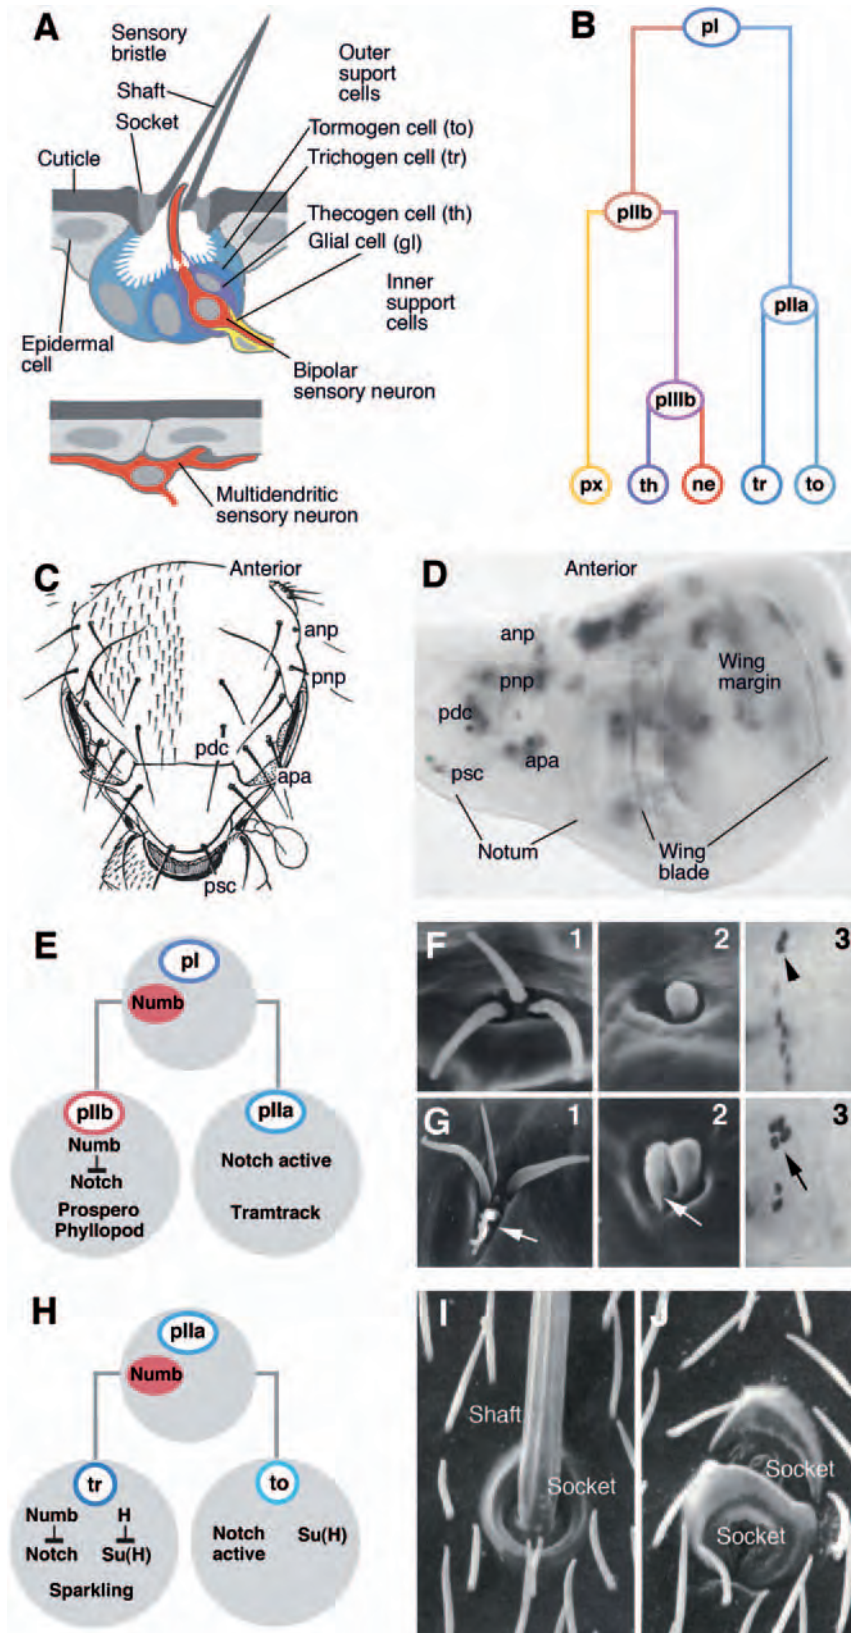

Homologues of most of the molecules involved in specification of peripheral sensory neurons also operate in the *Drosophila* sensory system. Indeed, molecular evidence shows that the proteins encoded by the *pax*, *eya*, and *six* genes form complexes that as a whole unit bind to DNA and regulates transcription. Genes that in this manner encode cooperating proteins are called gene networks. The fact that their function is dependent on all members of the complex explains why entire gene networks often are conserved throughout evolution. The *pax/six/eya* network, activated by BMP and/or Wnt signals, is one of the best-studied examples of such a conserved gene network.

In *Drosophila* and many other invertebrates, sensory organs are comprised of small clusters of sensory neurons and support cells, which together are called sensilla (Fig. 15.7). Sensilla are scattered over the entire body surface of the larval and adult fly. The cells that compose each sensillum are clonal descendents of a single Sensory Organ Progenitor cell (SOP) (Lai and Orgogozo, 2004). The special morphology and molecular composition of sensory neurons and accessory cells adapt sensilla toward the reception of a wide range of stimuli, including mechanical stimuli (touch, pressure, vibration, stretching), chemical stimuli (olfactory, gustatory), temperature, and humidity. Most sensilla have contact to the external surface; some sensillum types, in particular stretch receptors, are attached to the inner surface of the body wall or internal organs. Despite their great diversity, sensilla are built according to

only two main schemes (Fig. 15.7A) (Hartenstein, 2005). The large majority of sensilla (type I) contain bipolar sensory neurons surrounded by a pair of inner and outer support cells (Fig. 15.7A, top). The inner support cells form a sheath around the dendrite, and sometimes around the soma and proximal axon of the sensory neuron. The outer support cells are arranged concentrically around the inner ones. They form processes that, in case of sensilla situated at the surface (external sensilla or ES organs), secrete cuticle in the shape of hairs or bristles. Outer accessory cells of subepidermal stretch receptors, called chordotonal organs, form ligaments that attach the sensory neurons to the body wall. The second major type of sensilla (type II) consists of subepidermally located multidendritic neurons that are either “naked” (Fig. 15.7A, bottom) or are associated with variable types of accessory cells.

In most cases, all cells of a sensillum are born in three consecutive divisions. The SOP, also called the primary precursor cell or pI, divides into two pII daughters called pIIa and pIIb (Fig. 15.7B). pIIa divides one more time and gives rise to the outer accessory cells, the tormogen and trichogen cells. pIIb gives rise to the sensory neuron and inner accessory cells in two consecutive divisions. The first division produces precursor pIIIb, which divides into sensory neuron and thecogen cell, and the glial cell. Given that SOPs produce the different sensillum cells by a fixed lineage mechanism, it seems likely that intrinsic determinants expressed in the SOP and “forwarded” in a specific

**FIGURE 15.7** Sensory organ development in *Drosophila*. (A) Structure of mature sensilla. Schematic section of two main classes of sensilla. Top: external mechanoreceptor (microchaete). Bipolar sensory neuron (red) is surrounded by two inner support cells, the thecogen cell (purple) and glial cell (yellow). Two outer support cells, the tormogen cell (light blue) and trichogen cell (dark blue) form the socket and shaft of the bristle-shaped cuticular component of the sensillum. Bottom: multidendritic neuron. This type of sensillum does not possess external support cells; multidendritic neurons (stretch receptors) are attached to the basal surface of the epidermis and inner organs. (B) Tree diagram of canonical cell lineage of mechanoreceptive sensillum (microchaete). Progenitor of sensillum (SOP or pI; top) divides into two daughter cells, pIIa and pIIb. Division of pIIa gives rise to outer support cells (trichogen and tormogen cell). pIIb divides into progenitor pIIIb that then produces sensory neuron and thecogen cell; the other daughter of pIIb develops as glial cell (as shown here for the microchaete), or expresses a number of other different fates (not shown). (C and D) Sensillum patterning. (C) shows schematic dorsal view of *Drosophila* thorax (notum) indicating invariant pattern of mechanoreceptive bristles. Some of the large bristles (macrochaetes) are identified individually. Anp, anterior notopleural; apa, anterior postalar; pdc, posterior dorsocentral; pnp, posterior notopleural; psc, posterior scutellar. (D) Expression of the proneural gene *scute* (gray) in wing imaginal disc. In the proximal region of the disc, which gives rise to the notum, *scute* is expressed in proneural clusters that can be assigned to individual macrochaetes. (E–J) Distribution of fate determinants and Notch signaling in the sensillum lineage. (E) During the pI mitosis, Numb, an inhibitor of Notch signaling, is distributed to pIIb. This activates determinants of neurons like Prospero and Phyllopod. Loss of Numb in pI causes transformation of pIIb into pIIa, with a concomitant doubling of outer support cells and absence of neuron/inner support cells. (F, G) Examples of this transformation are the mechanoreceptive Keilin’s organ, which, in wild type (F1) has three sets of shaft/socket and, in numb mutant (G1), 4–5 sets of these outer support cells. Likewise, duplication of shaft/socket occurs in a basiconeuronal sensillum (F2: wild-type; G2: numb mutant). F3 shows molecular marker Cut expressed in two outer support cells of a mechanoreceptive sensory organ of the embryo (arrowhead). In the numb mutant (G3), these cells are doubled in number (arrow). (H) Following the pIIa mitosis, determination of the trichogen cell (tr) requires Numb, Hairless (H) and the Pax2 homolog, Sparkling. In the precursor of the tormogen cell (to), Su(H) and the N signaling pathway are active. (I) External structure of wild-type sensillum, consisting of shaft and socket. (J) In loss of Hairless mutation, or overexpression of Su(H), the shaft forming trichogen cell is transformed into a second tormogen cell, resulting in double-socket and lack of shaft.

sequence of events to the individual daughter cells play an important role. Several determinants of sensillum cell fate have been identified in genetic screens. Most of them have to do with the Notch signaling pathway, indicating that this signaling pathway is involved not only in selecting SOPs, and thereby determining the sensillum pattern, but also in differentiating sensory neurons and accessory cells. We will look at two examples of how regulation of the Notch pathway acts in the *Drosophila* sensillum lineage.

The first step in sensillum development, the determination of SOPs, is controlled in a manner similar to that regulating neuroblast determination. Thus, the expression of proneural genes of the AS-C defines proneural clusters in the ectoderm that are competent to form SOPs (Fig. 15.7C,D). At the same time, proneural genes activate the Notch pathway, mediated by the neurogenic genes, which single out one SOP and prompt all other cells of the proneural cluster to abort neural development. The identities of individual SOPs are specified by different proneural genes. For example, *Cut* (*ct*) is a homeobox gene expressed in precursors of all external sensilla. If *ct* is absent, external sensilla do not develop and chordotonal organs appear instead. *Poxn* and *Amos* are expressed and required in precursors of multiply innervated sensilla, in particular chemosensory receptors. *Atonal* (*ato*) is expressed and required in the proneural clusters that give rise to chordotonal organs. Loss of *ato* function results in the absence of these cell types; likewise ectopic expression of *ato* in other SOPs induces the production of chordotonal organs.

Once determined, SOPs divide asymmetrically. A crucial factor in generating this asymmetry is the protein Numb (Fig. 15.7E). In pI, the Numb protein becomes localized to one side of the cytocortex, so that when this cell divides, only one daughter “inherits” Numb. The cell containing Numb becomes pIIb. Numb disrupts the Notch signaling pathway by preventing Notch from translocating to the nucleus. Thus, upon activation of the Notch receptor in both pIIa and pIIb, the signal can get through only in pIIa. If Numb is deleted, Notch can act in both pII cells, which changes the fate of pIIb to that of pIIa, and causes a duplication of outer support cells (the descendants of pIIa) and loss of neuron/theogen cell (the descendants of pIIb; Fig. 15.7G).

Asymmetric activation of the Notch pathway also regulates cell fate at later divisions in the sensillum lineage. For example, pIIa starts out with an activated Notch signaling pathway. As the division into trichogen and tormogen cell occurs, Notch becomes inhibited in the trichogen cell. Again, asymmetrically inherited Numb is an essential player in inhibiting

Notch signaling. Numb appears in pIIa shortly before its mitosis and localizes to its anterior pole, whereby it ends up in the trichogen cell (Fig. 15.7H). Transcription factors that are downstream of Notch or collaborate with it are expressed differentially in the tormogen and trichogen cells. One protein, Suppressor of Hairless (Su(H)), becomes restricted to the tormogen cell. Loss of Su(H) or Notch causes a duplication of trichogen cell and loss of socket; overexpression of Su(H) in the trichogen cell causes its transformation into a second socket cell (Fig. 15.7J).

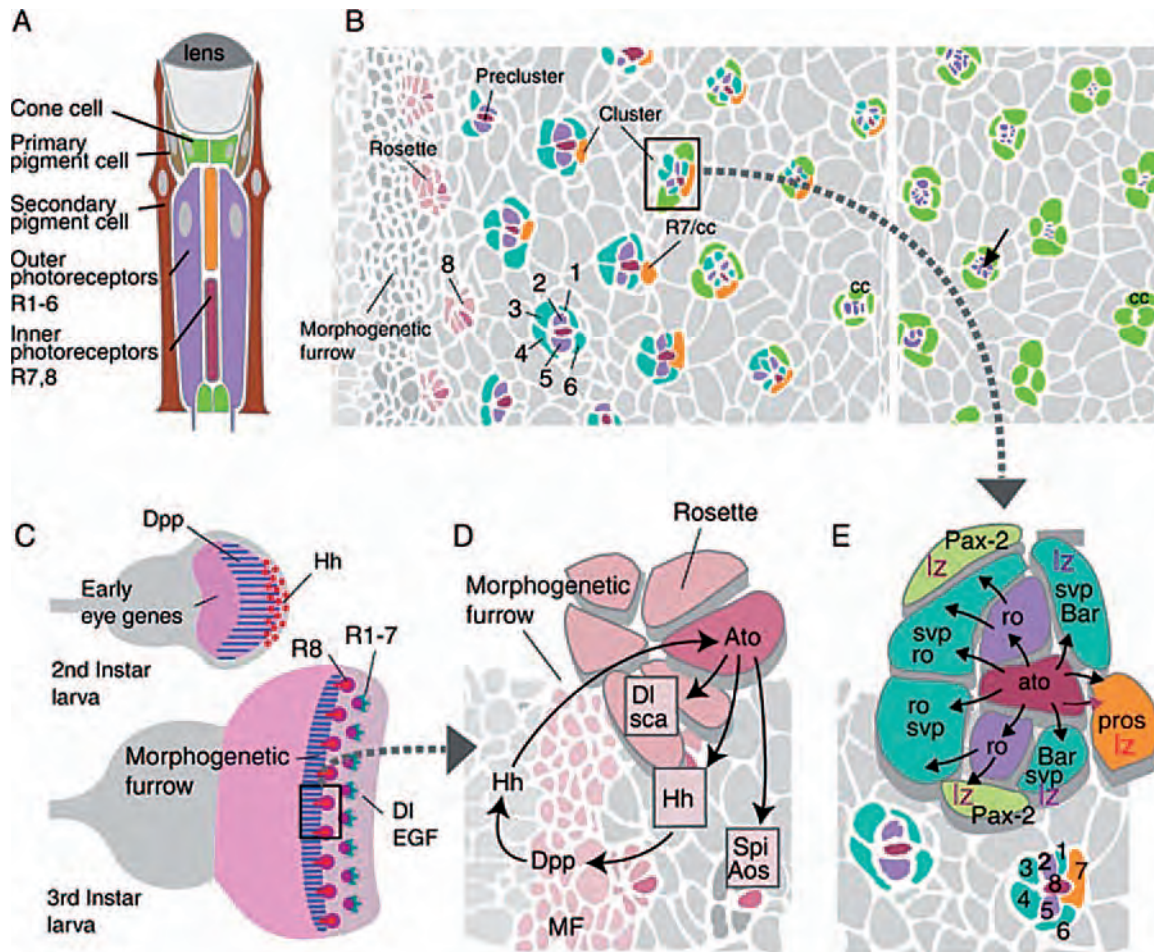

It is clear that recurring themes, such as spatially restricted homeobox containing transcription factors, proneural bHLH genes, asymmetric cell divisions, and Notch signaling, play a role in sensory neuron determination in vertebrates and invertebrates just as they do in the central nervous system of these animals.

### THE RETINA: A COLLABORATION OF INTRINSIC AND EXTRINSIC CUES

The retina is a sensory organ with different origins. The *Drosophila* retina arises from an imaginal disc, whereas the vertebrate retina arises from an outpocketing of the neural plate. Studies of how specific neurons arise and diversify in the retinas of these distinct animals reveals surprising similarities despite their very different embryological origins. These similarities may be due to the shared molecular evolution of visual organs that predates the separation of vertebrates and invertebrates.

The insect compound eye is built of a large number of identical facets, called ommatidia. *Drosophila* possesses approximately 800 ommatidia in each eye. Each contains several different types of photoreceptors and accessory cells. There are eight identifiably unique photoreceptors in each ommatidium; six of them (R1–R6) form an outer trapezoidal array, whereas two (R7 and R8) are located in the center (Fig. 15.8A). Among the accessory cells are cone cells, which form the lens of each ommatidium, and pigment cells, which surround the photoreceptors and optically shield the ommatidia from one another.

Cells of the ommatidia are formed from clonally unrelated, uncommitted precursor cells that are generated from the proliferation of cells in the eye imaginal disc (Mollereau and Domingos, 2005). The ommatidial cells do not appear all at once, but follow a reproducible temporal sequence (Fig. 15.8B). During late larval life, a wave of differentiation passes over the eye disc in a posterior-to-anterior direction. In front of the wave, cells are still dividing and uncommitted, whereas

**FIGURE 15.8** Determination of ommatidial cell fate in the *Drosophila* compound eye. (A) Schematic longitudinal section of ommatidium depicting cell types in different colors. (B) Surface view of part of the eye imaginal disc at a stage when photoreceptor clusters become assembled in a sequential fashion. Gray profiles indicate the apical surface of undifferentiated cells; colored profiles demarcate different types of photoreceptors and cone cells. At the left margin, all cells are undifferentiated. This is followed by a phase in which eye disc cells become more closely packed and constricted at their apical pole, thereby forming the morphogenetic furrow. As they leave the furrow, cells form more or less regularly spaced rosettes (light red). Within each rosette, a single cell becomes singled out as the photoreceptor R8 (dark red). At the time when it becomes distinguishable morphologically, four other photoreceptors (R2, R5: lilac; R3, R4: blue) have joined R8. Together, these five cells form the so-called preclusters. Three more photoreceptors (R1, R6: blue; R7: orange) join the preclusters, leading up to complete photoreceptor clusters. This step is followed by the appearance of four cone cells (green), which surround the photoreceptors in a circular fashion. On the right side of the panel, photoreceptors can be seen to segregate from the surface. Their apical membranes (all shown in purple) become increasingly smaller (arrow) and finally disappear altogether. (C) Initiation of compound eye development. During mid-larval stages (Top), the signal Hedgehog (Hh; red) is expressed at the posterior tip of the eye disc. Hh activates the expression of another signaling protein, Dpp (blue), which turns on several “early eye genes,” which commit the undifferentiated, proliferating cells that comprise the eye disc to an eye fate. During late larval stages, Hh and other factors initiate differentiation of the first ommatidial cells, the R8 photoreceptors, by turning on the proneural gene *atonal* (*ato*). This sets in motion other signaling pathways (EGFR signaling; Notch/Delta signaling) required for the proper spacing of ommatidia and the determination of other ommatidial cell fates. (D) Determination and spacing of R8 are controlled by the proneural gene *atonal* (*ato*), as well as the inhibitory signals Delta (DI) and Scabrous (Sca). Initially switched on in the entire morphogenetic furrow, *ato* expression then becomes restricted to a mosaic of regularly spaced cells, which subsequently differentiate as R8. Continued secretion of Hh, which signals across the MF toward the more anterior cells of the eye disc, drives the morphogenetic furrow across the eye disc. (E) Determination of photoreceptors R1–R7 and cone cells. Secretion of the TGF  $\beta$  homologue Spitz (Spi) from R8 stimulates cells surrounding R8 via the *Drosophila* EGF receptor homologue (DER), the Ras signaling pathway (symbolized by black arrows). In conjunction with other signaling events, including Notch/Delta, photoreceptors are induced to express specific transcription factors, which are required for their respective fates. The *lozenge* (*Iz*) gene is expressed in R1, R6, R7, and cone cells; *seven-up* (*svp*) is expressed in R1, 6, 3, and 4; *rough* (*ro*) in R2, 3, 4, and 5; *Bar1* in R1, and 6; *prospero* (*pros*) in R7, and *Pax-2* in cone cells.

behind the wave front, which is visible as a depression in the disc called the “morphogenetic furrow” (MF), cells are mostly postmitotic and are beginning to differentiate. As they leave the MF, cells of the eye disc become arranged in a pattern of “rosettes” that foreshadow the regular ommatidial pattern. Soon afterward, one cell, which will become the R8 photoreceptor, is singled out in each rosette. Being the first cells to differentiate, R8 cells can be considered as “crystallization centers” around which the other ommatidial cells aggregate in a stereotyped pattern.

R8 cells express the proneural gene *atonal* (*ato*). Atonal is turned on by the signaling protein Hedgehog (Hh, a homologue of vertebrate Sonic hedgehog, Shh). Atonal turns on in a continuous band of cells within the morphogenetic furrow and initiates a lateral inhibition through Delta Notch signaling (Fig. 15.8C,D). By this mechanism, *ato* expression becomes restricted to a mosaic of regularly spaced cells, which subsequently differentiate as R8 photoreceptors. These cells continue emitting Hh, which signals across the morphogenetic furrow toward the more anterior cells of the eye disc to induce the next set of R8 cells. This Hh-mediated feedback mechanism drives the wave of differentiation—the morphogenetic furrow—across the eye disc. Deleting *ato* results in the total failure of retinal development, which indicates that R8 plays a pivotal inductive role, triggering the determination of other cells that join the ommatidial clusters. The first cells to join the R8 cell shortly after its determination are R2, R3, R4, and R5 (Fig. 15.8A). Together with R8 they make up an ommatidial “precluster.” The next cells to join the cluster are R1 and R6, followed by R7 and four cone cells; the last cells to join the cluster are the different types of pigment cells.

Shortly following its own determination, R8 puts out signals that activate two different signaling pathways: Notch and Ras. The Notch pathway, as we know, is activated by Delta. The Ras pathway represents a highly conserved biochemical cascade of cytoplasmic kinases (Ras, Raf, MPK), which in this case are activated by the epidermal growth factor receptor (EGFR). R8 emits a signal, Spitz (Spi), that activates this receptor and another signal, Argos (Aos), that acts as an inhibitor. Activation of these signaling cascades spreads concentrically from R8 to the precluster cells (R2, R3, R4, and R5) and then the remainder of the ommatidial cells (Fig. 15.8D). The precise, temporally regulated activation of EGFR and Notch signaling pathways assigns distinct phenotypes to the cells that join the ommatidial clusters.

The way in which differential signaling pathway activation controls ommatidial cell fates has been studied most closely for two cell types, R7 and the cone

cells, which appear at a relatively late stage when all other photoreceptors are already in place. The *Pax-2* gene specifies cone cells (Fig. 15.8E). To express *Pax-2*, the cone-cell-to-be depends on three inputs (Flores *et al.*, 2000): (1) the previous expression of the transcription factor lozenge (*lz*); (2) activation of the Notch pathway, and (3) activation of the EGFR signaling pathway. If any one of these prerequisites is not met, the cells will fail to express *Pax-2* and will not differentiate as cone cells. Conversely, if a set of cells that normally does not receive all three inputs is exposed to them experimentally, these cells will express *Pax-2* and become cone cells. For example, the precluster cells that normally form R3 and R4 activate both Ras and Notch pathways, but do not express *lz*. If *lz* expression is turned on in these cells experimentally, they develop as cone cells. Conversely, R7 cells normally express *lz*, but do not activate the Notch pathway. Expression of activated Notch in the R7 precursor will turn this cell into a cone cell. Biochemical analyses have shown that the effect of *lz*, EGFR, and Notch signaling on *Pax-2* expression is a direct one.

The determination of the R7 cell deserves special mention in view of the pivotal role it has played in opening up the molecular-genetic study of signaling pathways (Zipursky and Rubin, 1994). The important advantage of a genetic model system like *Drosophila* has to offer is that developmentally relevant molecules, such as signaling proteins, receptors, and signal transducers, can be identified by mutant screens. One of the first of such screens in the field of cell determination took advantage of the fact that only one of the photoreceptor cells of each ommatidium, R7, is sensitive to ultra violet (UV) light. Thus, mutagenizing flies and screening for offspring that are blind to UV light yielded a fly line that lacked the R7 cell in every ommatidium and was therefore aptly called *sevenless* (*sev*) (Fig. 15.9). The close study of this gene showed that it encodes a receptor with tyrosine kinase activity and that this receptor is expressed (among other cells of the eye disc) in the cell that will become R7. Lack of the receptor causes the cell that would normally become R7 to develop as a cone cell instead.

In several follow-up screens, many signal transducing molecules and transcription factors activated by the Sev receptor were identified. Among them were the *Drosophila* homologues of Ras, Raf, and MAPK. One of the most rewarding findings was the identification of the signal that binds to Sev. Given the widespread expression of Sev, it was clear that a signal emanating from a point source must exist, in order to ensure that Sev would become active only in one cell. The logical candidate to emit such signal would be R8, the only cell in broad contact with the presumptive R7.

**FIGURE 15.9** Photoreceptors in the eye of normal and *sevenless* mutants. (A) If a light is shone from the back of a fly's head and focused in the facets of the eye, individual photoreceptors can be seen because of their ability to pipe light. The wild-type animal has the normal pattern of seven photoreceptors visible in each facet. The small one in the center is photoreceptor R7. (B) The same technique used in a *sevenless* mutant shows only the six large photoreceptors R1–6 in each facet. R7 is missing. Insets show electron micrographs through single facets.

A genetic screen for R7-less flies yielded identification of a membrane bound signaling molecule, called Bride of sevenless (Boss), which is expressed specifically in R8 cells and serves as the ligand for Sev. These experiments provided an impressive demonstration of the awesome power of genetic screens combined with precise knowledge of the developing system in identifying new genes and proteins controlling development.

The vertebrate retina, like the *Drosophila* retina, develops from a population of pluripotent neuroepithelial progenitors, which produce a diversity of neurons and glia (Fig. 15.10A). As in *Drosophila*, vertebrate neurogenesis and determination in the retina follows a temporal order (Livesey and Cepko, 2001). Thus, at any given time during retinogenesis, only a few fates are available to differentiating cells. Cells born early in mammals generally adopt fates as retinal ganglion cells (Fig. 15.11A–C). Horizontal cells and cones are also born early. Amacrine cells are produced subsequently, followed by rods, bipolars, and Müller cells. This is also similar to *Drosophila*, in which first R8s and then sequentially other cell types differentiate. This progressive shift in cell type genesis in vertebrates

is supported by dissociation experiments in which cells are put into culture at low density at various stages of development. If progenitors are isolated at the time when retinal ganglion cells (RGCs) are normally born, they tend to turn into ganglion cells in culture. If such cells are isolated at later stages, they become rod photoreceptors in the same culture medium. These results are consistent with an intrinsic progression of cell fates, such as seen in *Drosophila* CNS neuroblasts.

There is an intrinsic element to the succession of cellular fates in the vertebrate retina (Cayouette *et al.*, 2006), which is revealed when late progenitors are isolated and allowed to divide on their own in culture. These isolated progenitors give rise to clones of cells of same general birth order, size, and composition as clones *in vivo*. A vertebrate homologue of *ato*, *ath5*, is certainly one intrinsic factor in the process of RGC fate specification in the vertebrate retina. *ath5* is turned on in a subset of retinal progenitors that give rise to RGCs and it is essential for the production of RGCs. Some *ath5* expressing progenitors were followed by time-lapse analysis in the zebrafish retina (Poggi *et al.*, 2005). They were found to divide just once to generate one

**FIGURE 15.10** Clones of cells in the *Xenopus* and zebrafish retina. (A top) Daughters of a single retina progenitor in *Xenopus* injected with horseradish peroxidase are seen to form a column that spans the retinal layers and contributes many distinct cell types; (A bottom) p, photoreceptor; b, bipolar cell; m, Muller cell; a, amacrine cell; and g, ganglion cell. (B) Time-lapse images of an RGC progenitor in zebrafish dividing at the apical surface of the retina to produce two neurons, one of which (yellow) becomes an RGC. The other cell (red) is probably a photoreceptor. (C) A similar RGC progenitor in an *ath5* mutant retina in which there are no host RGCs. This cell divided to produce two daughters, both of which become RGCs (arrows point to emerging axons).

RGC and one other postmitotic retinal neuron by an asymmetric cell division (Fig. 15.10B). Seeing such a lineage pattern *in vivo*, however, does not mean that this pattern is immune from extrinsic influence. Indeed, when retinal cells are removed at the stage when RGCs are being born, mixed into aggregates, and cultured *in vitro*, they differentiate into RGCs as one would expect. However, if the same cells are mixed with an excess of retinal cells several days older (i.e., when photoreceptors are generated), they generally become photoreceptors (Fig. 15.11D). This work shows that individual cells have the capacity to differentiate into different cell types, and the fate they choose depends on the environment in which they are born. This makes good sense, for as retinal development proceeds, the environment changes simply as a result of various retinal cell types being generated, much as in the *Drosophila* retina. Indeed, there is strong evidence for feedback in influencing the fate of RGCs. Young embryonic chick progenitors are inhibited in their ability to produce RGCs when cultured adjacent to older retinas in which

there are lots of RGCs, and depletion of the RGCs from these older retinal cell populations abolishes this inhibition. Similarly, whereas *ath5*-positive cells in normal embryos generate only a single RGC daughter (see earlier), these same cells when transplanted into mutant retinas that lack RGCs often generate two RGCs daughters, providing evidence that such lineages are sensitive to feedback signals (Fig. 15.10C).

What could these feedback signals be? RGCs express Shh, and the Shh knockout mouse contains increased number of RGCs. These results suggest that Shh provides feedback inhibition signal in the developing mouse retina, echoing what happens in the *Drosophila* retina where R8 cells express Hh, which regulates the expression of *ato*. The growth differentiation factor 11 (GDF11) is another factor secreted by RGCs, and it acts by limiting the temporal window during which progenitors are competent to express *ath5* and thus produce RGCs. Finally, as in the *Drosophila* retina, the Notch signaling pathway contributes to retinal diversity in the vertebrate retina (Fig. 15.11E,F). When Notch

**FIGURE 15.11** Vertebrate retina development. (A) The neural retina bulges out of the ventral neural tube at the level of the diencephalon. It is joined to the brain by the optic stalk along which the axons of retinal ganglion cells will course on their way to the tectum. (B) The seven major cell types in the retina coded by color. Their laminar arrangement by cell type is evident. (C) Birth dating studies in the retina show that different cell types are born in different but overlapping periods of development. (D) When early generated retinal precursor cells (labeled by a pulse of BrdU) are mixed with older cells in culture, they show an increased probability of turning into late cells, such as rods. (E) Development of the retina. Schematic section of retinal neuroepithelium at three different stages (early: left; late: right). Dividing retinal progenitors (purple) produce different cell types depending on the developmental stage. Differentiation inhibitors (DI) released from postmitotic neural precursors inhibit retinal progenitors from producing more ganglion cells. Postmitotic cells also secrete differentiation factors such as GDF, which limit the time window during which postmitotic cells can become retinal ganglion cells. (F) Expression and function of DI in the developing retina. Left panel: expression of DI in postmitotic neural precursor; dividing progenitors of the ventricular layer (arrow) or differentiated neurons of the basal mantle layer (green) do not express DI. Middle: Loss of DI results in increased number of early born retinal cells (retinal ganglion cells), at the expense of undifferentiated retinal progenitors. Right: Overexpression of DI causes the opposite phenotype.

**FIGURE 15.12** Specification of motor neurons in the vertebrate spinal cord. (A) Schematic cross-section of the neural tube. The notochord, which is located underneath the floor plate, releases the signal Sonic hedgehog (Shh). Consecutively, Shh is released from the floor plate and forms a gradient with high concentrations ventrally and low concentrations dorsally. BMP molecules released from the dorsal epidermis and dorsal neural tube form an opposing gradient. (B) In a concentration-dependent manner, Shh directs expression domains of the class I and class II homeodomain genes (see text for details). (C) Polarized expression of FGF, among other signaling pathways, is responsible for the regionally specific expression of Hox genes along the antero-posterior axis of the neural tube. In addition, inhibitory interactions among the Hox genes themselves, sharpen the boundaries within which a given Hox gene is expressed. In such manner, the anterior Hox gene HoxC6 is expressed in the cervical spinal cord, and the posterior Hox gene HoxC9 is expressed in the thoracic cord. These genes direct the differentiation of the motor column into specific domains, such as the cervical lateral motor column (LMC) innervating forelimb muscles, or the column of Terni (CT) in the thoracic spinal cord that innervates sympathetic ganglia. (D) The motor column is subdivided into pools of motor neurons innervating specific muscles. These pools, including the Tri motor neuron pool and the CM motor neuron pool, occupy discrete locations in the ventral horn of the spinal cord and show distinct dendritic branching patterns. These properties, which depend on the expression of specific transcription factors such as the LIM gene PEA3, can be visualized by backfilling the motor neurons with fluorescent labels injected in the corresponding muscles. (E and F) Two different markers visualize the dendritic arborization (E) and cell body position (F) of the Tri motor neurons (green) and CM motor neurons (red). (G and H) Knockout of the PEA3 gene results in ventral shift of CM motor neuron location, and dorsal expansion of Tri motor neuron dendrites. (I) Reflex circuits between sensory afferents (from muscle spindles) and motor neurons innervating the corresponding muscle are formed because both spindle afferents and motor neurons targeted by them express a common transcription factor, such as ETS ER81 shown here. Among the downstream targets of ETS ER81 are homophilic adhesion molecules that allow the ingrowing sensory axon to “recognize” the proper motor neuron target. (E–H) (from Vrieseling and Arber, 2006).

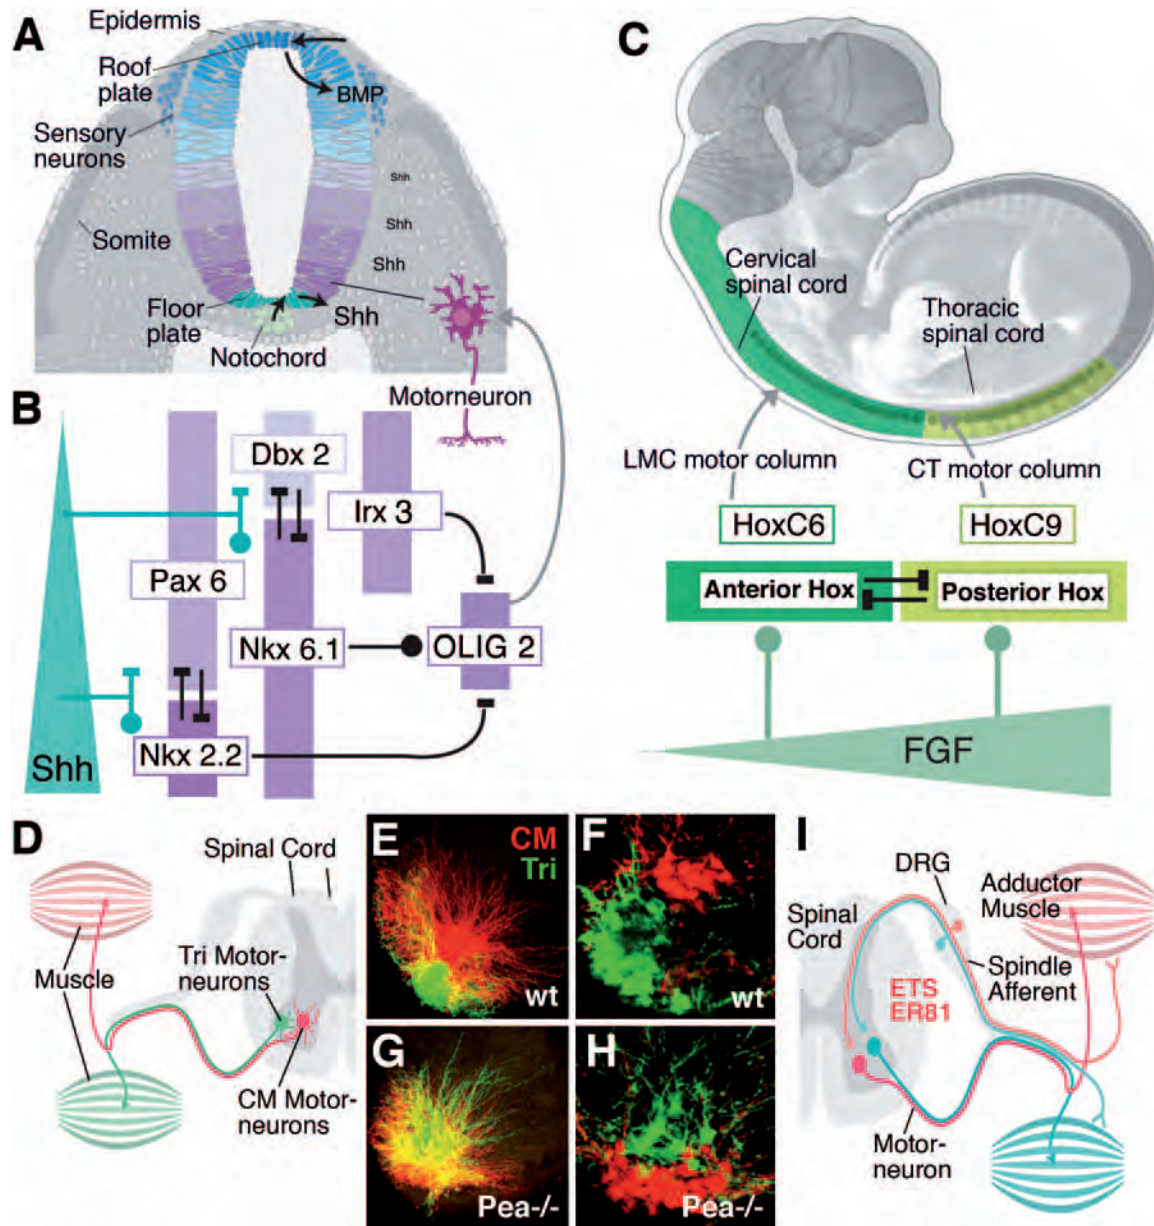

signaling is compromised in early retinal progenitors, too many cells differentiate as early cell types such as RGCs and cone photoreceptors, whereas later interference with Notch signaling leads to an increase in later-born cell types such as rod cells. When cells are released from the inhibition mediated by the Notch pathway, proneural basic helix-loop-helix (bHLH) transcription factors, such as *ath5*, bias cells towards particular fates, such as RGCs. The Notch signaling pathway, by allowing only a certain number of cells to differentiate at any one time, is thus important in creating cellular diversity in the vertebrate retina (Dorsky *et al.*, 1997).

### COMBINATORIAL CODING IN MOTOR NEURONS DETERMINATION

The most ventral part of the vertebrate spinal cord is the “floor plate” and just dorsal to this are the motor neurons (Fig. 15.12A). Transplantation experiments have shown that the floor plate is induced by a Shh signal emitted from the underlying notochord (Chapter 14). Once induced, the floor plate serves as a secondary source of Shh. As a result a gradient of the Shh signal percolates dorsally through the cord. At least five different neuronal types are generated in response to this single gradient. The most ventral neurons including motor neurons, require the high doses of Shh, and successively more dorsal neurons require correspondingly less (Jessell, 2000). When Shh is missing or antagonized with an antibody, there is no floor plate, nor indeed any ventral neuronal type, and in particular no motor neurons in the spinal cord.

How do cells at different dorso-ventral levels interpret their exposure to different levels Shh to acquire different fates? Threshold levels of Shh turn on some homeobox genes such as *Nkx2.2* and *Nkx6.1* (Class II) and turn off others such as *Pax6* and *Dbx2* (Class I). Thus neural tube neurons in different dorso-ventral regions express specific homeodomain proteins, which either are turned on or off at particular Shh thresholds (Fig. 15.12B). The boundaries between these domains are sharpened through reciprocal-repression of the two classes of genes. The ventral border of the class I *Pax-6* gene initially overlaps the dorsal border of the class II *Nkx2.2* gene, but then reciprocal repression sets in, so that only one of these genes is expressed in any particular cell. By this process, specific domains uniquely express particular combinations of Class I and Class II homeodomain transcription factors. Motor neurons arise from the domain that uniquely expresses *Nkx6.1* but not *Irx3* and *Nkx2.2*. *Nkx6.1* turns on OLIG2, a bHLH transcription factor that is required for motor neuron differentiation, and *Nkx2.2* and *Irx3* repress OLIG2 expression. OLIG2 in turn activates the expression of motor neuron specific transcription factors, such as *Mnr2*, *HB9*, *Lim3*, and *Isl1/2*, that are involved in motor neuron differentiation (Fig. 15.12B).

Motor neurons in the spinal cord are organized in columns that project to muscle groups along the anterior to posterior axis of the body (Dasen *et al.*, 2003). Thus, in the cervical region, the Lateral Motor Column (LMC) innervates forelimb muscles, and in the mid-thoracic region, the Column of Terni (CT) innervates the sympathetic chain (Fig. 15.12C). The patterning of motor neurons into motor columns is accomplished in response to a gradient of FGF8 (high posteriorly to low

anteriorly) secreted by the paraxial mesoderm. This gradient establishes domains of different Hox genes at different levels, boundaries between which are sharpened by reciprocal inhibition. This anterior-posterior logic of motor neuron identity is thus strikingly similar to that governing the positioning of the neurons in the dorsal ventral axis of the spinal cord.

Motor columns are subdivided into classes that innervate different groups of muscles. Transcription factors of the LIM homeodomain (LIM-HD) family are involved in this further specification, as motor neurons expressing different combinations of LIM-HD factors such as *Islet-1*, *Islet-2*, and *Lim-3* are expressed in dif-

ferent motor neuron classes that innervate different groups muscles. This is particularly well illustrated in the primary motor neurons (*Rop*, *Mip*, and *Cap*) of zebrafish, which can easily be distinguished by their relative rostral to caudal position in each spinal segment as well as their axon trajectories to distinct muscle regions. These three neurons express different combinations of LIM transcription factors. The identity of these neurons, as judged by their projection to different muscle regions, is influenced by the position in which they develop. These projection patterns can therefore be changed by transplantation in which the position of these neurons is changed prior to axonon-

genesis. Transplantations that lead to such switches in projection correlate with induced changes in LIM-HD code suggesting a causal link.

Motor neurons that innervate specific muscles are grouped into motor pools, which distinguished by the expression of distinct members of the ETS family of transcription factors. For example the ETS gene *ER81* is expressed in the motor neurons that innervate the limb adductor muscle in chicks, whereas the ilioprochanter motor neurons express the *PEA3* ETS gene (Fig. 15.12I). The initial expression of these ETS genes depends on peripherally derived signals such as GDNF and coincides with the arrival of motor neuron terminals in the vicinity of their specific targets. In *PEA3* knockout mice, the motoneurons that are normally *PEA3* positive fail to develop normally so muscles that are normally targets of these neurons are hypoinnervated and become severely atrophic. Not only do these motor neuron pools fail to branch normally within their target muscles, the cell bodies and dendrites of these motor neurons also are mispositioned within the spinal cord, which is critical for the control of their reflexive and descending innervation (Fig. 15.12D–H).

Recent work suggests that these ETS genes regulate the expression of cell adhesion and axon guidance factors that help motor neurons recognize their target. Interestingly, the sensory afferents that innervate the stretch receptors, in particular muscle, express the same ETS gene as the motor neurons that innervate that muscle, and this helps the sensory neuron axons find the dendrites of these motor neurons completing the monosynaptic stretch reflex.

The motor neuron system of the *Drosophila* larva, responsible for crawling, is relatively simple and has a reproducible segmental organization located in the ventral nerve cord of the larva (Landgraf and Thor, 2006). In each half segment, there are usually 36 motoneurons arising from about 10 neuroblasts (Fig. 15.13A,B). Some project through the intersegmental nerve (ISN) to innervate the more interior muscles that span the length of each segment and cause the animal to shorten, and others project through the segmental nerve (SN) to innervate the more exterior set of muscles that are more radial in orientation and cause the animal to lengthen. This is comparable to the division in vertebrate limbs, where the sets of (usually antagonistic) muscles derived from the ventral and dorsal muscle masses are innervated by motoneurons, whose axons project along divergent paths.

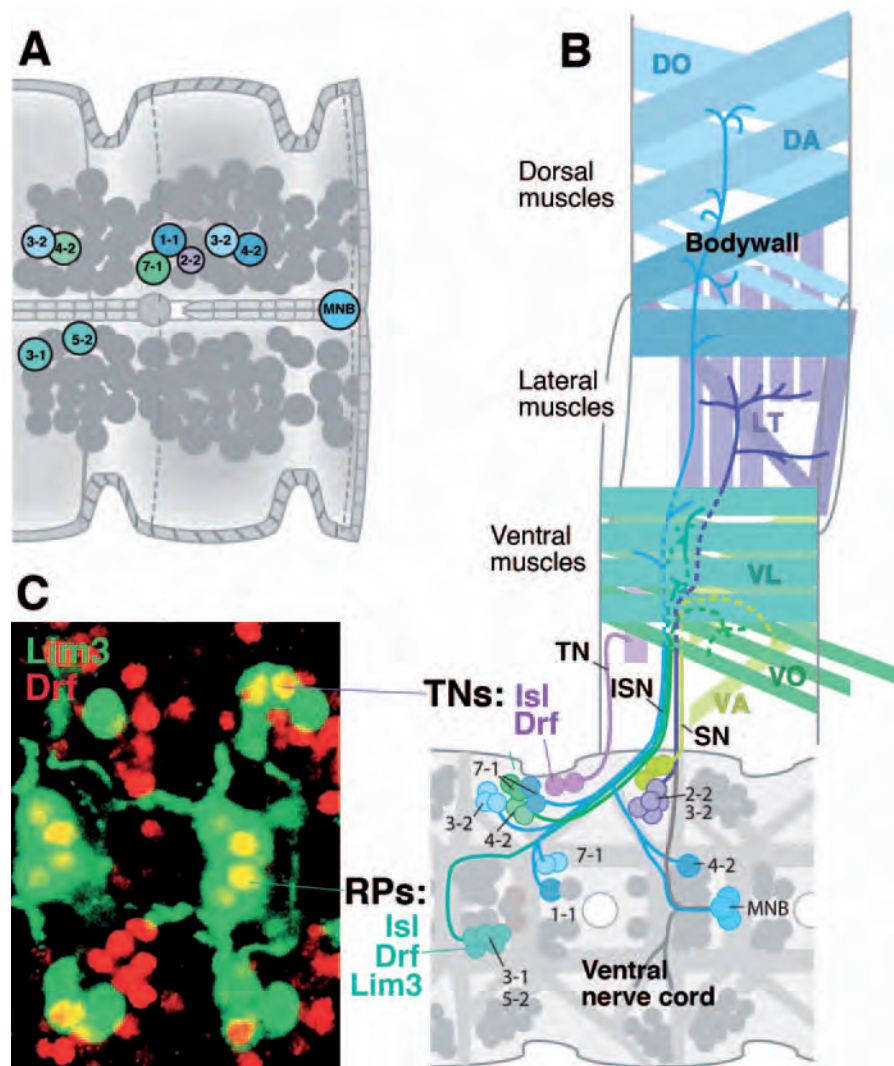

As in the vertebrate, combinatorial codes specify different motor neuronal types. In *Drosophila*, this subdivision works down to the level of single cells. The first subdivision in *Drosophila* is between ventral projecting motor neurons, vMNs, and dorsal projecting

motor neurons, dMNs. Interesting vMN identity is controlled by the combinatorial action of the *Nkx6* and *HB9* homeobox genes, a similar combination to that used to specify motor neurons in vertebrates. The vMNs in *Drosophila*, like the motor neurons in vertebrates, are specified into subclasses that project along specific nerves to innervate specific muscles by the further expression of combinatorial codes of LIM-HD factors, just as in vertebrates (Fig. 15.13C). In *Drosophila*, motor neurons often arise sequentially from a common neuroblast. For example, the neuroblast NB 7-1 generates five motor neurons that innervate nearby muscles. In this case, the temporal coordinate genes that were described earlier in this chapter (*Kr*, *Hb*, *Pdm*, *Cas*, and *Gh*) are involved in the specification of unique identities of these motor neurons.

What aspects of neuronal phenotype do these combinatorial codes of transcription factors control? *Islet* and *Lim3* are two transcription factors expressed in a particular subclass of motor neuron that sends axons out the transverse nerve. When either of these genes is lost, the axons of these motor neurons defasciculate, leading to the failure of transverse nerve formation. These motor neurons all express a specific immunoglobulin-containing cell-adhesion molecule called *Beat-1c*, and the *beat-ic* gene is likely a direct target of these transcription factors. The defasciculation observed in *islet* and *Lim3* mutants can be rescued by the forced expression of *Beat-1c* in these motor neurons, strongly suggesting that the combinatorial code in *Drosophila* motor neurons, like that in the vertebrate motor neurons, regulates cell adhesion factors that help motor neurons navigate to their targets.

## CELLS OF THE CEREBRAL CORTEX

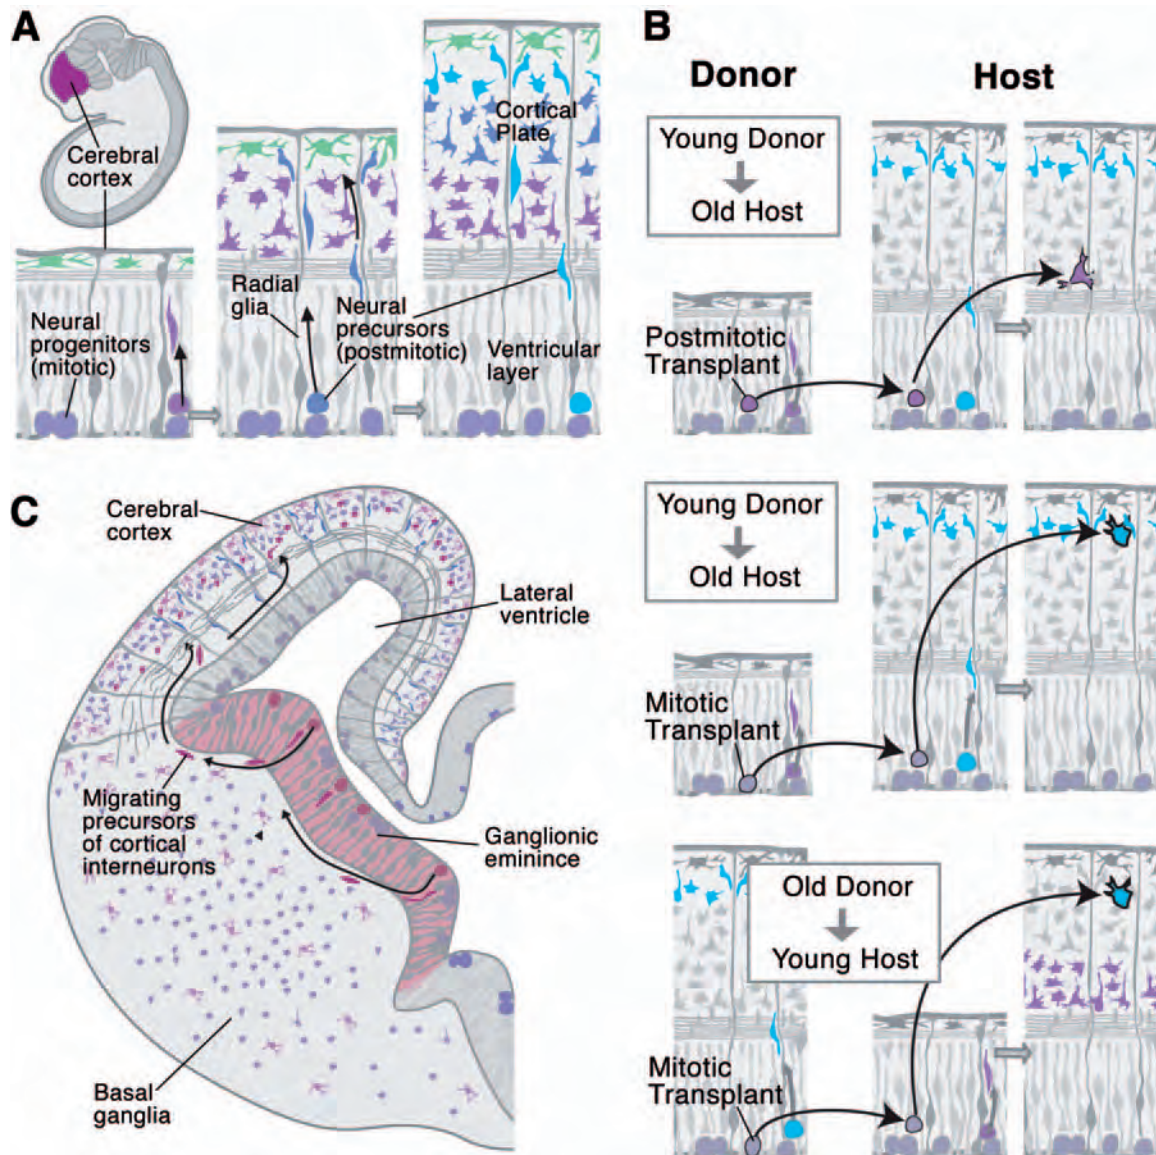

The cerebral cortex of mammals is the neural tissue where the conscious processing of information occurs. So, it is natural to want to know about the various neuronal types here and how they arise. Neuroepithelial cells in anterior-dorsal region of neural tube divide extensively to cause the ballooning out of two telencephalic vesicles. Further proliferation eventually produces an enormous folded sheet of tissue (about 4 mm thick and about 1.6 m<sup>2</sup> in area when unfolded in humans) that forms the cerebral cortex. The neocortex, which forms most of the cerebral cortex in humans, is a six-layered structure, with each layer having its own particular array of neuronal cell types. Differences in the thicknesses and cellular densities of particular layers have enabled histologists to distinguish as many as 100 cytoarchitecturally distinct cortical

**FIGURE 15.13** Specification of motor neurons in the *Drosophila* ventral cord. (A) Neuroblast map of two embryonic segments, showing in color the subset of neuroblasts that give rise to motor neurons. (B) Schematic flattened view of one body segment, showing in different colors the pattern of bodywall muscles and motor neurons innervating these muscles. The specific motor neuron(s) innervating each of the 30 muscle fibers comprising the musculature have been mapped. Motor neurons are color coded such that their color matches the one of the neuroblast from which it descends (see A), and the muscle it innervates. As in vertebrates, distinct groups of motor neurons are specified by expressing transcription factors of the LIM and POU family. Shown here and, photographically, in panel C are the RP neurons, expressing the combination *Isl*, *Drf*, and *Lim3*, and the transverse nerve (TN) motor neurons that express only *Isl* and *Drf*. Mutations in any of these genes result in motor neuronal abnormalities. (B) (From Certel and Thor, 2004).

areas in humans. Most neocortical cells and all glutamatergic ones originate from neuroepithelial cells at the apical surface or ventricular zone of the telencephalic vesicles. Asymmetric divisions of these cells generate one daughter that remains neuroepithelial and apical, and another daughter that migrates basally. Most of the time, the migrating daughter becomes a postmitotic cortical neuron, but in some of cases and increasing as development proceeds, the migrating daughter travels only a short distance to the subventricular zone, where it divides symmetrically, generating two neurons.

Cortical precursors, once generated, must then migrate basally away from the ventricular and subventricular zones, through an intermediate zone that will later be filled with axons, until they arrive at the cortical plate where they stop migrating and begin to differentiate into an enormous variety of specialized cortical cell types. This basal migration is coupled with an inside-out pattern of histogenesis in which the first-born cells take up the deep layers of the cortical plate and the later born cells migrate past the earlier generated neurons to occupy more superficial layers (Fig. 15.14A) (Angevine and Sidman, 1961). Cortical cells

**FIGURE 15.14** Lamina fate determination in the cerebral cortex. (A) Morphogenesis of the mammalian cerebral cortex. Neural precursors are born in the ventricular layer and migrate away from the ventricular surface, following tracks provided by radial glial cells. The first born cells are the Cajal-Retzius neurons (left in figure). Later born neurons accumulate in a dense matrix of cells, the cortical plate (middle of figure). In this plate, neurons are ordered by birth date in such a way that older neurons (magenta) remain in deep layers, and younger neurons (blue) migrate through the deep layers to attain a superficial position (right in figure). (B) Top: If postmitotic ventricular cells from young donors (which normally would become deep cells) are transplanted into an old host, they do not adapt to their new environment and develop as deep layer neurons (arrow). However, if ventricular cells that have not yet exited the cell cycle are transplanted from young donors when into an old host (middle panel), they adapt to their new environment and develop as superficial neurons (arrow). If, on the other hand, premitotic progenitors from old donors are transplanted into young brains, they can take later fates and become upper layer neurons. (C) Migration route of GABAergic interneurons from the ganglionic eminences in the ventral telencephalon into the cortical plate in a mammalian embryo.

are specified with respect to their fates before they migrate, for if postmitotic cells from the ventricular zone of a young embryo (destined for deep layers) are transplanted into the ventricular zone of an older one that is generating superficial cells, then the transplanted cells will still migrate to deep layers and have deep layer fates (Fig. 15.14B, top panel). Consistent

with this, markers of specific fates, such as the transcription factor NEX, first appear before cell migration (Wu *et al.*, 2005). However, if the progenitors from a young ventricular zone are in their last mitotic cycle when they are transplanted to the older environment, they can change their laminar identity, suggesting that cortical cell fate is still undetermined until the cells exit

## BOX 15.1

## NEURAL STEM CELLS

The proliferating progenitor cells or neuroblasts that give rise to more differentiated progeny but themselves remain in the cell cycle are called neural stem cells (NSCs) (Gage, 2000). Some frogs and fish continue to grow bigger throughout their lifetimes, and their brains grow with their bodies, adding new cells from localized stem cell populations. However, in most animals, including humans, most proliferating neural cells use themselves up during development so the sources of new neurons in an adult animal are extremely limited. This is why damage to the central nervous system is medically much more serious than damage to some other organs, such as the skin or liver, where stem cells that persist into adulthood can replace injured tissue. Nevertheless, it has been found that even in adult mammals, NSCs persist in certain “niches” near ventricular layers. Interestingly, one pocket of rich stem cell activity is in the hippocampus, where learning takes place. There is excitement about the potential of using NSC cells in a replacement strategy for brain damage due to injury, stroke, or degenerative diseases such as Parkinson’s disease, or retinal degeneration. In the future, one could imagine harvesting NSCs from a patient, proliferating these cells in culture under conditions where they begin to differentiate as dopaminergic neurons, and using these neurons to replace ones lost due to damage or disease.

Important questions about neural stem cells in the adult brain abound. Why do these cells remain undifferentiated and capable of division when their neighbors have exited the cell cycle and differentiated? What signals do these cells need in order to stimulate their proliferation and differentiation? How can their differentiation toward particular types of neurons or glia be controlled experimentally? Although there is much speculation on the role of various signaling and growth factors in regulating these processes, more work needs to be done to identify the molecules that prevent stem cells from differentiating and the signals that release their potential.

Interestingly, the environment of the organism may play a key role regulating NSCs. Rats raised in complex environments containing toys and exercise wheels show more proliferation and survival of hippocampal stem cells than rats raised in simple cages. Stress works in the other direction and seems to inhibit stem cell proliferation and survival in the hippocampus. The identification of the intrinsic regulatory factors that regulate these NSC activities might prove invaluable in treating neural or glial

degenerative conditions without the need for transplants.

Another source of stem cells in mammals is the inner cell mass of the early conceptus. These are the cells that give rise to all the tissues of the embryo proper (Vallier and Pedersen, 2005). When these embryonic stem cells (ESCs) are grown in culture, some of them turn into neural precursors. It seems that the lessons learned about the mechanisms of neural induction are paying off in this context, because neural inducing signals increase the probability that ESCs will follow a neural pathway. ESCs may have an advantage over neural stem cells from adults because they come from a stage in development when their potential fates are less restricted by the inheritance of intrinsic determinants.

Various laboratories are trying to turn ESCs into various types of neurons. As a great deal is known about the inductive signals that are critical to the generation of motor neurons in the vertebrate spinal cord, it may be asked whether this knowledge can be used to direct stem cells to a motor neuron fate. Jessell and colleagues (Wichterle *et al.*, 2002) combined inducers that first turn mouse ESCs into neural progenitors with factors such as retinoic acid that drives posterior regional identity such as spinal cord and Shh that drives ventral fates in the spinal cord to push these ESCs to differentiate into neural then spinal and finally into motor neurons that express the same combinatorial codes of transcription factors as motor neurons *in vivo*. These ESC-derived motor neurons can be labeled by Green Fluorescent Protein (GFP) under the control of the HB9 promoter (expressed only in motor neurons), and when these fluorescent cells are transplanted into the embryonic spinal cord of a chick embryo, they extend axons, and form synapses with target muscles. Moreover such ES-derived motor neurons develop appropriate transmitter enzymes and receptors, and electrical properties, such that they can make perfectly functional synapses with muscle fibers. Thus, by using signaling pathways discovered by studying normal cell determination in the developing nervous system, biologists may be able to direct stem cells to form specific types of neurons.

Clearly, the more we know about neuronal determination, the more likely we will be able to direct stem cells down appropriate developmental pathways that will be useful in treating the damaged nervous system.

*William A. Harris and Volker Hartenstein*

the cell cycle (Fig. 15.14B, middle panel). Interestingly, the reverse experiment of transplanting premitotic progenitors of old donors to younger ventricular zones does not result in these cells assuming earlier, deeper-layer fates (Fig. 15.14B, bottom panel), suggesting that progression of determination is a one-way street on which there is no going back (McConnell, 1995).

These findings demonstrate a relationship between the cell cycle exit and cell determination in the cortex reminiscent of what was described earlier in this chapter for the *Drosophila* CNS and the vertebrate retina, and provide a plausible mechanism for how cytoarchitectonic differences in cortical lamination can be achieved simply by altering cell cycle kinetics in a regionally specific way. Thalamic afferents that innervate the cortex may have a role in this, as the invading axons release trophic factors that promote proliferation. Thus, different regions of the cortex could have differences in the number of cells in specific layers, due to the timing and density of the innervation that they receive.

Not all cells in the neocortex originate from local ventricular zone. The oligodendrocytes and many classes of GABAergic interneurons migrate from more ventral part of the telencephalic vesicles, the ganglionic eminences (Fig. 15.14C) (Anderson *et al.*, 1997). We do not know very much about how these subtypes are generated, except that regional and temporal identity is also of significance here (Butt *et al.*, 2005). Once these cells exit the cell cycle, they begin a long tangential migration to the cortical plate where they join contemporaneously and more locally generated precursors on their radial migration to the developing cortical plate. Arriving together in the right layers, these cells from different location begin to differentiate and interconnect, building the local circuits that process conscious information.

## CONCLUSIONS

The generation of neurons involves a variety of extrinsic signals and intrinsic transcription factors that confer individual identities on postmitotic neurons. Whether vertebrate or invertebrate, this process of determination involves a similar set of molecular and cellular mechanisms, such as regional and temporal identity genes, proneural genes, signaling molecules and receptors, the Notch pathway, and asymmetric cell division. All these conspire, over the course of neuronal generation, to create progenitors with distinct combinations of transcription factors that uniquely specify the fates of the differentiating neurons down by regulating the expression of genes that affect

specific features of the cell such as axon and dendrite growth and targeting, the topics of Chapters 17, 18 and 21.

## Neurogenesis and Migration

One of the remarkable features of the developing nervous system is the wide-ranging migration of precursor cells. Over the past decade, genetic studies in invertebrate and live imaging of vertebrates have given insights into the mechanisms responsible for neuronal motility. In particular, signal pathways have been identified that initiate cell movements and govern the dynamics of cell motility. A conserved family of polarity protein complexes, and their signaling pathways, orient the mitotic spindle in dividing precursor cells during neurogenesis, and induce postmitotic progenitor cell to the extend motile protrusions, driven by actin polymerization dynamics and stabilized by adhering to adjacent cells or to the extracellular matrix (ECM) via transmembrane receptors linked to the actin cytoskeleton. The molecular nature of the cues guiding cell movement are only beginning to be understood and appear to differ between different regions of the nervous system. This chapter compares the strategies used to generate final cell pattern in the peripheral and central nervous systems, considering classical views of brain development that resulted from anatomical studies, as well as emerging molecular programs of neurogenesis and cell migration that have resulted from genetic and molecular genetic studies.

### INTRODUCTION

In the late nineteenth century, the Swiss histologist Wilhelm His (His, 1886) developed methods to section embryonic brain and resolve individual cells in the *neurospongium*. Subsequently the Spanish neuroanatomist Santiago Ramon y Cajal (Ramon y Cajal, 1995) developed protocols to fix nervous tissues of embryos

with barbiturates, and to modify methods discovered by the Italian histologist, Camillo Golgi, to stain cells with nitrates of silver, by immersing the tissue into photographic reagents. By examining embryos of different vertebrate species, Ramon y Cajal was able to discern detailed features of immature neurons during development and to chronicle the growth and connectivity of the major classes of nerve cells. In studies of CNS development, he imagined the extension of growth cones from nascent neurons, which he called "soft battering rams," and chronicled the arborization patterns of major classes of neurons in different brain regions.

The idea that CNS neurogenesis occurs in the thin epithelium of the embryonic brain vesicles became apparent when Fred and Mary Sauer showed that cells in the neuroepithelium contain different amounts of DNA, with diploid cells located on the ventricular surface (Sauer and Chittenden, 1959). Clear images of the pseudo-columnar character of the neuroepithelium of embryonic rat brain were achieved in <sup>3</sup>H-Thymidine labeling studies of the neocortex (Berry and Rogers, 1965), and in serial scanning and electron micrographs (Fig. 16.9A), which demonstrated movements of the nuclei during the principal phases of the cell cycle (Hinds and Ruffett, 1971). Cells in interphase extended processes across the thin wall of the epithelium, one cell deep at this stage. Cells entering mitosis retracted the processes and moved to the ventricular surface to divide. The changing shapes of the cells, and the apparent movement of the nucleus within the cells as they undergo morphological changes during the phases of the cell cycle are termed "interkinetic movements." A cardinal feature of the neuroepithelium is its "upside down" orientation relative to epithelia of other tissues. This relates to the fact that the neuroepithelium forms

a tube, which orients the apical surface of neuroblasts in the epithelial sheet toward the lumen of the neural tube. This “ventricular zone” (i.e., zone of the epithelium facing the brain vesicles) is the site of primary neurogenesis in the CNS.

The polarization of the epithelium of the neural tube depends on the formation of adhesion junctions between cells (Joberty *et al.*, 2000; Macara, 2004) (Fig. 16.9B). Two classes of trans-membrane adhesion proteins, cadherins and nectins, establish adhesions between epithelial cells. Aggregation of adhesion sites to an adherens or gap junction in the basal portion of the cells connects the cells, and initiates the movement of cytoskeletal elements to the junctions. A second adhesion site forms at the apical side of the cell, which typically becomes a tight junction. In polarized mammalian epithelial cells, the conserved polarity proteins PAR3/ASIP, PAR-6, and aPKC form a complex that is localized to the tight junction. Cdc42, a polarity regulator from yeast to humans, and Rac GTPases activate the Par-3/Par-6/aPKC-complex, which binds other polarity proteins in some cells (Gao and Macara, 2004; Macara, 2004; Chen and Macara, 2005). A key aspect of “tight” junctions is the requirement for Par-3.

During neuroblast division in ventricular zones, the microtubule-organizing center (MTOC) nucleates astral microtubules required for spindle orientation. Cdc42 is a master polarity regulator from yeast to humans. Cdc42, aPKC, and dynein/dynactin activity control spindle orientation and govern symmetric versus asymmetric patterns of neuroblast division (Yu *et al.*, 2006). Thus, Cdc42-induced MTOC orientation may contribute to whether a cell undergoes symmetric versus asymmetric divisions, and as discussed later, to the “to and fro” movements of dividing cells within the neuroepithelium. The mechanism of “checkpoint control” is critical for CNS neurogenesis as this step governs assembly of the mitotic spindle, and subsequent segregation of chromosomes into daughter cells. In *Drosophila*, Lis1/dynactin complexes physically associate and colocalize on centrosomes, spindle microtubules, and kinetochores to regulate spindle formation and cell cycle checkpoint release (Siller *et al.* 2005).

The neurons of both the peripheral and central nervous systems originate from the neural tube and the folds of the neural tube. The cells of the PNS are generated first, as they delaminate in a specialized region of the dorsal aspect of the neural tube called the neural crest. Neural crest neuroblasts migrate out into the developing nonneuronal tissues, where they will form the axon tracts of the periphery, as the progenitors of the CNS are beginning to establish the regions of the brain and spinal cord that will receive the sensory

information from the PNS and establish brain circuitry. We will therefore discuss neurogenesis and migration in the peripheral nervous system first, followed by patterns of neurogenesis and migration that establish the CNS.

## DEVELOPMENT OF THE PERIPHERAL NERVOUS SYSTEM

### The Neural Crest Is a Migratory Cell Population That Forms Multiple Derivatives

The *neural crest* is a transient population of cells, so named because they arise on the “crest” of the closing neural tube. This cell population is unique to vertebrates and forms most of the peripheral nervous system (PNS). Neural crest cells migrate extensively along characteristic pathways and give rise to diverse and numerous derivatives. All the *dorsal root, sympathetic, parasympathetic, and enteric ganglia* are derived from neural crest cells. Furthermore, most *cranial sensory ganglia* receive a contribution from the neural crest, with the remaining cells derived from *ectodermal placodes*. In addition to forming neurons and glia of the peripheral nervous system, neural crest cells form melanocytes, cranial cartilage, and adrenal chromaffin cells. This wide variety of cell types arises from precursors in the neural folds and neural tube that are multipotent and have stem cell properties (Bronner-Fraser and Fraser, 1988; Stemple and Anderson, 1992) (see Chapter 15 for a discussion of stem cells).

The neural crest originates at the border between the neural plate and the nonneural ectoderm by an inductive interaction between these two tissues (Selleck and Bronner-Fraser, 1995) (Chapter 14). Precursors with the potential to form neural crest initially are contained within the dorsal portion of the neural tube, and these premigratory neural crest cells subsequently emerge from the neural tube. Cells in the neural tube are epithelial and look much like contiguous soda cans that have a defined top (apical) and bottom (basal) side. They are closely apposed to one another and are connected by various types of adhesive junctions. In contrast, migratory cells such as neural crest cells are mesenchymal, having a fibroblast-like morphology that facilitates their movement. Thus, precursor cells within the neural tube change from an epithelial to a mesenchymal morphology as they turn into migratory neural crest cells. Such an *epithelial-to-mesenchymal conversion* is a common event in development during the formation of tissues and organs. The transcription factor *Slug* (also called *Snail2*) is expressed in premi-

gratory and early migrating cells and represents an early known neural crest marker. *Slug* has been associated with epithelial–mesenchymal conversions in a number of cell types and its function appears to be necessary for the emigration of neural crest cells. Initiation of neural crest cell migration proceeds in a rostral-to-caudal progression along most of the neural axis, following upon the heels of the head-to-tailward closure of the neural tube. After emigration, these cells move in a highly patterned fashion through neighboring tissues and localize in diverse sites.

### Initiation of Migration

As they change from epithelial to migratory mesenchymal cells, neural crest cells undergo changes in adhesive properties. While within the neuroepithelium, neural tube cells express high levels of the *cell adhesion molecules* N-cadherin and cadherin. Migrating cells down-regulate these cadherins during migration and up-regulate cadherin-7. Upon coalescing into ganglia and ceasing migration, cadherin-7 is down-regulated and N-cadherin-6b are again up-regulated (Nakagawa and Takeichi, 1998). This suggests that a shift in cell surface and adhesive properties may accompany the onset and cessation of migratory behavior. Neural crest cells also turn on RhoB during the initiation of migration.

After leaving the neural tube, neural crest cells encounter extracellular spaces that are rich in *extracellular matrix (ECM) molecules*, such as fibronectin, laminin, collagens, and proteoglycans. These may serve as a good migratory substrate and, indeed, the neural crest cell surface has abundant integrin receptors that mediate adhesion to ECM molecules. Furthermore, antibodies to the  $\beta_1$  subunit of *integrin* cause severe perturbations in neural crest development in the head. They appear to prevent the migration of some neural crest cells from the cranial neural tube. In the trunk, function-blocking antibodies that interfere with the  $\alpha_4$  subunit of *integrin* cause defects in neural crest cell movement, but fail to alter the segmental pattern of migration through the somites. These results suggest that perturbing integrin function alters the properties of migratory cells, but not their overall metameric pattern of migration. Thus, cell–matrix interactions may play a permissive role in the migration of neural crest cells through the somites, but cannot play an instructive role in directing the precise patterns or pathways for crest cell migration.

### Techniques for Following Neural Crest Cells

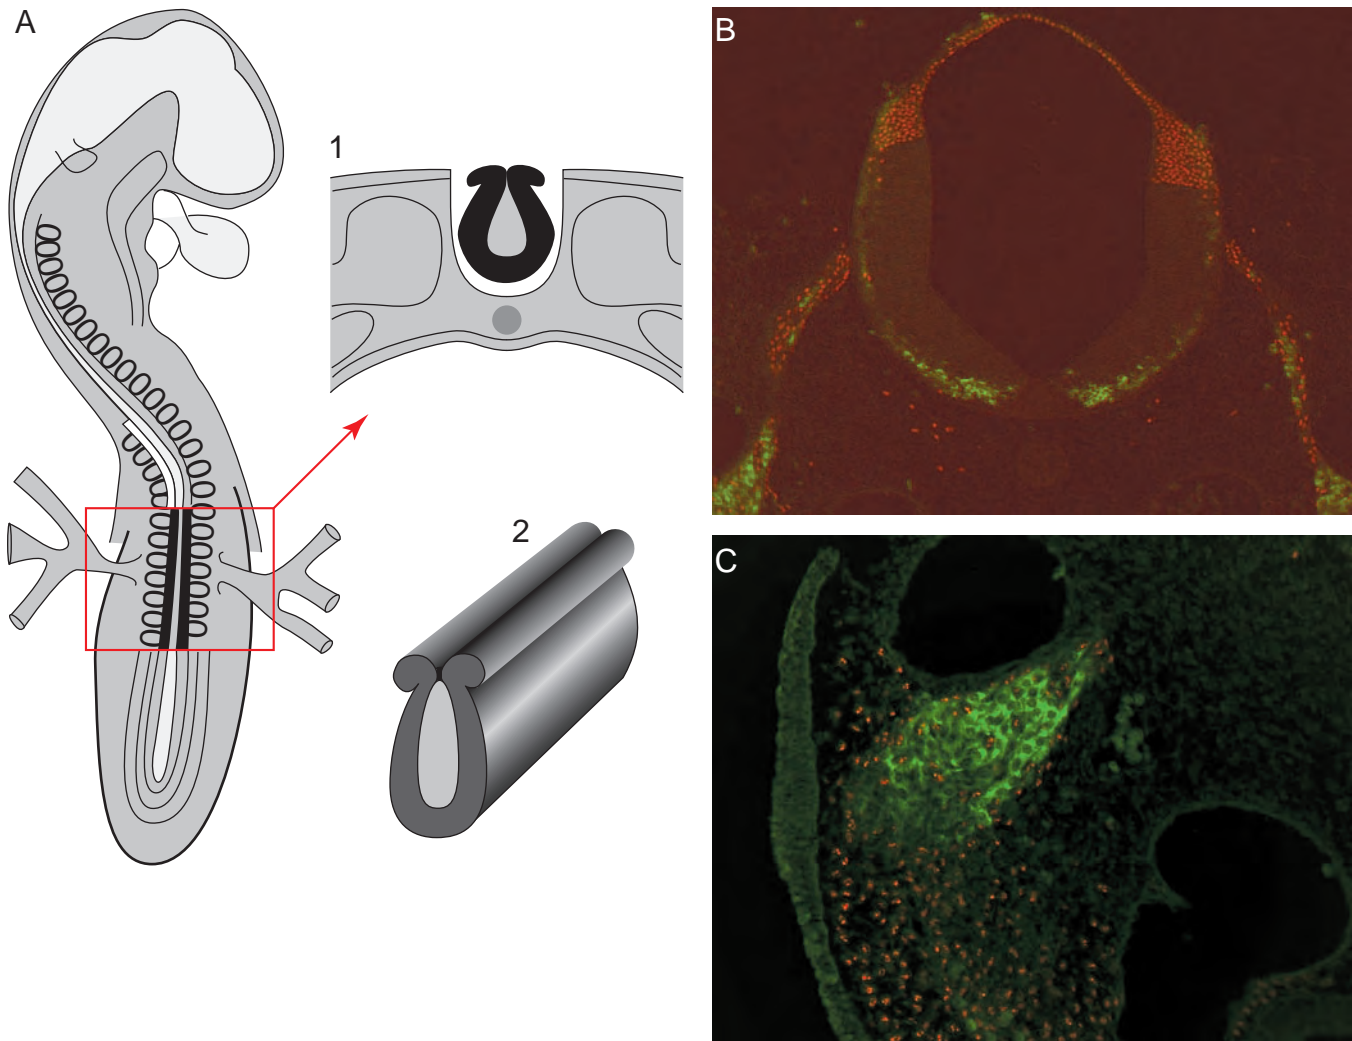

When neural crest cells emerge from the neural tube, they first enter a cell-free space in which they are easily identifiable (Fig. 16.1). Subsequently, they invade

FIGURE 16.1 A transverse section through a chick embryo showing neural crest cells initiating migration from the dorsal neural tube and into an ECM-filled space. Courtesy of Jan Lofberg.

other tissues in which they are difficult to distinguish. Therefore, it is necessary to *mark* neural crest cells in order to study their migratory patterns and derivatives. A variety of techniques have emerged for this purpose, ranging from transplantation of tissue containing premigratory neural crest cells to lineage tracers and molecular markers. *Neural tube transplantations* have provided a wealth of information about neural crest migratory pathways and, in particular, derivatives arising from this population. Although this approach was widely used in amphibians for studying numerous embryonic processes, it has been applied most successfully to the analysis of neural crest migratory pathways and derivatives in avian embryos (LeDouarin and Kalcheim, 1999). Initial experiments in birds involved transplanting a neural tube from a donor labeled with the radioactive marker [ $^3\text{H}$ ] thymidine into an unlabeled host (Weston, 1963). Neural crest cells generated from the labeled neural tube also were labeled and could be identified readily in the periphery. This technique yielded important information about early stages of neural crest migration, but the label became diluted with further cell division and was not useful for looking at long-term differentiation of neural crest cells into diverse derivatives.

To circumvent this problem, LeDouarin took advantage of the ability to perform grafts between related species of birds, such that the grafted cells were indelibly marked (Fig. 16.2). This created an interspecific *chimera*, from the Greek meaning “fabulous monster,” containing a donor quail portion of the neural tube and neural crest in an otherwise normal chick host embryo. Quail neural crest cells migrate away from the grafted neural tubes and can be recognized easily within the

**FIGURE 16.2** Procedures for grafting a fragment of the neural primordium from a donor quail into a host chicken embryo as used by LeDouarin and colleagues. host chick embryo by staining for condensed heterochromatin, which characterizes the quail but not chick cells.

More recently, this technique has been facilitated greatly by the advent of quail-specific antibodies. Use of the chick–quail marking system made it possible to demonstrate that neural crest cell populations originating from different axial levels follow distinct migratory pathways and give rise to different progeny once they reach their destinations. In addition to grafting experiments, antibodies that recognize neural crest cells, such as HNK-1 and NC-1 antibodies, made it

possible to identify early migrating neural crest cells without the necessity of performing microsurgery. The exclusive use of neural crest antibodies has several pitfalls because these antibodies are neither entirely specific nor stain the full complement of neural crest cells. However, they do provide important confirmatory information about the pathways followed by neural crest cells. More recently, a number of other molecular markers for early neural crest populations have become available. These include the cell adhesion molecule cadherin-6b and the transcription factor *Slug*, expressed in the neural folds and neural crest cells

during early stages of migration and Sox10, expressed in early migrating neural crest cells and later in neural crest-derived glia.

One problem with using antibodies or molecular markers to follow cell migratory patterns is that these do not represent true lineage markers. Shifts in their expression patterns could just as easily reflect up- or down-regulation of these molecules as changes in cell position. Therefore, approaches for labeling small groups as well as large populations of neural crest cells have been employed to follow individual cell movements and interactions within the population. One successful approach has been to inject the *lipophilic vital dye DiI* or electroporating GPF constructs into the neural tube or neural folds. Because the dye is hydrophobic and lipophilic, it intercalates into all cell membranes that it contacts. Injection into the neural tube marks all neural tube cells, including presumptive neural crest cells, within its dorsal aspect. Because the time and location of injection can be controlled, this provides a direct approach for following migratory pathways. When dye injections are made focally into neural folds, this technique can be used to label very small numbers of cells. It has the further advantage of being applicable to almost all vertebrates. A disadvantage, however, is that the dye becomes diluted with each cell division and, therefore, is not useful for examining the long-term differentiation of neural crest derivatives.

Because most studies of cell migration *in vivo* look only at the beginning and end point, little is known about the dynamics of neural crest cell movement. Advances in imaging technologies have made it possible to acquire more refined images *in ovo*. Time-lapse movies of cranial neural crest migration can be generated by injecting DiI into the lumen of the chick neural tube, and high-resolution confocal images can be made of the labeled cells over time (Fig. 16.3). These movies make it possible to visualize the migratory behavior of neural crest cells as they emerge from the cranial neural tube and migrate toward the branchial arches. As the embryo develops, it is possible to follow individual cell movements within the branchial arches, which will give rise to the bone and cartilage of the jaw. Neural crest cells move in defined streams and appear to form distinct chains in which cells are oriented along the same trajectory and remain in contact via their processes. This suggests a large degree of intercommunication between migrating populations of cranial neural crest cells.

A number of different methods have proved useful for following the pathways of neural crest migration, including neural tube transplantations, vital dye labeling, and antibody staining. These have made it possible not only to establish the various routes of neural

crest migration occurring at different axial levels, but also to follow the derivatives of neural crest cells arising from distinct locations.

### Regionalization of the Neural Crest Along the Body Axis

Despite differences in the nature of the techniques involved, quail/chick chimeras, molecular markers, and cell labeling have provided similar pictures of the migratory pathways followed by neural crest cells. These migratory pathways and the derivatives formed by neural crest cells are regionalized according to their original position along the anterior/posterior axis, such that cells from a given axial level give rise to a characteristic array of progeny and follow distinct pathways from those arising at other axial levels (LeDouarin and Kalcheim, 1999; Noden, 1975). The different populations of neural crest cells arising along the neural axis have been designated as cranial, vagal, trunk, and lumbosacral (Fig. 16.4). Distinct cell types differentiate from these different populations.

At cranial levels, some neural crest cells contribute to the *cranial sensory ganglia* and the *parasympathetic ciliary ganglion* of the eye, whereas others migrate ventrally to form many of the *cartilaginous elements of the facial skeleton*. One of the interesting things about neural crest-derived bones of the head is that these are the only skeletal elements in the body that are derived from ectoderm. Precise quail/chick grafting experiments have determined the regions of neural tube from which neural crest cells arise to contribute to cartilaginous elements and cranial ganglia (Noden, 1975). Neural crest cells originating in the midbrain migrate primarily as a broad, unsegmented sheet under the ectoderm; they contribute to derivatives ranging from the skeleton around the eye, connective tissue, and membranous bones of the face, to the ciliary ganglion and trigeminal ganglia (LeDouarin and Kalcheim, 1999). Neural crest cells arising in the hindbrain migrate ventrally and enter the branchial arches to form the bones of the jaw.

Vagal neural crest cells migrate long distances to form the *enteric nervous system*, which also receives a contribution from the lumbosacral neural crest. Within the gut, the earliest generated crest cells move as a wave from anterior to posterior to populate the bowel, which they appear to populate in sequence such that the anterior portions are populated by neural crest cells first and the cells move to progressively more posterior sites. Mice bearing a "lethal spotted" mutation lack neural crest cells in a portion of their bowel. This leads to a lack of innervation in the region called aganglionic bowel. As a consequence, food waste fails

**FIGURE 16.3** Labeling of neural crest cells with lipophilic tracer dyes. (A) On the left is a chick embryo viewed shortly after unilateral ablation of the neural folds of roughly half the neural tube at the level of the presumptive midbrain. A spot of DiO (green) was focally injected into the remaining neural tube, and DiI (red) was injected into the bordering intact neural folds. On the right, the same embryo after 48 h of further development. Cells that were originally in the neural tube had dispersed as migratory neural crest cells from both the green- and the red-labeled spots. (B–D) Different views of time-lapse movies of embryos in which the neural tube and premigratory neural crest cells were labeled with DiI. (B) Two views of the same embryo immediately after DiI labeling (left) and several hours after neural crest migration from the hindbrain. Rhombomeres (r1–r7) are indicated. (C) A similar embryo at a later time point by which time neural crest cells have migrated into the branchial arches (BA). (D) At higher magnification of neural crest streams in the branchial arches, cells seem to be in close contact as if following each other in narrow streams. to move through this portion of the bowel, leading to a disorder called “mega-colon.” A similar defect is observed in humans leading to Hirschsprung’s disease. One cause of this disorder is from a defect in molecules called endothelins and their receptors. The failure of neural crest migration in the aganglionic bowel of lethal spotted mutant mice is caused by a defect in mesenchymal components of the gut, whereas the neural crest cells themselves are normal.

Trunk neural crest cells follow two primary migratory pathways (Fig. 16.5): a *dorsolateral pathway* between the ectoderm and the somite and a *ventral pathway* through the rostral half of each sclerotome, the mesenchymal portion of the somite that will go on to form the vertebrae.

Cells following the dorsolateral stream give rise to *melanocytes*. Those cells following the ventral pathway give rise to the peripheral nervous system of the trunk, including the chain of *sympathetic ganglia* and *dorsal root ganglia*, as well as *chromaffin cells* of the adrenal medulla. In addition to these neurons, these cells generate *glia* of the peripheral ganglia and *Schwann cells* that ensheath and myelinate peripheral axons.

The neural crest can be subdivided into specific subpopulations based upon their level of origin along the neural tube. Different populations follow different migratory pathways and form characteristic types of derivatives. For example, cranial bone and cartilage only arise from the cranial neural crest.

#### **Grafting of Neural Crest Cells to New Locations—Intrinsic versus Extrinsic Cues?**

Neural crest cells that arise and migrate at different axial levels assume different fates. Thus, it is possible that they are specified at early times to take on particu-

**FIGURE 16.4** Schematic diagram showing different levels of the neural axis from which neural crest cells arise. From anterior to posterior, the neural axis can be divided into cranial, vagal, trunk, and lumbosacral levels. Each gives rise to distinct derivatives.

lar fates. For example, one possibility is that neural crest cells are preprogrammed by their axial level to populate specific derivatives; alternatively, neural crest cells might be multipotent and migrate naively into available locations, where local cues provide them with instructions about their fates. To test the role of migratory pathways in choice of fate, neural tubes from particular axial levels have been grafted to new locations. This is referred to as a “heterotopic” graft. These experiments have revealed, for example, that when vagal neural crest cells are grafted to trunk regions, they form normal trunk derivatives (dorsal root ganglia, sympathetic ganglia, etc.) and normal vagal derivatives (enteric ganglia of the gut) (Fig. 16.6). The gut is immediately ventral to the trunk region and is connected to it by a narrow piece of tissue called the dorsal mesentery. Despite their close proximity, trunk

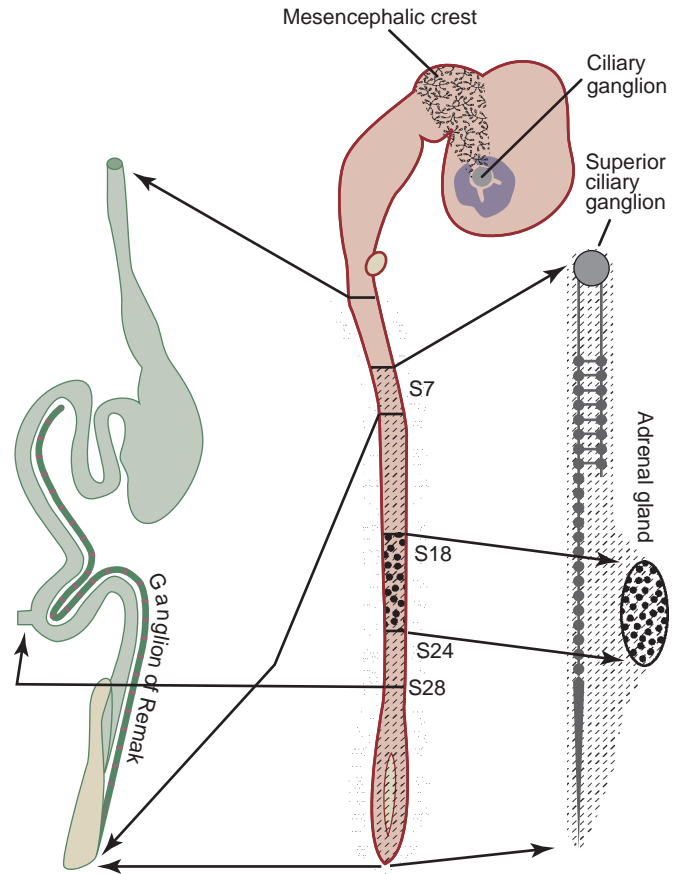

**FIGURE 16.5** Schematic diagram of an idealized embryo in cross-section showing pathways of neural crest migration in trunk and derivatives formed. Neural crest cells migrate along two primary pathways: dorsally under the skin or ventrally through the sclerotome. Dorsal migrating cells form pigment cells, whereas ventrally migrating cells give rise to dorsal root and sympathetic ganglia, Schwann cells, and cells of the adrenal medulla. Drawn by Mark Selleck.

neural crest cells normally fail to invade the gut where enteric ganglia form. When vagal neural tubes are grafted in place of trunk neural tubes, however, donor vagal neural crest cells do invade the gut and form enteric ganglia. Therefore, these cells can respond to normal trunk neural crest migratory pathways, but, in addition, some cells behave in a “uniquely vagal” fashion and migrate directionally to the gut. This indicates some intrinsic differences between the two populations.

Along similar lines, when cranial neural tubes are grafted in place of the trunk neural tube, donor cranial neural crest cells form some normal derivatives in the trunk-like dorsal root and sympathetic ganglia. Other cells, however, fail to migrate and instead differentiate into ectopic cartilage. In the reciprocal experiment, avian trunk neural crest cells grafted to the head region appear unable to generate cartilage at all, although they can participate in the formation of elements of the cranial ganglia (LeDouarin and Kalcheim, 1999) (Fig. 16.6).

These experiments suggest two things: (1) environmental factors can influence neural crest cells from different axial levels to express a broader range of fates than they would normally express when left *in situ* and (2) some neural crest cells undergo their intrinsic

**FIGURE 16.6** Neural crest cells at different levels along the anterior–posterior axis give rise to distinct autonomic and adrenomedullary derivatives in avian embryos. In the cephalic region (center), mesencephalic crest cells populate the ciliary ganglion. Ganglia of the sympathetic chain (right), including the superior ciliary ganglion, are formed from spinal neural crest cells originating caudal to somite 5. Cells of the adrenal medulla (right) originate exclusively from neural crest cells between somites 18 and 24. Vagal neural crest cells generated between somites 1 and 7 form enteric ganglia (left), whereas cells of the ganglion of Remak (left) are derived from the lumbosacral neural crest posterior to somite 28. Drawing provided by Dr. M. Bronner-Fraser.

program even when grafted to an ectopic site. Thus, some combination of *intrinsic* and *extrinsic information* is likely to govern neural crest cell fate decisions. The migratory pathways taken by neural crest cells are likely to play an important regulatory role in cell fate specification. Indeed, different migratory pathways contain different distribution patterns of important inducing factors. A number of factors, including BMPs, neuregulins, and glucocorticoids, have been demonstrated to influence the choice of neural crest cells into neural, glial, or chromaffin lineages (see Chapter 15). When added to multipotent neural crest stem cells in culture, these factors can drive these cells into neural, glial, or chromaffin lineages, respectively. Accord-

ingly, BMP-7 is present in the dorsal aorta adjacent to the location where trunk neural crest cells differentiate into sympathetic neurons. Similarly, glucocorticoids are produced by the adrenal cortex, which surrounds the adrenal medullary cells.

In addition to specific growth factors, the timing of emigration may play an important role in eventual neural crest cell fate decisions. Neural crest cells exhibit an orderly pattern in the timing of migration, with cells initially following the ventral pathway and later contributing to progressively more dorsal derivatives. Although early and late migrating cranial neural crest cells appear to have a similar developmental potential, it is likely that the cell population does undergo a change in the range of fates that the cells can assume. For example, the last emigrating trunk neural crest cells in the bird give rise to pigment cells and appear to have a limited capacity to form sympathetic neurons. However, *stem cells* appear to persist in the neural tube and retain the potential to form neural crest. Well past the normal time of neural crest cell emigration, cells with the full range of neural crest potential can be isolated from various neural crest derivatives (Kruger *et al.*, 2002; Joseph *et al.*, 2004). In the embryo, these late-emigrating cells appear to contribute to a subpopulation of neural crest derived cells in the dorsal root ganglia.

### Summary

Neural crest cells are somewhat plastic with respect to their prospective fates. When put into a new environment, they sometimes behave according to their new location. However, some cells act according to their original location and thus have some “intrinsic” information. With time, the developmental potential of neural crest populations becomes restricted, although a subpopulation of “stem cells” may remain until late stages.

### Segmental Migration of Neural Crest Cells

A hallmark of the developing peripheral nervous system is its inherent *segmentation*. After neural crest cells migrate from the neural tube and through the somites, they condense to form segmentally arranged sensory and sympathetic ganglia. For each somite, a single sensory and sympathetic ganglion forms. This exquisite and reproducible pattern suggests the presence of some inherent segmental information in the embryo that is responsible for segmental migration and gangliogenesis of neural crest cells. In longitudinal sections through early embryos, it is clear that neural crest cells migrate in a metameric pattern, moving exclusively through the rostral half of each somite while failing to enter the caudal half (Fig. 16.7).

**FIGURE 16.7** Trunk neural crest cells migrate in a segmental fashion. (A) Schematic diagram demonstrating that neural crest cells migrate through the sclerotomal portion of the somites, but only through the rostral half of the sclerotome. (B) In longitudinal section, neural crest cells (green) can be seen migrating selectively through the rostral half of each somitic sclerotome (S). From Bronner-Fraser (1986).

Such a segmental pattern of migration could be caused by inherent cues within the neural tube that direct neural crest cells to migrate segmentally. Alternatively, tissues through which neural crest cells migrate may contain patterning information that results in segmental migration. The relationship between neural crest cells and their surrounding tissues has been explored by manipulating the neural tube and/or somites in a series of grafting experiments. Removal of the somites results in the formation of huge, unsegmented neural crest-derived ganglia, suggesting that somites are necessary for the segmental migration of neural crest cells. However, inversion of the segmental plate in the rostrocaudal dimension reverses the pattern of neural crest migration, such that neural crest cells migrate through the half of the rotated sclerotomes that was originally rostral but is now caudal. Motor axons, which also traverse the rostral sclerotome in normal animals, exhibit similar behavior to neural crest cells after segmental plate rotation. This suggests that the information necessary to guide neural crest cells and motor axons is intrinsic to the somites. Furthermore, these

experiments show that the rostrocaudal polarity of the somites is already established at the segmental plate stage.

Other experimental manipulations demonstrate that the caudal half of each somite is inhibitory whereas the rostral half somite is permissive for neural crest migration and motor axon guidance. If somites are constructed to contain only caudal sclerotome tissue, neural crest cells and motor axons fail to migrate altogether. Conversely, an all-rostral somite results in the absence of segmentation for both neural crest cells and motor axons. Taken together, these findings demonstrate that the segmental migration of both neural crest cells and motor axons is due to cues inherent in the somite. These cues may be caused by attractive cues in the rostral-half sclerotome, inhibitory cues in the caudal-half sclerotome, or a combination of both. The finding that somites containing all caudal-half sclerotomes cannot support neural crest migration strongly suggests that some of the guidance cues are inhibitory. This segmentally arranged streams of migrating neural crest cells, in turn results in the segmental organization of the neural crest-derived ganglia of the peripheral nervous system.

Although it was suggested that Eph/ephrin signaling might direct the pattern of trunk neural crest migration (Krull *et al.*, 1997; Wang and Anderson, 1997), the Eph and ephrin mutant mice that have been examined fail to exhibit trunk neural crest migration defects (Orioli *et al.*, 1996; Wang *et al.*, 1998). Another receptor expressed by neural crest cells is Neuropilin-1 (Npn-2), which is expressed in premigratory and migratory neural crest in both chick and mouse. Strikingly, trunk neural crest cells no longer migrate segmentally through the somites of *Npn-2* mutants and are distributed equally in rostral and caudal sclerotome. These defects are the result of *Npn-2/Sema3F* signaling, as *Sema3F* mutants have an identical phenotype. These results demonstrate that *Npn-2/Sema3F* signaling is necessary to restrict neural crest migration to the rostral somite (Gammill *et al.*, 2006). Interestingly, metameric dorsal root ganglia still form in *Npn-2* mutants in the absence of segmental neural crest migration, suggesting that segmental migration may be separable from ganglion formation.

As in the trunk, the migration of neural crest cells in the hindbrain is also segmented. Three broad streams of migrating cells are found adjacent to rhombomere 2 (r2), r4, and r6, whereas no neural crest cells are apparent adjacent to r3 and r5. Focal injections of DiI at the levels of r3 and r5 have demonstrated that both of these rhombomeres generate neural crest cells and that the apparent segmental pattern results from the DiI-labeled cells that originated in r3 and r5 deviating

**FIGURE 16.8** Distribution of Eph receptors (A and C) on neural crest cells in the rostral sclerotome and ephrin ligands in the caudal sclerotome (B and D) of chick embryos. Eph receptors are on neural crest cells in the rostral half of each somite, whereas inhibitory ephrin ligands are expressed in the caudal halves of each sclerotome. From Krull *et al.* (1997).

rostrally or caudally and failing to enter the adjacent preotic mesoderm or otic vesicle region.

Trunk neural crest cells move in a segmental pattern, which is controlled by inhibitory molecules present in the caudal-half of each somite. Neural crest cells have Neuropilin-2 receptors on their surface. When they encounter Sema3F ligands in the caudal somite, they are diverted from this location, leading to selective migration through only the rostral-half somite.

### Cessation of Neural Crest Migration

Neural crest cells exhibit an orderly pattern in their migration. Whereas the first cells to migrate tend to move most ventrally, later migratory cells contribute to progressively more dorsal derivatives. The different destinations of neural crest derivatives are therefore populated in a sequential order during development. One possibility is that the early migrating cells “fill” the more ventral sites, effectively clogging up the pathway. Alternatively, the sites themselves may change with time so that they can no longer support migration.

Surprisingly little is known about how neural crest cells know that they have reached the appropriate destination and stop their migration. This is in marked contrast to the developing CNS, where a number of mutations affect the ability of neuroblasts to cease migrating. It is clear that cell adhesion molecules such as N-cadherin and N-CAM are up-regulated after cells reach their final sites and condense to form peripheral ganglia. However, there is no evidence for a causal role for cell adhesion molecules in this process.

### Neurogenesis in the PNS

Some of the factors and signaling cascades that result in neurogenesis in the developing PNS are beginning to be understood (see Chapter 15). Many neural crest cells appear to be multipotent and not yet committed to a neural fate. However, particular external factors can influence their fate decisions. For example, clonal populations of neural crest cells become neural in the presence of BMPs and glial in the presence of glial growth factor. Similarly, activation of Notch signaling promotes gliogenesis at the expense of neurogenesis in neural crest cells and their derivatives. Certain transcription factors may bias cells toward certain fates; for example, whereas *mash-1* is essential for sympathetic neuron formation, neurogenins are essential for sensory fates (Christiansen *et al.*, 2000).

An interesting contrast between the developing PNS and the CNS is that migrating neural crest cells

proliferate rapidly as they move. In fact, even after exhibiting defined neuronal characteristics, some neural crest derivatives continue to divide. For example, in the developing sympathetic ganglia, neural crest-derived cells express neurotransmitters and other proteins characteristic of sympathetic neurons but remain actively mitotic. However, other neural crest cells such as sensory neurons appear to withdraw from the cell cycle well before they express neuronal traits.

### Summary

Neural crest cells migrate over long distances throughout the body to form diverse cell types, including neurons, glia, melanocytes, and cells of the adrenal gland. The migratory pathways of neural crest cells vary along the rostrocaudal body axis, and the local environments through which cells migrate and eventually differentiate play an important role in phenotypic specification. The migration of neural crest cells is guided by both positive (attractive or permissive) and inhibitory (repulsive) cues that are found in the environment.

## CELL MIGRATION IN THE CNS

In developing CNS, a series of complex cell movements organizes young neurons into a series of layers, or neuronal laminae. The relationship of neurogenesis to the formation of neural layers in developing cortex emerged from the pioneering work of Richard Sidman who discovered the technique of thymidine “birthdating” (Sidman, 1970). The broad application of this approach to different brain regions and times of development demonstrated the spatiotemporal pattern of neurogenesis in the vertebrate CNS.

The discovery of directed neuronal migration along glial fibers by Pasko Rakic in the 1970s (Rakic, 1972; Sidman and Rakic, 1973) set the stage for a period of intense focus on the process of neuronal migration in cortical histogenesis. Their review of neuronal migration in the human neocortex demonstrated that directed migrations establish the principal neuronal layers by the end of the second trimester (Sidman and Rakic, 1973). The studies on the architectonics of human cortical malformations (Dobyns, 1995; Barkovich, 1996) revealed populations of heterotopic cells and suggested that pathogenic processes disrupted normal glial-guided neuronal migration (Rakic, 1988). The hypothesis that cortical malformations resulted from migration defects became even more attractive with the analysis of spontaneously occurring neurological

mutations. Cell and molecular studies of identified neurons from the cerebellar cortex and hippocampal formation provided real time imaging of neuronal migration along glia (Edmondson, 1987; Gasser and Hatten, 1990a). All these studies underscore the critical role of neuronal migration in brain development.

### Cortical Histogenesis

The histogenesis of the cortex requires both directed migrations and the formation of two intermediate scaffolding zones, the preplate and the cortical plate. The preplate forms in the initial cell cycles of cortical neurogenesis (between embryonic days 11 and 12 in the mouse) and gradually transforms into the cortical plate. During the preplate stage, pioneer axons begin to extend from neurons within the preplate zone, and somatosensory and motor areas begin to emerge within the neocortex. The preplate contains cells that express specific markers and project axons along defined pathways (Valverde *et al.*, 1995; Super and Uylings, 2001; Jimenez *et al.*, 2003; Garcia-Moreno *et al.*, 2007; Meyer, 2007). As the preplate matures, extensive cell movements occur across the *dorsoventral* (DV) and radial planes of the preplate. The latter apparently orients the cells into a colonnade, which splits into a superficial marginal zone of Cajal-Retzius cells and small neurons, and the cortical plate (Rakic and Zecevic, 2003). The latter contains the immature Pyramidal neurons destined for layers V and VI as well as a smaller population of interneurons.

As first proposed by Shatz, in studies that demonstrated the critical role of the subplate in establishing cortical architectonics (McConnell *et al.*, 1989; Ghosh and Shatz, 1993; Allendoerfer and Shatz, 1994; Kanold and Shatz, 2006), and more recently as a site of action of the *reeler* gene, the cortical plate is an essential transient structure in cortical development. When the preplate fails to form the cortical plate, as in the *reeler* mutant mouse, the normal laminar architecture of the neocortex is disrupted. As development proceeds, directed migrations of Pyramidal neuron precursors along the radial glial fibers establish layers IV, I, and II with vast populations of interneurons (80%) entering the cortex tangentially from their site of origin in basal forebrain, as discussed in the next section.

Detailed studies of the cell cycle by Takahashi and Caviness (Caviness *et al.*, 2003) demonstrate that the murine neocortex is generated over an epoch of 11 cell cycles. Recent studies show that the polarity protein Numb is expressed in early phases of cortical histogenesis (Petersen *et al.*, 2002) that colocalizes with EGFR by a process that is actin-dependent (Sun *et al.*, 2005). To determine whether the roles of Numb and Numb-

like (*Numbl*) proteins change as neurogenesis progresses, Zhong and colleagues (Petersen *et al.*, 2004) conditionally ablated both genes in the neocortex at later phases of neurogenesis. The loss of *Numb* and *Numbl* caused premature progenitor cell depletion and malformations of the neocortex. This finding led to the idea that *Numb*-mediated asymmetric cell divisions provide a general mechanism for cell cycle control during cell fate allocation events in the developing mammalian brain (Petersen *et al.*, 2004). An especially interesting aspect of cortical polarity in CNS neurogenesis is the fact that proteins related to the *Drosophila Notch* and *Numb* function both as polarity proteins and as mitogens (Solecki *et al.*, 2001).

Within the neocortical VZ, one of the first cells to express markers of differentiation is a specialized form of glial cell, called the radial glial cell. This cell, recognized by its expression of the RC2 antigen, extends long processes perpendicular to the ventricular surface toward the overlying cerebral wall, and continues to grow as the laminae develop such that it spans from the ventricular surface to the pial surface throughout development (Misson *et al.*, 1991). As discussed later, these radial processes presage the basic columnar plan of development, providing a scaffold "in plane" with the layer of dividing cells for a subpopulation of neurons to migrate away from the primary germinal matrix.

### Formation of the Basic Embryonic Zones

As development proceeds, rapid cell division thickens the proliferative zone, and several layers of cells develop above the neuroepithelium. The first step in this process is the creation of the marginal zone (M), a cell-sparse zone from which nuclei are apparently excluded during interkinetic movements in the epithelium. Second, a zone of growing, afferent axons appears, forming an intermediate zone (I) between the VZ and the marginal zone (Fig. 16.11). In the cortex, these axons are pioneering the connections in both directions between the cortex and the thalamus. The neuroepithelium thus progresses from a single layer of dividing cells to three and then four zones, termed the ventricular zone (proliferating cells), intermediate zone (axons), preplate zone (postmitotic neuronal precursors), and the marginal zone (Committee, 1970).

#### *Cell Movements within the Primary Proliferative Matrix*

Imaging of dye-labeled cells in slices of embryonic cortex reveals extensive movements of the neuroblasts within the neuroepithelium. Labeled cells move intermittently within the plane of the epithelium at speeds

between 10 and 100  $\mu\text{m}/\text{h}$  (Fishell *et al.*, 1993). Since cells can move within the plane of the neuroepithelium, the spatial organization of the neuroblasts in the VZ does not provide a “protomap” of the adult neocortex. Experiments using retroviral markers to follow the dispersion of clonally related cells in the developing brain confirmed this result, demonstrating widespread dispersion of cells within the developing cortex (Walsh and Cepko, 1992).

### *Molecular Mechanisms of Cell Motility:* *General Features*

Neuronal motility in the developing CNS, like that of all metazoan cells, occurs in response to a migration-

promoting signal(s), which polarizes the cell and induce the extension of protrusions in the direction of migration (Ridley *et al.*, 2003) (Fig. 16.13). These protrusions can be large, broad lamellipodia or spike-like filopodia, driven by actin polymerization and microtubule dynamics, and stabilized by adhering to the extracellular matrix (ECM) in the case of migrating neural crest cells or adjacent to radial glial cells or to bundles of axons in the case of radial, glial-guided migrations and tangential migrations. Adhesions serve as traction sites for migration as the cell moves forward.

A number of labs have provided evidence that the small GTPase Cdc42, and homologs of the *C. elegans* polarity signaling complex Par6, orient

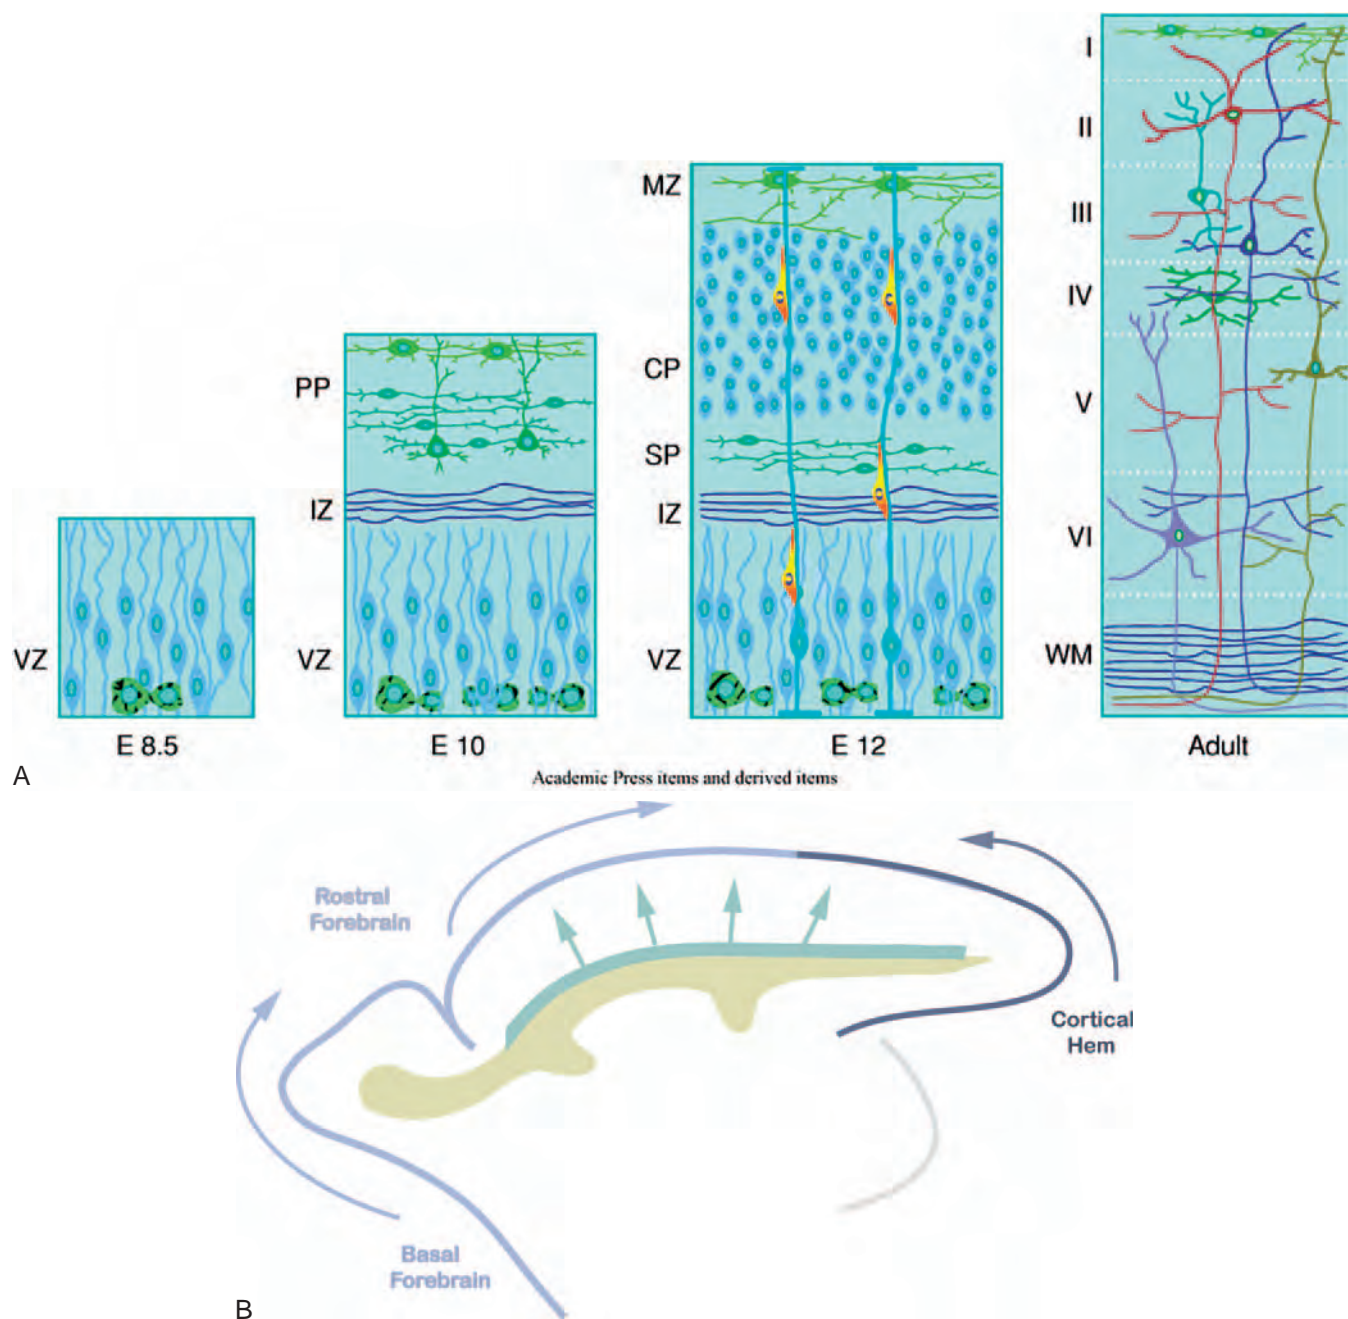

**FIGURE 16.9** (A) The ventricular zone forms a pseudostratified columnar epithelium. Here neural progenitor cells have been visualized in the cerebral vesicle of a hamster embryo using scanning electron microscopy. Neuroepithelial cells are elongated bipolar cells that, at this early stage of development (E9.25), span the entire wall of the cerebrum. Some of the cells at the ventricular surface (bottom) appear spherical; these cells have retracted their cytoplasmic processes and are presumably rounding up in preparation for mitosis. Other rounded cells at the external surface (top) may be young neurons beginning to differentiate. (Inset) A low-power view of the hamster cerebral vesicle, corresponding roughly to that of a human embryo at the end of the first month of gestation. From Sidman and Rakic (1973). (B) Polarity proteins and vertebrate epithelia. Three classes of cell–cell junctions form between cells in a vertebrate epithelium. Conserved polarity proteins function in the formation of tight junctions (red). The cadherin and nectin cell adhesion proteins are required to form adherens junctions (green) and connexins form gap junctions (purple). During cell division in the neuroepithelium, the mPar6 polarity complex positions the spindle of the dividing cell (see text for details).

**FIGURE 16.10** Radial glial cells provide a pathway for neuronal migration. (A) In the late nineteenth century, the Italian histologist G. Magini used Golgi impregnation methods to visualize a system of glial fibers that spanned the cortical wall. He proposed that the glial fibers provided a scaffold for neuronal migration. (B) In the late twentieth century, Rakic and Sidman again used the Golgi impregnation method to map radial glial cells in the developing primate neocortex. As described later, they used EM to visualize the relationship of young neurons to the glial fiber system. (C) Three-dimensional reconstruction of serial EM sections of a migrating neurons in the intermediate zone of the primate neocortex illustrate the cytology and neuron-glia relationships of migrating neurons *in vivo*. The cell soma of the migrating cell apposes to radial glial fibers (striped vertical shafts, RF1-6), which extend short lamellate expansions (LE). Nuclei (N) of migrating neurons are elongated, and their leading processes (LP) are thicker and richer in organelles than their trailing processes (TP). The lower part of the diagram depicts the numerous parallel axons of the optic radiations (OR). These axons have been deleted from the upper portion of the figure to reveal the radial glial fibers. The leading process extends several pseudopodial endings (PS), which appear to explore the territory through which the neuron is migrating. In cross-section (a-d), a migrating neuron partially encircles the shaft of the radial glial fiber. From Sidman and Rakic (1973).

**FIGURE 16.11** Development of the cerebral cortex. (A) *Formation of the Fundamental Layers*: The ventricular zone (VZ) contains the progenitors of neurons and glia. The first neurons to be generated establish the preplate (PP); their axons, as well as in growing axons from the thalamus, establish the intermediate zone (IZ). The subsequently generated neurons of cortical layers II–VI establish the cortical plate (CP), which splits the preplate into the marginal zone (MZ), or future layers I, and the subplate (SP), a transient population of neurons. After the completion of neuronal migration and differentiation, six cortical layers are visible overlying the white matter (WM) and the subplate has largely disappeared. Neural precursors in the subventricular zone (SVZ) continue to generate neurons that migrate rostrally into the olfactory bulb, even during postnatal life. (B) *Emerging Complexity on the Origin of Layer 1 Neurons*. Recent experiments in rodents and primates reveal multiple origins and migratory pathways of the precursor neurons in layer 1 of the developing neocortex. As discussed earlier, the neocortical VZ is a primary source of preplate neurons, which contains layer 1 cells. However, subsets of layer 1 neurons also arise in the rostral aspect of the neocortex, the basal forebrain, and the cortical hem. The latter progenitor cells migrate along the surface of the emerging brain from their sites of origin into the superficial layer of the neocortex. (This population of cells migrates several days before progenitors destined to become cortical interneurons). See text for details.

the nucleus, and centrosome/Golgi apparatus in both nonneuronal and neuronal motility (Etienne-Manneville and Hall, 2001; Burakov *et al.*, 2003; Etienne-Manneville and Hall, 2003). The spatial localization of protrusive activity in the extending growth cone occurs by a mechanism that involves Cdc42 signaling that localizes Rac activity to the leading edge, and recruits  $\zeta$ PIX Rac-GEF to the front of the cell. Thus, Cdc42 signaling orchestrates the polarization of actin and microtubule dynamics in migrating cells through separate signaling pathways (Cau and Hall, 2005).

Actin polymerization in lamellipodia is mediated by the Arp2/3 complex, which binds to the sides or tip of a preexisting actin filament and induces the formation of a new daughter filament that branches off the mother filament. Activation of the Arp2/3 complex is localized by WASP/WAVE family members, which are also activated at the cell surface. During migration, an “elastic Brownian ratchet” mechanism, in which thermal energy bends nascent short actin filaments, and pushes the membrane forward. Thus, unbending a growing axon filament against the leading edge of the cell provides a driving force for the motility of neural crest cells and extending axons. The local activation of the Arp2/3 complex, through downstream signaling events, induces lamellopodia to extend in a particular direction (Krause *et al.*, 2003), providing the basis for directional migration (reviewed in Ridley *et al.*, 2003).

The binding of myosin II to the actin cytoskeleton regulates the contraction of the actin cytoskeleton, which transmits tensile force and moves the cell toward adhesion sites (Kim and Chang, 2004; Gomes *et al.*, 2005). Myosin II activity therefore regulates the generation of force necessary to move the cell along a glial fiber, in the case of glial-guided migration (Fig. 16.13A), or along axons or other substrates discussed later. Myosin II activation involves phosphorylation of the myosin light-chain (MLC) by the MLC kinase (MLCK) and the Rho kinase (ROCK1). MLC phosphatase dephosphorylates MLC, which decreases Myosin II activity and slows cell motility. Recent studies by Clace Waterman-Storer reveal that microtubule-based contractions also regulate the tensile force of the cell, by a complex feedback system that uses Myosin II concentrations to measure the density of adhesion sites and regulate the speed of migration (Gupton, 2006). Thus, Myosin II-actin contractile systems and microtubule contractile systems move cells toward adhesions on cellular or extracellular pathways. In addition to generating force at sites of adhesion, Myosin II also localizes the nucleus in migrating cells, a feature that will be discussed again later.

## Migration through the Intermediate Zone and Glial-Guided Migrations

As neurons in the VZ of cortical regions of brain exit the cell cycle, polarity proteins and their signaling cascades establish the polarity of the young neuron and control the extension of a short leading process. As the post-mitotic cell delaminates from the epithelium, movement of the cell soma occurs by interkinetic nuclear movement (Nadarajah *et al.*, 2001). Subsequently, postmitotic neurons bind to the processes of radial glial cells and use the glial cell as a substrate to migrate through the thickening cortical wall. During glial-guided migrations, immature CNS neurons express a highly polarized morphology and mode of movement. During migration, the Golgi, centrosome, and associated microtubule networks polarize the neuron in the direction of movement (Fig. 16.3; Edmondson and Hatten, 1987; Gregory *et al.*, 1988; Hatten, 1999). Whereas the extending growth cone forms focal adhesions at the leading edge, migrating cells establish a broad interstitial junction beneath the cell soma (Gregory *et al.*, 1988). In contrast to extending growth cones, the movement of the tip of the leading process does not correlate with the movement of the cell soma (Edmondson and Hatten, 1987; Gregory *et al.*, 1988), arguing that there is no “leading edge” at the tip of the leading process. Instead, the “motors” for glial-guided migration appear to be localized in the cell soma.

To examine the role of polarity proteins in neuronal migration, Solecki *et al.* (2004) imaged the conserved polarity complex mPar6 $\alpha$  in migrating and stationary cerebellar granule neurons. As the neuron migrates, Par6 $\alpha$ /PKC $\zeta$  localizes to the centrosome (Fig. 16.12A) and signals forward movement of the centrosome prior to the translocation of the cell soma. Thus, migration occurs by a two-stroke mechanism controlled by mPar6 $\alpha$  signaling (Fig. 16.3; Solecki *et al.*, 2004). Rather than localizing actin assembly and regulatory elements to the front of the cell, neurons migrating on glial fibers assemble a specialized motility apparatus in the cell soma and proximal region of the leading process. This apparatus includes a perinuclear tubulin cage that holds the nucleus in the rear of the cell and a specialized *adherens* junction beneath the cell soma (rather than focal adhesions at the front of the cell). As the neuron moves, bundles of F-actin form in the proximal portion of the leading process. Activation of Myosin IIB moves the cell forward, suggesting that Myosin IIB binding to the actin cytoskeleton in this zone generates tensile force that releases the adhesion site and controls the forward movement of the nucleus within the perinuclear tubulin cage (Fig. 16.13A).

The specific roles of dynein and microtubule contractions are being studied by a number of labs, as are the mechanisms that control signaling events that initiate the dissolution of the adhesion site via endocytosis of the neuron-glia adhesion ligands, including ASTN1/2 (Stitt *et al.*, 1991; Zheng, 1996). The ability to combine the tools of molecular biology, using retroviruses or electroporation methods to express cytoskeletal proteins and their downstream regulators, and state of the art imaging methods have been key steps in deciphering the mechanism of glial-guided neuronal migration. Understanding this critical step in cortical histogenesis in detail is an important tool in the discovery of genes that cause human cortical malformations (Hatten, 1999; Ross and Walsh, 2001; Bielas *et al.*, 2004; Hatten, 2005; Tsai *et al.*, 2005).

### *Radial Glial System of the Neocortex*

Radial glial cells are a transient population of cells that provide scaffolding for neuronal migration. The histologists Albert Kölliker and Wilhelm His described the development of glial cells in the late nineteenth century. The silver impregnation method, described earlier, played a crucial role in the detection of radial glial processes. The Italian anatomist Giuseppe Magini used Golgi's silver stain to visualize radial fibers that extended from the ventricular epithelium to the surface of the neocortex or mammalian embryos (Fig. 16.10A). Moreover, Magini observed cells along these processes and proposed that the neurons migrate on radial glia from the ventricular zone out through the thickening cortical wall.

Ramon y Cajal rejected Magini's theory of neuronal migration along glial fibers, which discouraged further studies on glial guidance of migration, until the 1970s, when Richard Sidman and Pasko Rakic confirmed the idea that young neurons migrate along radially arranged glial processes. In a series of studies, Rakic and Sidman used EM studies to document the proposal that the neurons were closely apposed to the radial glial fibers (Rakic, 1972; Sidman, 1973) (Fig. 16.10B,C). Rakic and Sidman further proposed that the radial glia guide the migrations of young neurons from the VZ to the neural layers, in a spatiotemporal order that positioned the youngest born neurons in the most superficial layers. This "inside-out" model relied upon coordinating 3H-thymidine labeling of neuroblast proliferation in the VZ with light and EM analysis (Sidman, 1970). Cells born at successively later times after administration of labeled thymidine would be lighter than those born the day of the injection (their "birthday"), due to dilution of the label with continued proliferation.

Experiments by Nowakowski and Rakic (Nowakowski and Rakic, 1979) on the developing hippocampus provided the most compelling argument for glial guidance of migration, as young neurons in the hippocampal formation followed the undulating paths of the glial fibers, rather than a straight radial line, during their migrations. Real time imaging of the migration of identified neurons—purified from cerebellum, hippocampus, and neocortex—on glial processes provided critical support for this model (Hatten and Edmondson, 1987) and revealed the dynamics of cell movement along the glial guide described earlier (Fig. 16.12B). Cell-based assays further showed that neurons from one brain region could migrate freely on glia from other brain regions (Fig. 16.12C), suggesting that the glial fibers were a generic "monorail" system, rather than a track that specified the duration and direction of migration (Gasser and Hatten, 1990a, 1990b; Hatten, 1999). In addition, migration assays with purified cell populations provided cell-based assays for neuron-glia adhesion systems, such as the astrotactin (Stitt *et al.*, 1991; Zheng, 1996), for growth factor systems that regulate glial differentiation (Gierdalski *et al.*, 2005) and thereby influence migration such as Neuregulin (Rio *et al.*, 1997), and for soluble factors that act as chemoattractants or chemorepellants.

As methods became available to culture acute slices of developing brain, it became feasible to acquire real time images of neurons migrating in the complex setting of developing brain tissue. Lipophilic dyes (Rivas and Hatten, 1995), retroviral constructs that tagged the cells with fluorescent markers such as EGFP (Bhatt *et al.*, 2000) and *in vivo* electroporation of retroviral constructs into embryonic neocortex followed by the generation of acute slices several days later made it possible to alter gene expression (Zhang *et al.*, 2002) of particular cohorts of developing neurons and to follow their fate in the emerging neocortex. Moreover, this approach facilitated real time imaging of cells with altered levels of gene expression, by the introduction of shRNAs to knockdown gene expression, to test the function of proteins associated with human cortical malformations (Tsai *et al.*, 2005), identify transcription factors (Hand *et al.*, 2005), polarity proteins (Solecki *et al.*, 2004), cytoskeletal proteins (Tsai *et al.*, 2005), and components of downstream signaling pathways.

Methods for real time imaging, such as spinning disc confocal imaging, and for imaging cells deep in living tissue with multiphoton systems are evolving rapidly, providing neurobiologists with the tools to study the molecular regulation of CNS migrations. These experiments have occurred in parallel with cell biological studies of the fundamental mechanisms of metazoan motility, described briefly earlier. The avail-

ability of a host of new methods for marking proteins with fluorescent tags by genetic methods, combined with the discovery of more sensitive fluorescent tags to measure protein-protein interactions (FRET) and protein turnover rates (FRAP) in organelles within migrating neurons, are rapidly accelerating the range of experimental approaches to elucidate the mechanisms of neurogenesis and motility of particular classes of neural progenitors in specific regions of the developing nervous system.

#### ***Lineage Analysis of Radial Glial Cells: Glia Generate Neurons in Late Phases of Cortical Development***

Ultrastructural, molecular, and physiological characteristics of radial glial cells distinguish them from neuronal progenitors in the ventricular zone and migrating neurons in the intermediate zone. During the past five years, real time imaging of labeled radial glial cells and genetic experiments on the lineal descent of radial glia have shown that a large number of neurons are descended from glial progenitor cells. In the developing neocortex, imaging experiments by Noctor *et al.* (2002) and Kriegstein and Noctor (2004) revealed the surprising finding that radial glial cells can also generate neuronal precursors, which immediately, or after several rounds of cell division, migrate along the radial processes of the glial mother cells that stretch across the expanding cerebral wall (Fig. 16.14).

Genetic studies by Anthony and Heintz (Anthony *et al.*, 2004) used Cre/loxP fate mapping and clonal analysis to demonstrate that radial glia throughout the CNS serve as neuronal progenitors and that radial glia within different regions of the CNS pass through their neurogenic stage of development at distinct time points. They went on to show that the promoter region of the radial glial cell marker gene *Blbp* (Feng *et al.*, 1994) contains a binding site for the Notch effector CBF1 that is essential to *Blbp* transcription in radial glia (Anthony *et al.*, 2005). These results identified *Blbp* as the first predominantly CNS-specific Notch target gene. Their results also confirmed earlier studies by Gaiano and Fishell (2002), who showed that Notch signaling regulates radial glial differentiation in the neocortex.

#### ***Tangential Migration Pathways***

***Cortical Interneurons*** Although radial migration was once thought to be the primary mode of CNS migrations in cortical regions of vertebrate brain, we now realize that a small subset of the total population

of neurons in the murine neocortex migrate from the neocortical VZ to form the layers of the mature cerebral cortex (Tan *et al.*, 1995, 1998). These neurons are the large output neurons, the pyramidal cells (Parnavelas *et al.*, 1991), and a subpopulation of cortical interneurons. The majority of cortical interneurons originate in the basal forebrain and migrate into the neocortex (Fig. 16.15). The importance of this ventral to dorsal mode of migration is evidenced by the rather remarkable fact that the GABAergic neurons are about 20% of the total neuronal population in the cortex. A detailed view of the migratory routes of cells migrating from the basal forebrain into the neocortex emerged from genetic and transplantation studies. Initial experiments with mice lacking the transcription factors *Dlx1/2* suggested that cortical interneurons originate in the medially ganglionic eminence (MGE) (Anderson *et al.*, 1997; Tamaki *et al.*, 1997). More detailed transplantation and fate mapping studies refined this original view, providing support for the general model that majority of cortical interneurons originate in the MGE and migrate into the neocortex (Polleux *et al.*, 2002; Xu *et al.*, 2004). The LGE likely contributes a small population of interneurons to the cortical interneuron population, but current experiments show that the many LGE cells migrate into the olfactory bulb intermingling with cells that migrate from the cortical SVZ.

***The Rostral Migratory Stream*** Between E12.5 and E14 in the mouse (E14–16 in the rat), a secondary proliferative zone is formed along the third ventricle of the forebrain (Pencea and Luskin, 2003). This progenitor zone, known as the subventricular zone (SVZ), persists in the adult, where it continues to generate neurons. The subventricular zone has been the subject of intense interest, because it continues to generate new neurons into adulthood, providing GABAergic neurons for the olfactory bulb (Luskin, 1998). As a renewable population of partially committed, CNS precursors, the cells from the RMS are an ideal system for studying adult neural “stem” cells (as indicated, they are not “stem cells” in the strict definition of the term). RMS cells differentiate into interneurons when transplanted into the wide variety of target areas, including the septum, thalamus, hypothalamus, and midbrain of embryonic brain (Alvarez-Buylla *et al.*, 2000). Thus, many labs are studying the molecular mechanisms that control the differentiation of these cells when placed in ectopic positions, especially in the adult brain.

RMS neurons migrate from the SVZ to the olfactory bulb by a unique mechanism. As the neurons move, they use other migrating neurons in the stream as a substrate (Lois and Alvarez-Buylla, 1994; Lois *et al.*,

1996). This mode of neuronal migration is termed "chain migration" as the neurons form chains within glial sheaths. Recent experiments by Muller and colleagues show that neuroblasts express integrins containing the  $\beta 1$  and  $\beta 5$  subunits (Belvindrah *et al.*, 2007). Using genetic and cell biological approaches, they demonstrated that  $\beta 5$  integrins are dispensable for chain migration, whereas  $\beta 1$  integrins promote cell-cell interactions that link neuroblasts into chains. The  $\beta 1$  integrin ligand laminin is recruited to the cell surface of migrating neuroblasts and induces chain formation in SVZ explants and the aggregation of purified neuroblasts. Thus,  $\beta 1$  integrins and their laminin ligands promote the formation of cell chains in the adult RMS (Belvindrah *et al.*, 2007).

Several secreted signaling molecules are thought to guide the migration of RMS neuroblasts to the olfactory bulb, including the diffusible chemoattractants netrin-1 (Murase and Horwitz, 2002), the glial cell line-derived neurotrophic factor (Paratcha *et al.*, 2006), and the chemorepellent slit1/2 (Wu *et al.*, 1999; Nguyen-Ba-Charvet *et al.*, 2004). In addition, receptor tyrosine kinases of the Eph families and their ephrin ligands (Conover *et al.*, 2000), and Neuregulin and ErbB ligands (Ghashghaei *et al.*, 2006) apparently guide neuronal migration in the RMS.

### Layer 1 Cells Follow Diverse Migratory Pathways

The neurons of the marginal zone, later the preplate and layer 1 of the neocortex, have long been assumed to be the earliest generated neurons in the cortical VZ. Classical studies held that these cells exited the cell cycle beginning on about E10 in the mouse and then migrated away from the VZ to form the overlying preplate between days 11 and 12 (Valverde *et al.*, 1995; Jimenez *et al.*, 2003) (Fig. 16.11B). Recent evidence from genetic and molecular genetic studies supports a long discounted view that some preplate cells originate in the rostral forebrain (or even the basal forebrain) (Meyer *et al.*, 1998), whereas others emerge from the cortical hem, and migrate across the surface of the developing cortex (Garcia-Moreno *et al.*, 2007; Meyer, 2007). Support for this view came from studies on gene expression patterns in Egfp-BAC transgenic mice of the GENSAT project (Gong *et al.*, 2003), which showed that cells marked by the gene Pde1c migrate from the rostral forebrain back over the surface of the emerging neocortex.

Similarly studies on *Wnt3a+* cells showed that cells of the cortical hem also contribute to the preplate via a superficial migratory pathway across the surface of the neocortex. Recently cloning of genes related to migration genes in *C. elegans* led to the discovery that preplate neurons express Mig-13A, a gene related to

**FIGURE 16.12** Live imaging of glial-guided neuronal migration. Live imaging of cells with vide-enhanced differential contrast (VEC-DIC) optics. The cytology and neuron-glial relationship of a cerebellar granule neuron migrating on a glial fiber. With live imaging of neuronal migration along glial fibers, the granule neuron closely apposes the cell glial fiber (GF) along the length of the neuronal soma (MN) and extends a leading process (LP) in the direction of migration along the glial guide. The nucleus is in the posterior aspect of the cell during periods of movement, the centrosome is just forward of the neuronal nucleus. (A) In migrating neurons, the polarity signaling complex mPar6a localizes to the centrosome, and apparently orchestrates the movement of the neuron along the glial guide. Labeling with antibodies against p50 dynactin labels the centrosome and dynein on the surface of the nucleus. Antibodies against tubulin reveal a perinuclear "cage" of tubulin in migrating neurons. (B) Live imaging of a cerebellar granule neuron migrating on a glial fiber. (C) Cytology of cerebellar and hippocampal neurons migrating along homotypic and heterotypic astroglial fibers: Cerebellar granule neuron migrating along a hippocampal glial fiber (CB/HP), a cerebellar granule neuron migrating on a cerebellar glial fiber (CB/CB), a hippocampal neuron migrating along a cerebellar glial fiber (HP/CB), or a hippocampal neuron migrating on a hippocampal glial fiber (HP/HP). In heterotypic cocultures, migrating neurons have a stereotyped cytology, extending their cell soma along the glial guide and extending a leading process in the direction of migration.

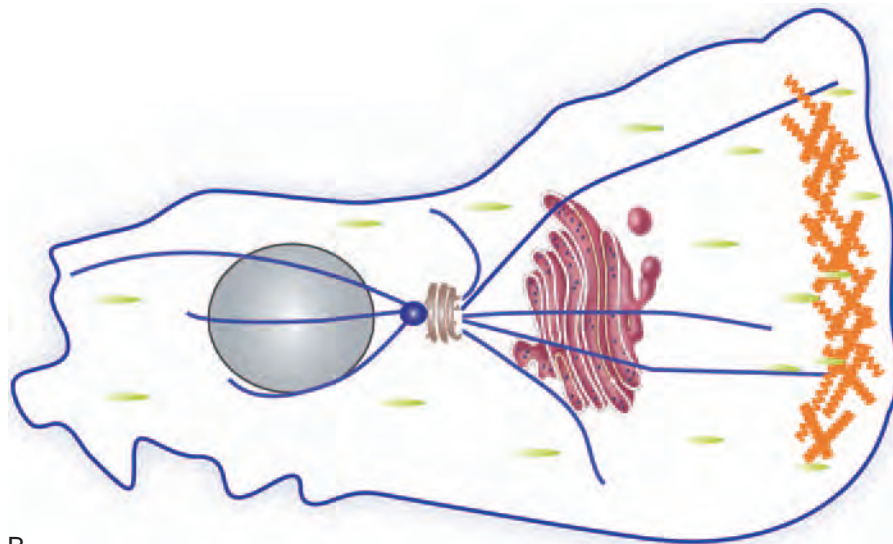

the *C. elegans* Mig-13 gene. The dynamics of cell migrations and patterns of axon outgrowth of apparent precursors of neurons within sensory areas of the neocortex are revealed by imaging the movements of labeled cells in *Egfp-Lrp12*-BAC transgenic mice (Schneider *et al.*, 2007).

**Cerebellar System** During embryogenesis, the cerebellar territory arises from rhombomere 1, delineated

by the expression of *Hoxa2* (posterior) and *Otx2* (anterior). In the mouse, between E9.0 and E9.5, the pontine flexure creates an area along the border of the mesencephalon and metencephalon, where the neural tube fails to close, the rhombic lip (Harkmark, 1954). The embryonic rhombic lip is a specialized germinative epithelium that arises relatively late in development at the interface between the neural tube and the roofplate of the fourth ventricle. The rostral (cerebellar) and

**FIGURE 16.13** Comparison of the cellular organization of neurons migrating on glial fibers (A) and fibroblasts migrating *in vivo* (B). As the neuron migrates, the polarity complex mPar6 $\alpha$  and signaling pathways, polarize the migrating cell. mPar6 $\alpha$  localizes to the centrosome, paces the timing of the movement of the neuron along the glial fiber via Myosin IIB-mediated contraction of F-actin in the proximal aspect of the leading process. A perinuclear cage of tubulin positions the nucleus in the posterior aspect of the cell. Microtubules grow out of the centrosome into the leading process and support vesicle transport during movement. As the neurons moves, it forms attachments beneath the cell soma (blue), which provides traction for neuronal locomotion along the fiber. (B) The model shown represents a polarized cell that has distinct leading and trailing edges. This is a common feature of fibroblastic motility. The leading edge points in the direction of movement and is driven by actin-polymerization-mediated protrusion. Red spots represent points of interaction of the cell with the substrate. The larger spots represent stable adhesions (a classic feature of fibroblastic motility that is absent in faster-moving cells), and smaller spots at the periphery represent nascent adhesion complexes. Color gradients within the spot represent the dynamics of adhesion turnover (at the front) and disassembly (at the back). Other structures depicted include the nucleus (light brown), the Golgi apparatus (dark brown), and the microtubule-organizing center (MTOC), from which the microtubule network (gray) radiates, as well as an actin-rich lamellipodium at the front. Insets show specific features within the migrating cell, such as the regulation of actin polymerization at the protrusion sites, adhesion dynamics, MTOC- and nucleus-based cell polarity and tail retraction, as well as a node map depicting some of the key molecules involved in regulation of the process Reproduced from Vicente-Manzanares *et al.* (2005).

**FIGURE 16.14** (A–F) Schema of the evolving concepts of the relationship between radial glial cells and migrating neurons in the developing mammalian cerebral. As discussed in the text, initial theories of neuronal migration ignored the glial cells. In the early 1970s Sidman and Rakic proposed that neurons migrate along glial fibers. Live imaging of labeled radial glia and migrating neurons revealed that during the epoch of migration, glial cells produce neuronal progeny, which immediately or after several rounds of division use the mother glial cell as a guide for their migration. As indicated in the diagram, there are some differences in this process among vertebrate species. Neurons, red; radial glial cells, green. Reprinted from Rakic (2003).

hindbrain domains of the rhombic lip form a continuous proliferative epithelium, which contains overlapping pools of progenitor cells that express combinatorial patterns of transcription factors. Recent lineage tracing experiments demonstrate that progenitor cell populations in the rhombic lip generate both cerebellar granule cells and neurons of the cerebellar nuclei, the lateral pontine nucleus and the cochlear nucleus (Machold and Fishell, 2005; Wang *et al.*, 2005). Moreover, lineage tracing experiments define the neurons of the precerebellar nuclei, which project afferent axons to cerebellar neurons (Rio *et al.*, 1997).

Thus, experiments on the allocation of cell fate among RL precursors destined for the cerebellar cortex, the cerebellar nuclei, and the precerebellar nuclei of the chick and mouse demonstrate that combinatorial patterns of transcription factor expression mark progenitors of the cerebellar nuclei (*Irx3/Meis2/Lhx2/9*), granule neurons (*Meis1*) of the cerebellar cortex, and the lateral pontine nucleus (*Pcsk9, Pde1c, Math1*). In addition to marking classes of cerebellar progenitors, patterns of transcription factor expression illustrate the complex migrations that generate the nuclear and cortical regions of the cerebellum (Morales and Hatten, 2006). These patterns include both radial and tangential migratory pathways.

### Summary

During CNS development, a remarkable range of neuronal migrations set forth the architectonics of the brain. In general, these migrations can be seen as DV or AP migrations, pathways thought to be prominent in lower organisms but not in vertebrates. Indeed, genes discovered in *C. elegans* and *Drosophila* provide molecular cues for guiding migrations in higher vertebrates, and conserved polarity proteins and their signaling pathways play a key role sensing directional cues, polarizing cellular extrusions, and generating forces required to propel cells along pathways defined by specific adhesions and/or chemoattractants. Insights from studies on fibroblast motility have been especially informative to general aspects of neuronal motility, and will likely continue to provide novel methods for studying the molecular controls of neuronal migrations. The relationship of cell migrations, the establishment of the neuronal layers and brain circuitry will ultimately require novel insights into the role of the transient scaffolding systems of cortical development, the preplate, subplate, and cortical plate, which appear to pattern the connections between laminar, cortical areas of the brain, subcortical nuclei, and the formation of sensorimotor pathways.

**FIGURE 16.15** Nonradial pathways of neuronal migration. Over the past decade, a number of tangential migratory pathways have been described, in addition to radial pathways (black), including the migration of interneurons from the basal forebrain into the developing neocortex (blue), the migration of neurons from the SVZ to the olfactory bulb along the rostral migratory stream (red), and migrations of progenitors from the rhombic lip to cerebellar cortex (green), and the precerebellar nuclei of the brainstem (purple). Reprinted from Hatten (2002).

## Growth Cones and Axon Pathfinding

Approximately 100 years ago, Ramón y Cajal described the trajectories taken by nerve cell processes as they extend toward their intermediate and final targets. From these observations he inferred that multiple influences likely guide growing axons. Cajal also observed for the first time the growing tips of axons and named them growth cones. In an unparalleled feat of scientific conjecture based on morphological observations of fixed material, he described their behavior:

From the functional point of view, one might say that the growth cone is like a club or battering ram endowed with exquisite chemical sensitivity, rapid ameboid movements, and a certain motive force allowing it to circumvent obstacles in its path, thus coursing between various cells until reaching its destination. (Ramon y Cajal, 1890)

Decades later, Harrison developed the technique of growing living tissue in culture and demonstrated the truth of Cajal's description of a highly motile, ameboid specialization at the tips of growing axons. Shortly after, Speidel took advantage of the thinness and transparency of tadpole fins to examine living growth cones extending *in situ*. Viewed in real time, their shape changes very slowly, at a rate just detectable by an observer. Viewed with modern time-lapse techniques, however, the dynamism of their ever-changing morphology as they crawl forward is striking. The pioneering studies of Cajal, Harrison, and Speidel identified the growth cone as the key decision-making component in the elaboration of axonal pathways and inspired subsequent studies of the cell biology and behavior of growth cones *in vivo* and *in vitro*.

The growth cone at the distal tip of an axon extending in tissue culture is flattened into a thin fan-shaped sheet with many long, very thin spikes radiating

forward (Fig. 17.1). The fan-shaped sheets are called lamellipodia, and the spikes are called filopodia or microspikes. Many growth cones growing *in situ* have a similar appearance, however it is not unusual to observe spindle-shaped growth cones with tufts of forward-directed filopodia within axon bundles. More complex growth cone shapes are often characteristic of slowly extending growth cones choosing between possible routes of extension, whereas simpler morphologies are characteristic of rapidly extending growth cones coursing along permissive tracts.

### GROWTH CONES ARE ACTIVELY GUIDED

Growth cones crawl forward as they elaborate the axons trailing behind them, and their extension is controlled by cues in their outside environment that ultimately direct them toward their appropriate targets. What is the nature of these guidance cues and how do they affect growth cone behavior? One view to account for the ability of the nervous system to wire itself, already implicit in Ramon y Cajal's writings and reinforced by Speidel's observations, held that axonal growth is highly directed, with each class of axons navigating along a distinctive prescribed pathway to reach its target. For example, during neural development spinal commissural axons extend seemingly unerringly toward the ventral-most region of the spinal cord, cross to the contralateral side, and then extend rostrally to targets in the brain (Fig. 17.2A). These neurons could be influenced by a variety of repulsive and attractive cues at different points along their trajectory, with each portion of the journey directed

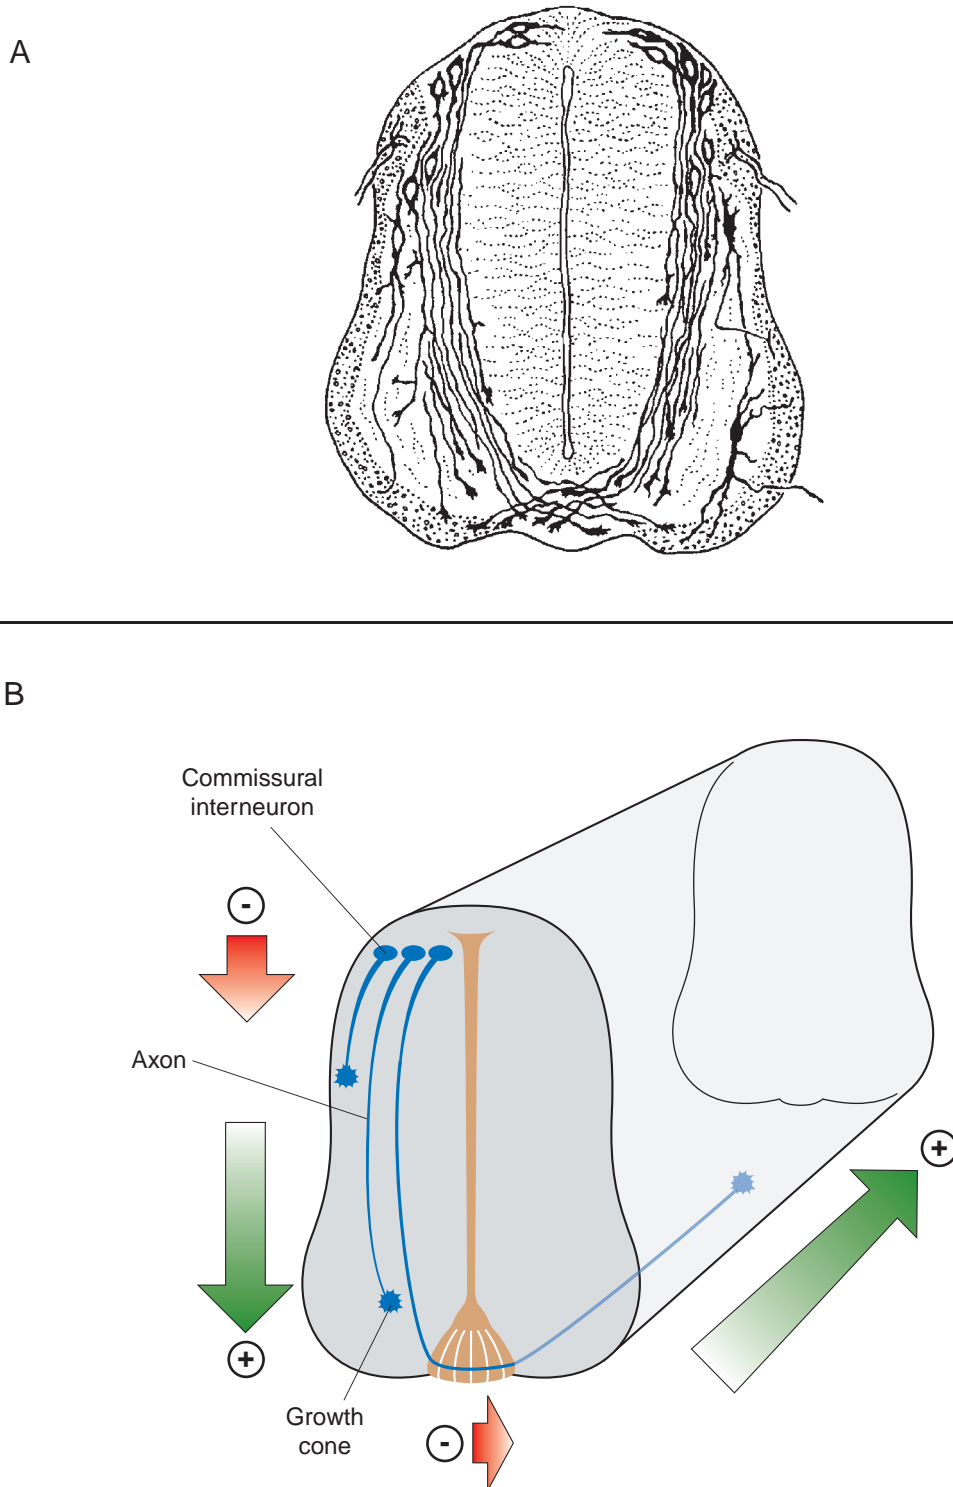

**FIGURE 17.1** Scanning electron micrograph of a growth cone in culture. Growth cones extending on a flat surface are typically very thin, with broad lamellae and numerous filopodia. From Wessells and Nuttall (1973).

anew by distinct guidance mechanisms (Fig. 17.2B). An alternative view for wiring the nervous system postulated that axonal growth involves a random wandering of axons throughout the embryonic environment with connections appropriate for proper functioning of the nervous system somehow being maintained and reinforced at the expense of inappropriate connections.

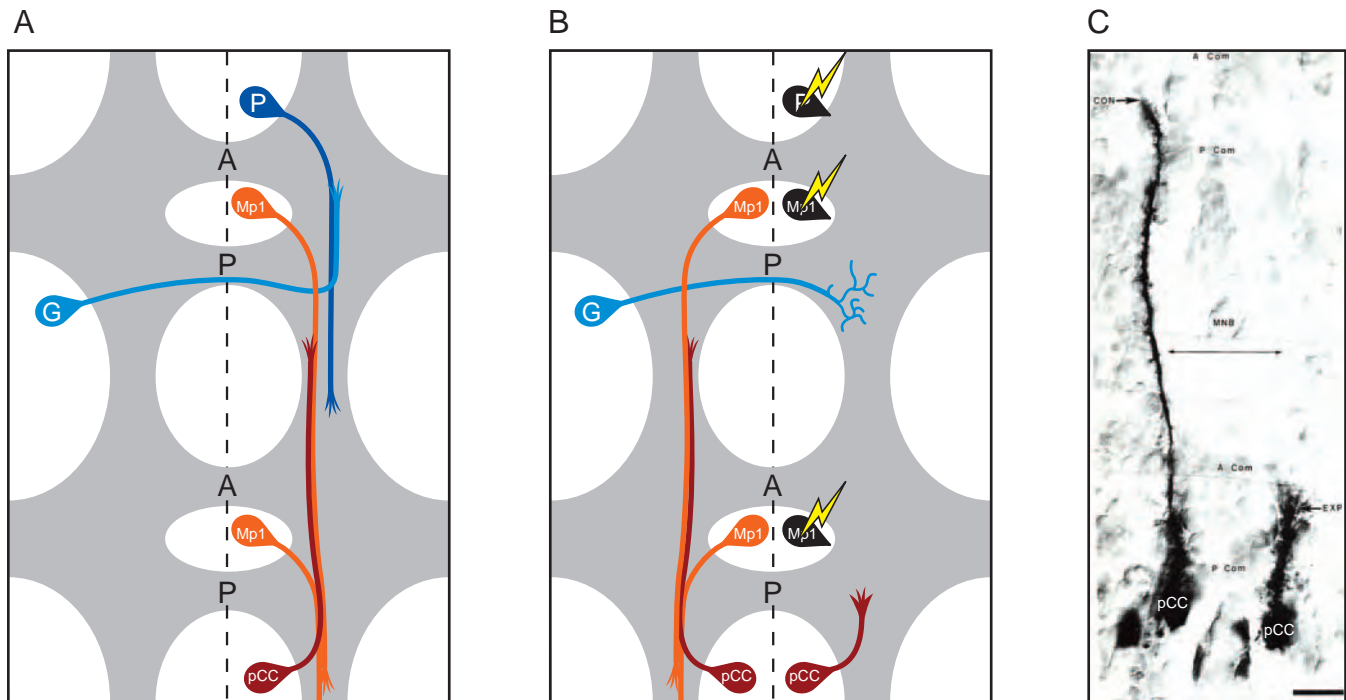

A number of experiments provided evidence supporting directed axon growth, including the classic experiments of Sperry, started in the 1940s, demonstrating highly specific targeting of regenerating retinal ganglion cell axons to the optic tectum (Sperry, 1963). The application of axonal tracing techniques has made it possible over the past 30 years to observe in multiple species a variety of different classes of axons en route to their targets. These studies show that the establishment of complex neural wiring patterns occurs through a combination of initial neuronal activity-independent guidance events and subsequent refinement of connections requiring electrical signaling among neurons (Goodman and Shatz, 1993). When projecting to the vicinity of their target field, axons grow along very stereotyped trajectories, making few projection errors. This growth is highly directed and selection of the target cell is equally precise. A good example is the highly stereotyped and reproducible extension of indi-

vidual axons arising from defined insect neurons as they grow within the central and peripheral nervous systems (Raper *et al.*, 1984; Bastiani *et al.*, 1986; Caudy and Bentley, 1986). Neuronal ablation experiments demonstrate that individual neurons show selective affinity for certain axon bundles and in the absence of these targets fail to extend upon alternative neuronal, or nonneuronal, substrates (Fig. 17.3). Studies in vertebrates have also supported the idea that neurons are programmed to connect with specific targets. One of the first was the demonstration that axons of vertebrate motoneurons that have been surgically moved to abnormal nearby locations can reach their normal and appropriate targets even when they must traverse unusual routes to do so (Lance-Jones and Landmesser, 1980). Thus guidance to target fields occurs prior to and is independent of the functioning of neuronal circuits. However, once many similar axons arrive at a target field containing numerous similar target cells, as occurs when groups of motor axons all innervate many muscle fibers in a single muscle or when thalamic neurons receiving input from both eyes establish overlapping axonal arborizations in the visual cortex, neuronal function does come into play. In these circumstances, individual axons initially arborize widely within the target field and contact many target cells, only later refining their pattern of connections in a

**FIGURE 17.2 Multiple guidance cues direct spinal cord commissural axons during neural development.** (A) This original drawing by Cajal illustrates neuronal pathways in the developing chick spinal cord, showing several commissural axons extending to the ventral spinal cord and crossing the floor plate. Note the distinct growth cone morphologies observed at different portions of the pathway, with growth cones at or crossing the midline exhibiting complex and expanded morphologies. From Cajal, (1890). (B) At least four classes of guidance cues are now known to instruct commissural axons during development: repellents from the dorsal spinal cord, initially directing commissural axons on a ventral course; attractive cues emanating from the ventral spinal cord guiding commissural axons toward the ventral spinal cord; repulsive cues in the ventral spinal cord, facilitating midline crossing and preventing re-crossing; and attractants that guide post-crossing commissural axons anteriorly toward targets in the brain.

**FIGURE 17.3** Extending axons demonstrate exquisite selectivity in choosing their pathways during neural development. (A) A simplified diagrammatic representation of the embryonic grasshopper central nervous system shows the establishment of two distinct axon pathways (or fascicles): the joining of the G neuron with the P trajectory, and the joining of the pCC neuron with the MP1 pathway. The G neuron extends across the CNS midline (dotted line) within the posterior commissure (“P”) and selectively joins (or fasciculates) with axons from the P neurons (one of which is shown here), extending anteriorly along these descending P axons. The pCC neuron does not cross the midline and instead extends anteriorly along descending MP1 axons. (B) Ablation of neurons that contribute the P or MP1 pathways results in the inability of the G or pCC neurons, respectively, to extend anteriorly—these neurons do not fasciculate with numerous other axon pathways present very close by at this stage of development (not shown), and they instead stall at the point where they would have selectively fasciculated with their axonal targets. (C) Dye filling of pCC neurons on the experimental (right) and control (left) sides of a grasshopper embryo shows that when pCC does not encounter descending MP1 neurons, which are absent on the right side owing to ablation of these neurons, its growth cone stalls near the point where normally this contact would take place and no directed extension on alternative substrates occurs. From Bastiani *et al.* (1986) and Raper *et al.* (1984).

process that depends on the precise patterns of electrical activity in these neurons and their target cells.

The rest of this chapter focuses on the first step in the formation of connections: the directed growth of axons to target fields. The selection of target cells and the role of electrical activity in this process are discussed in Chapters 18 and 20.

### GUIDANCE CUES FOR DEVELOPING AXONS

How do axons succeed in navigating through the embryonic environment to targets that in some cases can be many centimeters away? The trajectories of many axons appear to be broken up into short segments, each perhaps a few hundred micrometers long.

The daunting task of reaching a distant target is then reduced to the simpler task of navigating each of these successive segments. This task is well illustrated by the projections of commissural neurons in the spinal cord, illustrated in Figure 17.2. The pathway of these axons can be divided into discrete segments, each bounded by a specific cell or group of cells that marks the end of one segment and the beginning of the next. Such cells, forming an intermediate target for the axons, are sometimes termed “guidepost” cells. For example, commissural axons initially grow from the dorsal spinal cord to a set of guidepost cells at the ventral midline termed “floor plate cells,” which serves as an important intermediate target. Commissural axons cross the midline at the floor plate, then turn and extend alongside the midline, before eventually leaving the midline to seek out their ultimate targets. In mice, genetic ablation of floor plate cells results in profound

misrouting of the axons when they reach the midline (Matisse *et al.*, 1999). Evidence for the existence of such guidepost cells harboring important guidance information in fact has been obtained throughout the animal kingdom.

The appreciation that axonal trajectories are formed in small segments pushes the question back one step: How do axons navigate each small segment of their trajectory? Axons appear to be guided along their appropriate trajectories by their responses to selectively distributed molecular signals within the developing embryo. Studies over the past three decades have led to the view that axon guidance involves the coordinate action of four types of cues: short-range (or local) cues and long-range cues, each of which can be either positive (attractive) or negative (repellent) (Fig. 17.4). The operations of short- and long-range guidance mechanisms and of attraction and repulsion are not mutually exclusive. Rather, axons may generally be guided over each individual segment of their trajectories by several different types of mechanisms acting in concert to ensure reproducible and high-fidelity guidance. Many experiments have shown that axons may navigate short segments by using several and, in some cases, even all four types of cues (Fig. 17.4): a repellent from behind the axons to “push,” a corridor marked by a permissive local cue and bounded by an inhibitory local cue to “hem in” the growth, and an attractant at the end of the corridor to “pull” (Tessier-Lavigne and Goodman, 1996). Push, pull, and hem: these forces working together can ensure accurate guidance.

The identification of signaling molecules that function as guidance cues has depended primarily on three experimental approaches: (1) pairing biochemistry and

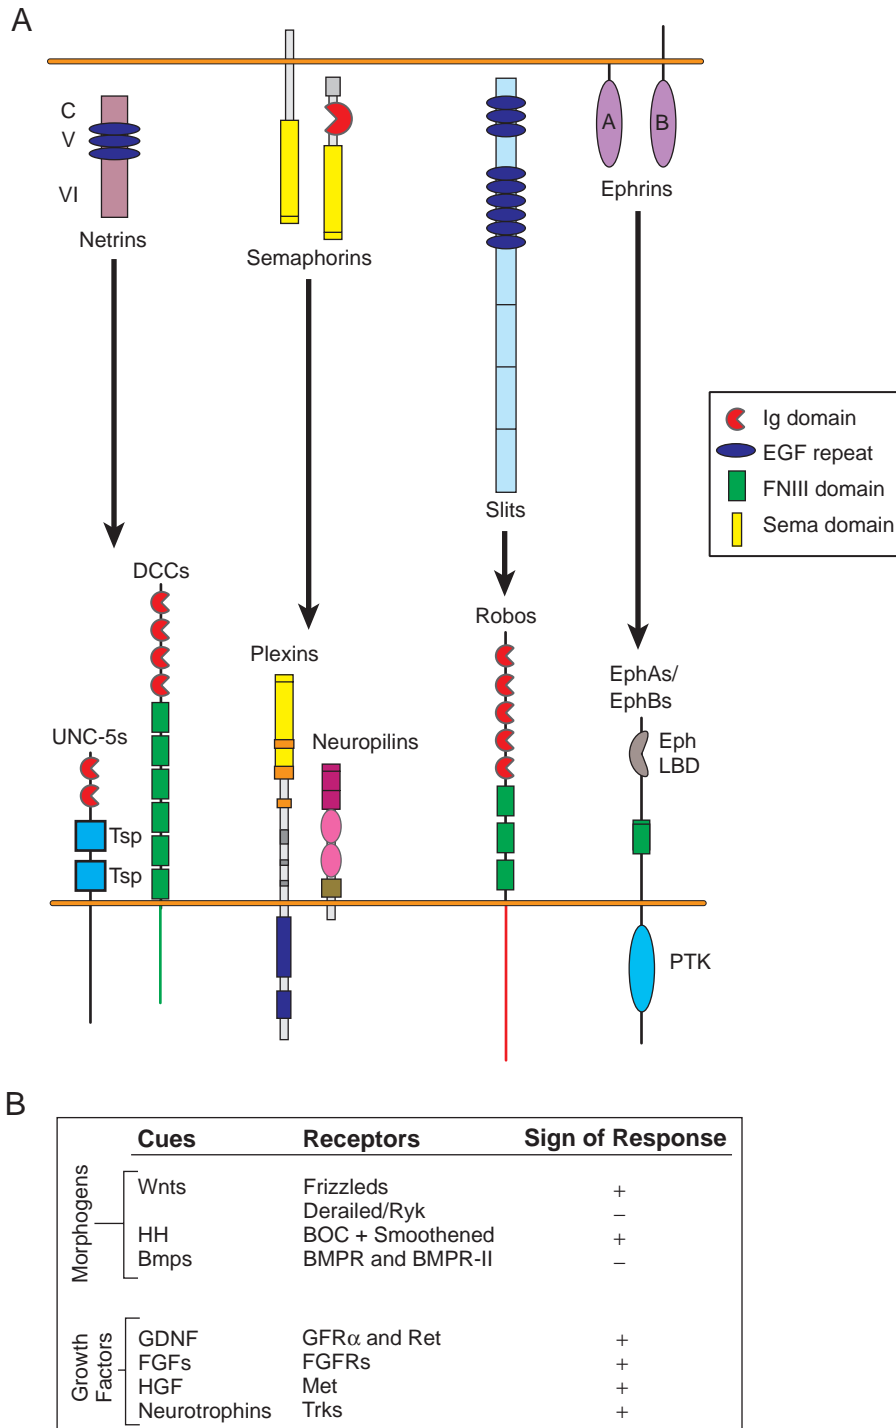

*in vitro* tissue culture assays to detect proteins with either attractive or repellent properties, (2) using forward genetics to identify mutations that affect axon trajectories *in vivo*, or (3) using genetic and tissue culture approaches to characterize the functions of molecules with distributions or molecular structures that make them attractive candidate guidance cues.

Studies over the past decade and a half, in this way, have led to the identification of several prominent families of signaling molecules that function as instructive guidance cues. A first wave of studies in the 1990s identified four major families that have well-established and widespread roles in axon guidance: semaphorins, netrins, slits, and ephrins (Fig. 17.5A). These are sometimes referred to as the “canonical” axon guidance molecules. More recently, two additional classes of molecules initially identified in other contexts were shown to function as guidance cues as well: proteins that are usually classified as morphogens (including members of the Bone Morphogenetic Protein, Hedgehog, and Wnt families), as well as some proteins initially identified as growth factors (Fig. 17.5B). The identification and characterization of these cues and their receptors have led to several important generalizations about guidance mechanisms (Tessier-Lavigne and Goodman, 1996; Chisholm and Tessier-Lavigne, 1999; Dixon 2002). First, guidance cues come in families, which may, in some cases, comprise both diffusible members that can function in long-range axon guidance, as well as nondiffusible members functioning at short range. Second, many guidance cues are multifunctional, attracting some axons, repelling other axons, and sometimes controlling other aspects of axonal morphogenesis such as axonal branching or arborization. Different axons may respond to the same cue differently because they express a distinct complement of surface receptors or contain particular components of the relevant signal transduction pathways. Third, many (although not all) cues are evolutionarily conserved between vertebrates and simpler invertebrate organisms, with species homologues often performing similar roles in axon guidance. Higher vertebrates typically have many more members within a given family of guidance cues, and these cues are likely to have overlapping functions.

These different families of guidance cues are discussed briefly to illustrate these features of wiring mechanisms. We start by reviewing each of the four families of “canonical” guidance cues, before briefly describing the roles of morphogens and growth factors in guidance. We also focus specifically on members of the immunoglobulin gene superfamily, which have diverse roles as ligands and receptors in axons guidance.

**FIGURE 17.4** Axons are guided by the simultaneous and coordinate actions of four types of guidance mechanisms: contact attraction, chemoattraction, contact repulsion, and chemorepulsion. Individual growth cones might be “pushed” from behind by a chemorepellent, “pulled” from in front by a chemoattractant, and “hemmed in” by attractive and repulsive local cues (cell surface or extracellular matrix molecules). Adapted from Tessier-Lavigne and Goodman (1996).

**FIGURE 17.5 Multiple families of molecules serve as guidance cues.** (A) Structures of the “canonical” axon guidance cues: netrins, semaphorins, slits, ephrins, and their receptors. Netrin receptors include members of the DCC and UNC5 family. There are seven classes of semaphorins (two invertebrate and five vertebrate). Of the ~20 mammalian semaphorins, 5 are secreted (class 3) and the others are divided into four families of transmembrane or GPI-linked proteins (represented here by a single diagram). Semaphorin receptors include plexins (of which nine are known in mammals, divided into classes A–D) and neuropilins (two in mammals). Class 3 semaphorin signaling is mediated by complexes of neuropilins (which serve as binding moieties) and plexins (signaling moieties). Slit receptors are members of the Roundabout (Robo) family. The receptors for Ephrins are members of the Eph family. Ephrin-As are GPI-anchored and predominantly bind EphAs, whereas Ephrin-Bs are transmembrane proteins and preferentially bind EphBs. Adapted from Winberg *et al.* (1998) and Chisholm and Tessier-Lavigne (1999). (B) Morphogens (members of the Wnt, Hedgehog and BMP families) and various growth factors listed here also serve to guide neuronal processes. Known receptors functioning to mediate their effects in guidance are indicated.

## Netrins

The netrin family (Fig. 17.5) comprises about half a dozen members in vertebrates. The first vertebrate members were identified in studies on the guidance of commissural axons in the spinal cord. As described earlier, these axons project from the dorsal spinal cord to floor plate cells at the ventral midline (Fig. 17.6A). Experiments in tissue culture using microdissected pieces of rat spinal cord showed that floor plate cells secrete a diffusible outgrowth-promoting and chemoattractive activity for commissural axons, and netrins were identified as proteins that can mimic these activities (Tessier-Lavigne *et al.*, 1988; Serafini *et al.*, 1994). In the spinal cord, a dorsal-to-ventral increasing gradient of netrin-1 protein has been detected, as diagrammed in Figure 17.6Ai and visualized by immunohistochemistry in Figure 17.6Aii. This gradient appears to provide guidance information that is interpreted by commissural axons and that guides them to the floor plate.

Two types of experiments have supported this view. First, netrin-1 can clearly attract the axons in various assays. For example, when pieces of dorsal spinal cord are placed in tissue culture and viewed from the side, commissural axons grow within the tissue along a vertical dorso-ventral trajectory, but when cells secreting netrin-1 are placed alongside the dorsal spinal cord pieces, the axons are deflected from this trajectory and turn toward the source (Fig. 17.6B). Second, removal of netrin-1 function, which occurs in a netrin-1 knockout mouse, results in significant misrouting of commissural axons, with many failing to reach the floor plate (Fig. 17.6C), supporting a key role for netrin-1 in guiding the axons. Interestingly, a few axons do reach the floor plate even in the absence of netrin-1 (Fig. 17.6C), showing that one or more additional cues must collaborate to guide the axons. As we will see later, the morphogen sonic hedgehog is one of these additional cues. The collaboration of multiple guidance cues even over short segments of an axon's trajectory helps reduce the risk of guidance errors and contributes to the high degree of accuracy of wiring of the nervous system.

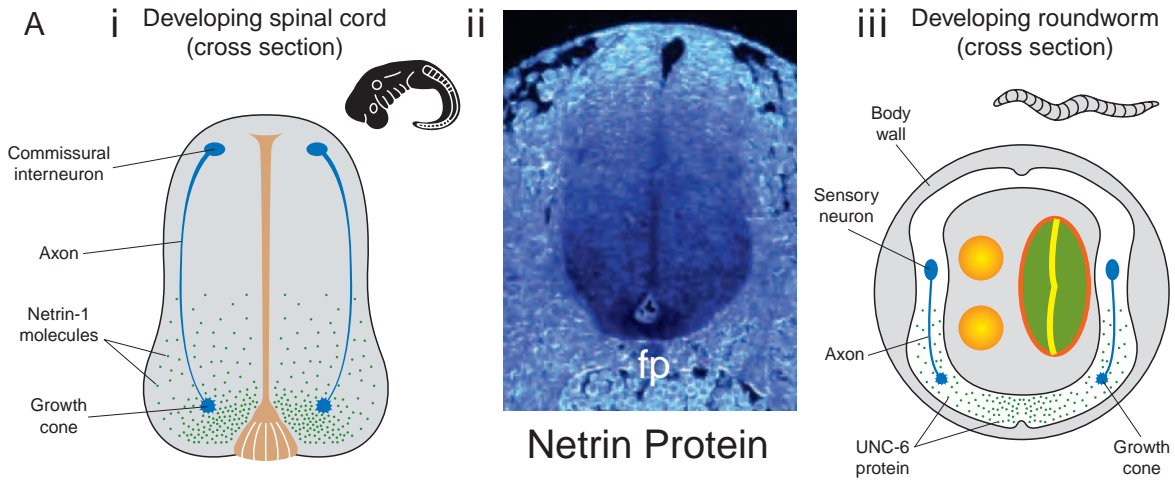

In addition to attracting commissural axons, netrins have been shown to function in attracting other subsets of axons to various targets in the retina and brain. Remarkably, netrin-1 also appears to function as a long-range repellent, providing a push from behind for a group of axons in the hindbrain that grow away from the midline, thus illustrating the bifunctionality of guidance cues.

Strikingly, netrins are vertebrate homologues of the UNC-6 protein of the nematode *Caenorhabditis elegans*, a protein similarly involved in both attract-

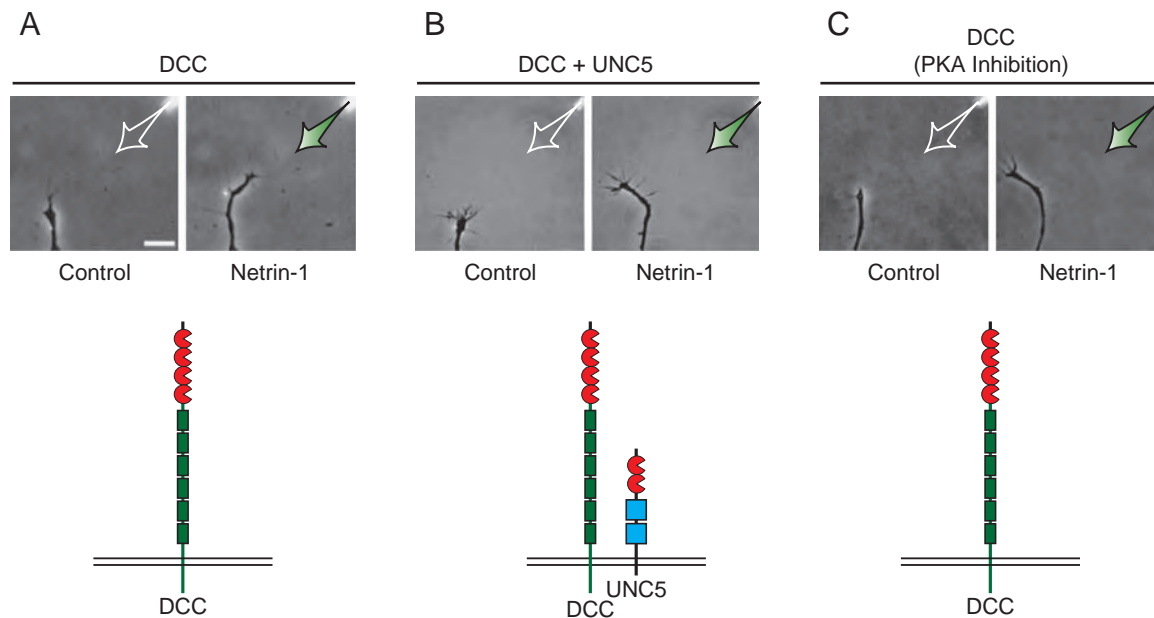

ing some axons toward the nervous system midline and in repelling others away from it (Fig. 17.6Aiii) (Wadsworth *et al.*, 1996). Netrin homologues are also expressed at the midline of the nervous system of *Drosophila melanogaster*, where they contribute to attracting axons to the midline. In all of these organisms, the attractive effects of netrins on axons are mediated by receptors of the DCC family, whereas repulsive actions require receptors of the UNC5 family; both sets of receptors are members of the immunoglobulin gene superfamily (Fig. 17.5) (Chisholm and Tessier-Lavigne, 1999). In fact, as first shown in *C. elegans*, and illustrated with a vertebrate neuron in Fig. 17.7, it is possible to convert netrin attraction, mediated by DCC, to repulsion by introducing an UNC5 family member into the neuron (Hamelin *et al.*, 1993; Hong *et al.*, 1999). These findings on netrins and their receptors vividly illustrate both the bifunctionality of guidance cues and the remarkable conservation of axon guidance mechanisms (ligands and receptors) during evolution.

The signaling mechanisms mediating attraction and repulsion are currently the subject of intense investigation. One interesting finding suggests that the signaling machinery within growth cones is organized to allow rapid switching from attractive to repulsive responses. Specifically, the responses of growth cones that are attracted to netrin-1 can be converted to repulsive responses through pharmacological manipulations that result in a reduction in cyclic AMP (cAMP) signaling (for instance, incubation with a membrane permeable inhibitor of the cAMP effector protein kinase A (PKA)) (Fig. 17.7) (Ming *et al.*, 1997). Although it is not known how cAMP signaling impinges on the netrin response, the fact that the response can be converted provides evidence that the growth cone turning machinery is organized to facilitate such switching.

Identification of netrins as long-range guidance cues also illustrates the fact that long-range and short-range guidance mechanisms can be closely related. Although netrins are capable of long-range attraction, they are closely related in structure to one region of the archetypal nondiffusible extracellular matrix (ECM) molecule laminin-1. In fact, the extent to which netrins can diffuse in the embryo appears to be regulated so that in some circumstances they function as local rather than long-range cues, as shown in some regions in the nematode *C. elegans*, in the vertebrate retina, and at the *Drosophila* midline (Wadsworth *et al.*, 1996; Deiner *et al.*, 1997; Brankatschk and Dickson, 2006). Thus, as in the distinction between attractive and repulsive cues, there is not a hard and fast distinction between local and long-range cues.

**FIGURE 17.6 Netrins are phylogenetically conserved axon attractants.** (A) Distribution and function of netrins in axon guidance. (i) Diagram of a cross section through the embryonic vertebrate spinal cord depicting the role of netrin-1 (here and in all subsequent schematic figures shown in green) in guiding commissural axons from the dorsal spinal cord to the ventral midline. (ii) A ventral to dorsal gradient of netrin protein in the developing mouse spinal cord visualized using an immunohistochemical stain (from Kennedy *et al.* (2006)). (iii) Diagram of a cross section through the developing nematode *C. elegans* illustrating the role of the netrin/UNC-6 in guiding axons along a dorso-ventral trajectory. (B) Attractive effect of netrin-1 on rodent commissural axons in an *in vitro* assay for chemoattraction. Pieces of the dorsal half of the spinal cord, viewed from the side, were placed in culture for 40 hours with either control COS cells or COS cells secreting Netrin-1. In control conditions (left), all the commissural axons grow from their cell bodies at the top (dorsal) side of the explants along a vertical (dorso-ventral) trajectory (shown in diagrammatic form at the top, and visualized within the spinal cord explants using an immunohistochemical axonal marker (red) at bottom). In the presence of cells secreting netrin-1, however, the axons within  $\sim 150\mu\text{m}$  of the cells (arrowheads) turn towards the netrin source. Dots mark the boundary between COS cells and spinal cord tissue. In the presence of netrin-1 axons can be seen invading the netrin-secreting COS cell clump. (From Kennedy *et al.*, 1994.) (C) Netrin-1 is required for guidance of commissural axons to the ventral midline. Shown are cross-sections through the spinal cord of embryonic day 11.5 mice. Left: wild-type (control); right: *netrin-1* knockout mouse. Axons are visualized with an axonal marker. Normally (left), commissural axons (c) extend along a smooth dorsal-to ventral trajectory to the floor plate (fp) at the ventral midline. In the absence of netrin-1 (right), they extend normally in the dorsal half of the spinal cord, but when their trajectory through the ventral half is profoundly perturbed, with many projecting medially or laterally, and only a very few axons reaching the floor plate. (From Serafini *et al.*, 1996.)

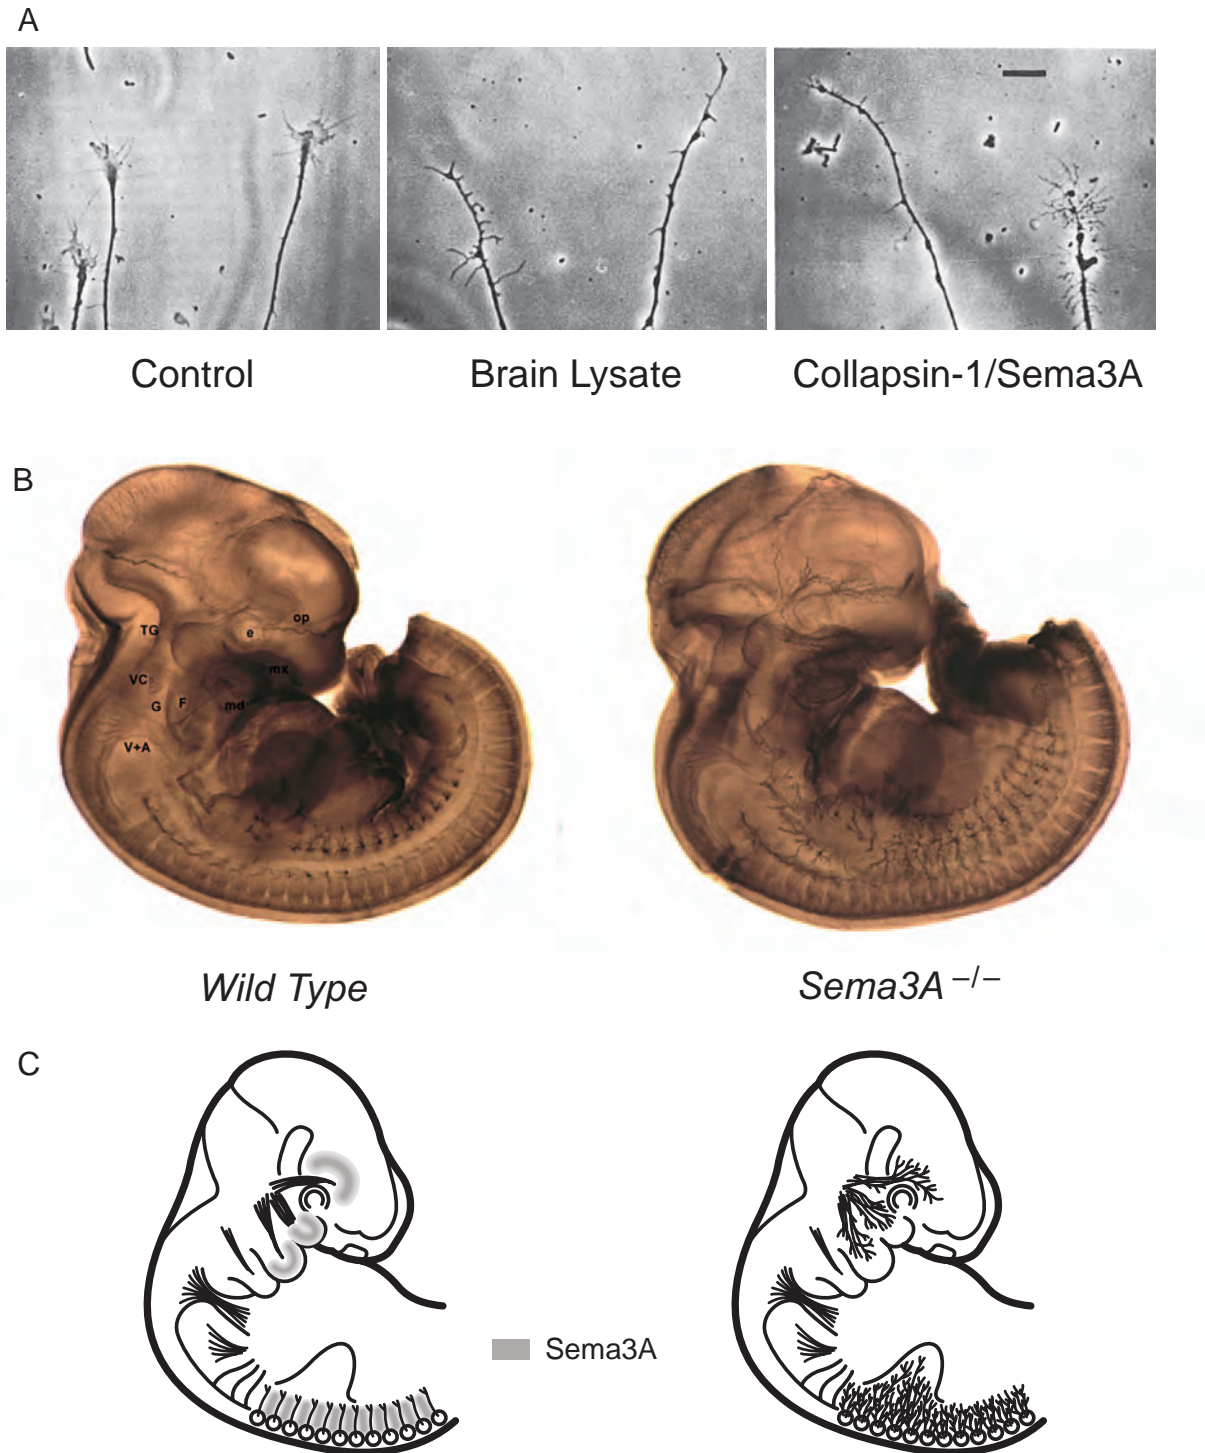

**FIGURE 17.7 Netrin bifunctionality depends upon both receptor composition and intracellular signaling.** (A) Single *Xenopus* spinal neurons in culture are attracted and steer along an increasing gradient of netrin-1 originating from a micropipette (hollow arrow, upper right: green arrow, netrin; white outlined arrow, control). These neurons express DCC on their surface. (B) If a *Xenopus* neuron expresses both DCC and UNC5 receptors, these proteins form a signaling complex which now interprets netrin-1 as a repellent, and they steer down the gradient. (C) Inhibition of cAMP-mediated signaling using a protein kinase A (PKA) inhibitor also converts netrin-1 attraction to repulsion, even though these neurons only express DCC. (From Ming *et al.*, 1997 and Hong *et al.*, 1999.)

## Semaphorins

The semaphorin family of proteins includes many secreted and membrane-associated proteins, suggesting that these cues also act at both long and short-range (Raper, 2000). The first known semaphorin was grasshopper semaphorin 1a, a transmembrane protein required for correct pathfinding of pioneer sensory axons in the developing limb (Kolodkin *et al.*, 1992). The first vertebrate semaphorin, semaphorin 3A

(Sema3A, originally called collapsin-1), was identified utilizing an *in vitro* axon repulsion assay to facilitate the biochemical purification of axonal repellents from brain extracts (Fig. 17.8A) (Luo *et al.*, 1993). There are approximately 20 distinct semaphorin family members in higher vertebrates and all contain the family's signature semaphorin domain, an approximately 500 amino acid domain that is the key extracellular signaling domain of these proteins (Fig. 17.5). Semaphorin biological specificity is in part determined by a

**FIGURE 17.8 Secreted semaphorins are potent repellents.** (A) Dorsal root ganglion neurons in culture exhibit a dramatic collapse when exposed to biochemically enriched fractions derived from chick brain lysates or to conditioned medium from tissue culture cells engineered to express recombinant Sema3A/collapsin-1. Medium from control non-transfected cells has no effect on DRG growth cone morphology. From Luo *et al.* (1993). (B) Mouse whole mount, embryonic day 11.5, wild-type and *Sema3A* mutant embryos immunostained for neurofilaments to illuminate spinal and cranial peripheral nerve projections. In *Sema3A* mutants cranial nerves including the trigeminal nerve (TG), are dramatically defasciculated, extend branches into ectopic locations, and overshoot their normal target regions. Spinal nerves, too, are defasciculated and extend into intersomitic regions they normally avoid (cranial nerves: ophthalmic, op; maxillary, mx; mandibular, md; facial, F, glossopharyngeal, G; vestibulocochlear, VC; vagus and accessory, V + A. Eye, e. Spinal nerves, arrow). Observations first reported by Taniguchi *et al.* (1997); whole-mount photographs courtesy of J. Merte and D. Ginty. (C) Schematic of whole mount embryos in B showing cranial and spinal nerve projections, and also Sema3A localization (gray).

relatively short stretch of amino acids within the semaphorin domain.

Most semaphorins have the capacity to act as potent inhibitory cues for neuronal or nonneuronal cells, and in a variety of assays semaphorins have been shown to repel very specific subsets of cultured axons. *In vivo* genetic analyses in invertebrates and vertebrates demonstrate conclusively that semaphorins serve as key axon repellents during neural development (Tran *et al.*, 2007). For example, mice in which the *Sema3A* gene has been disrupted by homologous recombination exhibit dramatic axon guidance defects (Fig. 17.8B) (Taniguchi *et al.*, 1997). How does *Sema3A*-mediated repulsion contribute to normal axon guidance? Once axons have begun to grow, often they are observed to extend upon the surfaces of axons that have preceded them on the same route. Thick bundles of axons, called fascicles, are built up over time, and many closely associated fascicles generally make up a nerve. Growth cones grow within fascicles in part because axons can be a preferred substratum compared to surrounding tissues. Though various permissive cues expressed on axons promote axon outgrowth on axonal surfaces, the presence of repellents in the surrounding tissue also restrains axon outgrowth into these regions, thereby driving axon–axon fasciculation—a process termed “surround repulsion.” *Sema3A* is expressed in tissues surrounding many peripheral nerves and acts as a repellent for sensory and motor axons. In *Sema3A* mutants many, but not all, peripheral nerves are defasciculated, extending and branching excessively into regions where normally *Sema3A* would inhibit their growth (Fig. 17.8B and C). Interestingly, many of these axons in *Sema3A* mutants with abnormal and incorrect trajectories are eliminated later in development, very likely through the mechanisms described in Chapter 20. Transmembrane semaphorins expressed on axons within fascicles also serve as repellents, however rather than providing “surround repulsion” like secreted *Sema3A*, they serve to counter attractive axon–axon interactions, allowing axons to respond to other cues and defasciculate from main bundles in order to extend toward their specific targets (see later, and Fig. 17.9B).

The major receptors for semaphorins are members of the plexin family, transmembrane proteins that are distant relatives of the semaphorins themselves and include nine different proteins in higher vertebrates (Fig. 17.5A) (Tamagnone and Comoglio, 2000). Many transmembrane and some secreted semaphorins bind plexins directly. However, several secreted vertebrate semaphorins, including *Sema3A*, do not. Instead, these secreted semaphorins bind to the obligate coreceptors neuropilin-1 or neuropilin-2, which, together with a plexin family member, form an active receptor

complex (Fig. 17.5A). Different secreted semaphorins appear to require specific combinations of neuropilin-1 or neuropilin-2 and select plexins in order to evoke guidance responses in distinct neuronal subtypes. This was shown through analysis of *plexin* mutants in invertebrates and vertebrates, and *neuropilin* mutants in mice, which display axon guidance phenotypes quite similar to those observed in the absence of the corresponding semaphorin ligand (Tran *et al.*, 2007).

Plexin receptor activation can initiate a series of intracellular signaling events that results in the local disassembly of growth cone cytoskeletal components and substrate attachments, ultimately producing inhibition of axon outgrowth or repulsive steering (Kruger *et al.*, 2005). However, as has been observed for many guidance cues, semaphorins include both attractants and repellents, and the same semaphorin under certain circumstances may serve both functions. For example, the secreted semaphorin *Sema3B* in the mouse embryo functions as an attractant for one subset of axons in the developing anterior commissure tract in the brain, and as a repellent for a different subset of axons in this same tract (Falk *et al.*, 2005). Remarkably, *Sema3A* can act as both an attractant and a repellent for distinct neural processes extending from mouse cortical pyramidal neurons (Polleux *et al.*, 1998, 2000). These neurons normally extend axons and dendrites in opposite directions, and in a neuronal culture paradigm *Sema3A* repels cortical pyramidal neuron axons but attracts dendrites from these same neurons. *Sema3A* mutant mice display misoriented cortical pyramidal neuron axons and dendrites, demonstrating how guidance cue bifunctionality participates in organization of cortical connectivity. Like netrin-1, *Sema3A* repulsive steering of isolated growth cones *in vitro* also is modulated by cyclic nucleotide signaling, however it is modulation of cGMP signaling, not cAMP signaling, that switches *Sema3A* repulsion to attraction (Song *et al.*, 1998). Stimulation of cGMP-dependent signaling switches *Sema3A* repulsion to attraction, which is intriguing since this same signaling pathway is required for *Sema3A*-mediated attraction of cortical neuron dendrites (Polleux *et al.*, 2000).

Semaphorins facilitate the formation of central and peripheral axon pathways by regulating axon pathfinding and fasciculation, however semaphorins also have been implicated in targeting axons to the specific locations of their synaptic partners, in directing the pruning of exuberant projections in the hippocampus, and in regulating the morphology of cortical pyramidal neuron dendrites (Tran *et al.*, 2007). The multiple roles played by semaphorin-plexin interactions in the establishment of neuronal connectivity showcases the versatility of plexin signaling.

## Slits

Slits are large secreted proteins (Fig. 17.5A) that are also multifunctional. They were identified as axonal repellents through studies of chemorepellent factors in *Drosophila* and in vertebrates (Kidd *et al.*, 1999; Brose *et al.*, 1999; Li *et al.*, 1999), and as stimulators of axon branching through studies of sensory axon arborization in vertebrates (Wang *et al.*, 1999). A single slit gene is found in *Drosophila* and in *C. elegans*, whereas there are three in mammals. Extensive studies in all three organisms have demonstrated key roles for slit-mediated repulsion in guidance of many axonal classes, including a variety of axons in the mammalian forebrain, as well as guidance at the midline of the spinal cord (discussed later). The branching activity of slits, so far documented only in vertebrates (Ma and Tessier-Lavigne, 2007), has been implicated in regulating dendritic branching as well (Whitford *et al.*, 2002).

In all species, the repulsive actions of slit proteins are mediated by receptors of the Roundabout or Robo family (Kidd *et al.*, 1998) (Fig. 17.5A), which, like DCC and UNC5 family netrin receptors, are also members of the immunoglobulin superfamily. Interestingly, whereas in the case of netrins where different receptors mediate attraction and repulsion, in the case of slits it appears that both repulsion and branching are mediated by Robo family receptors, presumably activating distinct downstream effectors within the axons.

## Ephrins

The fourth family of “canonical” guidance cues are the ephrins, cell surface signaling molecules that play important roles in a large number of developmental events including axon guidance (Klein, 2004). There are two subfamilies (Fig. 17.5A): eight class A ephrins are tethered to the cell surface via GPI linkages, and six class B ephrins are transmembrane molecules. Ephrins must be clustered together to activate their receptors and do not appear to be active if released from the cell surface, so they are thought to function exclusively as short-range guidance cues. These ligands bind receptor tyrosine kinases of the Eph family. Class A ephrins interact with various degrees of selectivity with five class A Eph receptors, whereas class B ephrins interact with three class B Eph receptors (Fig. 17.5A).

Ephrins have been shown to play an essential role in organizing topographic projections that connect, for example, retinal ganglion cells in the eye with their target cells in the appropriate portion of the optic tectum in lower vertebrates, or the lateral geniculate nucleus of the thalamus in higher vertebrates. These

mapping functions demonstrate the versatility of ephrins, which can function as attractants for some axons and repellents for other, as well as either positive or negative regulators of axonal branching. These functions in topographic mapping are discussed in detail in Chapter 18. In addition to topographic mapping, ephrins are implicated as short-range attractants and repellents in the guidance of a variety of central and peripheral axons.

## Morphogens and Growth Factors

As important as the “canonical” guidance cue families are, they do not account for all of axon guidance. Studies over the past decade have revealed that various morphogens and growth factors have also been coopted to guide axons (Fig. 17.5B). We are still learning how widely these molecules are used in this role.

Morphogens are proteins that function to specify cell fates at earlier stages of embryonic development; the term refers specifically to factors that can induce different fates in a dose-dependent fashion. Three key families of developmental morphogens have been implicated in axon guidance as well: members of the hedgehog (Hh), bone morphogenetic protein (BMP), and Wnt families. These families were introduced in Chapter 15 in the discussion of cell fate determination. The evidence implicating these factors in axon guidance is growing, and is particularly well established in the vertebrate spinal cord. Here, members of all three families having been shown to collaborate with classic guidance cues of the netrin and slit families, as we will discuss in detail in a later section of this chapter. Outside the spinal cord, evidence for guidance functions of members of the BMP and hedgehog families is still limited. An example has been described in the vertebrate retina (involving sonic hedgehog), but just how widely these factors function as guidance cues remains to be determined. The evidence implicating Wnt family members in guidance is, however, already quite extensive, as they appear to play key roles in axon guidance along the longitudinal (anterior-posterior) axis in *C. elegans*, *Drosophila*, and vertebrates, and they are also implicated in topographic mapping in the retinotectal system (Zou, 2006). A list of these factors, and the receptors implicated in mediating their guidance effects, is provided in Figure 17.5B.

Whereas morphogens that function at early stages of development have been coopted to guide axons at later stages, various growth factors initially known for their functions at later stages of nervous system development—particularly in regulating the survival of

neurons (Chapter 19)—have been found also to play an earlier role in axon guidance. So far, these factors are all implicated as attractants: hepatocyte growth factor (HGF), fibroblast growth factors (FGFs) and glial cell-derived neurotrophic factor (GDNF) for subsets of motor axons, neurotrophins (BDNF and NT3) for sensory axons, and neuregulins for thalamocortical axons (Fig. 17.5B). In each case, the factors have been implicated in guidance of just one subset of axons, and just in vertebrates. Thus, it remains an open question how widely growth factors are used to guide axons, and whether they can also function as repellents *in vivo*. There is, however, already considerable evidence that many of these factors function to stimulate branching of diverse classes of axons at their targets (for example, the neurotrophin NGF regulates branching of sensory axons at their targets, whereas BDNF regulates branching of thalamocortical axons in the cortex).

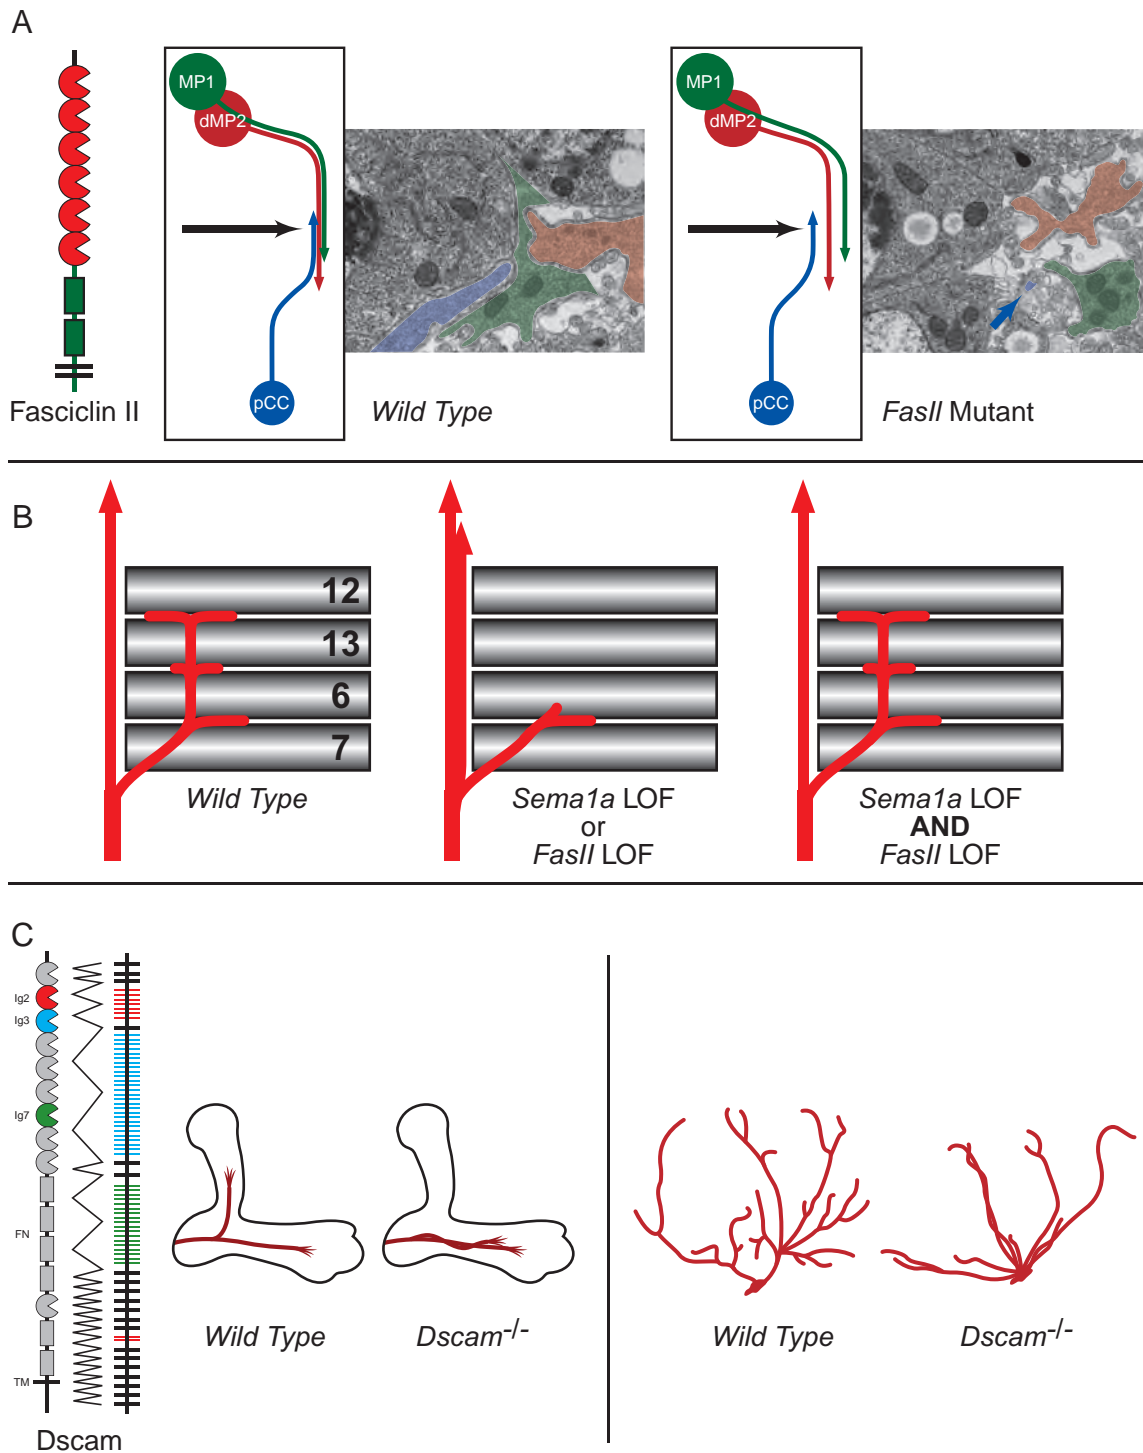

The following sections of this chapter explain how the guidance cues just discussed are deployed *in vivo* to affect accurate guidance. Before turning to this, however, we describe one family of proteins, already discussed to a limited extent, that has diverse roles in regulating nervous system wiring: the Ig superfamily proteins.

### Ig Superfamily Proteins: Cell Adhesion Molecules, Guidance Cue Receptors, and Repellents

Initial work directed toward understanding nervous system connectivity in part focused on identifying factors that promote neuronal adhesion to substrates, with the hope this might explain complex wiring patterns. In the 1980s several cell adhesion molecules (CAMs) were identified, including a protein called neural cell adhesion molecule (NCAM) that was shown to mediate *in vitro* adhesive interactions in a homophilic (like-binds-like) fashion. NCAM contains a large extracellular domain structure that includes multiple repeats of an immunoglobulin (Ig)-C2 motif, and also several fibronectin type II repeats (Edelman, 1986). In several cell culture settings NCAM can regulate axon-axon associations, but mice harboring mutations in NCAM, or in other vertebrate Ig superfamily adhesion molecules such as L1, do not exhibit guidance defects indicative of these proteins playing major instructive roles in nervous system wiring. However, the *Drosophila* cell adhesion molecule fasciclin II (FasII), the fly orthologue of NCAM, provides insight into how selective CAM expression can contribute to more subtle aspects of nervous system wiring, namely fasciculation (or bundling) of axons.

FasII is expressed on a defined subset of fascicles in the developing insect CNS and PNS. Axons that contribute to FasII-expressing pathways still extend in approximately correct directions in *FasII* mutants. However, ultrastructural analysis reveals that in *FasII* mutants, axons that normally express FasII on their surface and maintain very close contact now fail to bundle together, and instead proceed independently (Fig. 17.9A) (Lin *et al.*, 1994). In insects, FasII also is expressed on motor axons as they extend into the periphery, and overexpression of FasII on motor axons *in vivo* causes them to remain bundled where normally they would defasciculate from the main fascicle and extend to their individual muscle targets (Fig. 17.9B). Interestingly, removal of the axonal repellent Sema-1a through genetic means results in a similar failure of motor neuron defasciculation, however simultaneous removal of both FasII and Sema-1a significantly restores normal patterns of axon-axon association and motor neuron pathfinding (Yu *et al.*, 2000) (Fig. 17.9B). These results highlight the role played by adhesive and repulsive guidance molecules in maintaining the balance of attraction and repulsion critical for allowing axons to extend as part of the same bundle toward target regions but then separate so as to contact unique synaptic targets.

A myriad of different Ig superfamily proteins is expressed in developing neurons, including CAMs and also receptors for canonical guidance cues (such as DCC, Robo, and Unc5; see earlier). Recent work also demonstrates a novel repulsive function for homophilic interactions involving the CAM Dscam (Down Syndrome CAM) in *Drosophila* neural development (Schmucker *et al.*, 2000; Zinn, 2007). Dscam is distinguished from all other Ig superfamily members by its genomic structure; alternative splicing of numerous exons has the capacity, at least in *Drosophila*, to result in the generation of close to 40,000 different Dscam isoforms (Fig. 17.9C). Homophilic Dscam interactions occur only between identical Dscam isoforms; a difference of even seven amino acids in otherwise identical isoforms precludes homophilic association. This astounding molecular diversity, coupled with expression of only a few isoforms in any one neuron, has the potential to allow processes from individual neurons, either axon branches or dendrites, to distinguish between self and nonself. This is because it is extremely unlikely that any two neurons will express the same complement of Dscam isoforms. Indeed, in the mushroom body of the *Drosophila* brain, isoform-specific Dscam interactions are required for axon branches from the same neuron to separate from one another and bifurcate at a single choice point (Zhan *et al.*, 2004) (Fig. 17.9C). Further, the elaboration of individual

sensory neuron dendritic arborizations with nonoverlapping branches (allowing for an even distribution of sensory endings), also requires homophilic interactions between identical Dscam isoforms. Both of these examples demonstrate that Dscam isoform diversity

allows neuronal processes emanating from a single neuron to be repelled from one another while simultaneously maintaining contact with processes from other neurons. Though in vertebrates Dscam is not extensively alternatively spliced, several other verte-

◀ **FIGURE 17.9 Ig superfamily members regulate axon fasciculation and can also serve as repellents.** (A) The fasciclin II (FasII) protein, an Ig superfamily member, is required for axons that make up the FasII-expressing MP1 fascicle to remain in close apposition to one another. Wild-type (left) and *FasII* mutant (right) embryonic CNS regions that include the MP1 pathway are depicted schematically as viewed from above, and are viewed in cross section in an electron microscopy section (one of a complete serial reconstruction) taken at the location of the arrow, and with MP1, dMP2, and pCC axonal projections colored to highlight their position. In wild-type embryos, the dMP2, MP1, and pCC neurons are closely associated in the same fascicle and share extensive cell membrane contacts. However, in *FasII* mutants these same neurons do not share extensive membrane contact and extend separately (blue arrow indicates tip of pCC axon). Modified from Lin *et al.* (1994). (B) Schematic representation of embryonic *Drosophila* motor neurons extending from the CNS onto muscles (rectangles) in the periphery. In wild-type embryos (left) motor axons exit the CNS as part of a single bundle but then, at specific choice points, subsets of these axons defasciculate from the main bundle and enter regions that contain the different muscles upon which they will elaborate synaptic arborizations. When FasII is over-expressed in all motor neurons (*FasII* gain-of function (GOF)), motor axons often fail to defasciculate and instead bypass their normal choice points (middle). A similar result is observed in the absence of the axonal repellent Sema 1a: *Sema-1a* loss of function (LOF) (middle). However, the combination of *Sema-1a* LOF and *FasII* LOF restores the balance of attraction and repulsion along these axons and results in significant rescue of normal motor axon pathfinding (Lin and Goodman, 1994; Yu *et al.*, 2000). (C) Dscam is required for homophilic repulsive interactions that allow neuronal processes extending from individual neurons to distinguish self from non-self. Dscam is an Ig superfamily member whose extracellular domain contains Ig and fibronectin repeats, however extensive alternative splicing from a large number of exons (color-coded to illustrate Ig domains that contain one from among multiple possible exons) generates ~40,000 different Dscam isoforms (left). In the developing *Drosophila* brain, axons that project into the mushroom body bifurcate in order to extend branches into different lobes of this structure. Individual neurons lacking Dscam, however, generate branches that fail to separate from one another and instead extend in close association within the same lobe (middle) (Zhan *et al.*, 2004). Dendrites of sensory neurons in the body wall of *Drosophila* larvae elaborate arborizations in which processes do not overlap. If Dscam is not present in a sensory neuron, however, dendritic arborizations are less elaborate and processes overlap (right). For both axons and dendrites, ectopic expression of a single Dscam isoform in *Dscam* mutant neurons (not shown) rescues these Dscam LOF phenotypes (Hughes *et al.*, 2007; Mathews *et al.*, 2007; and Soba *et al.*, 2007).

brate neuronal proteins, and also families of proteins, have the potential to be represented by comparable diversity. Therefore employing extreme protein isoform diversity in the service of distinguishing neuronal uniqueness may be generally applicable across species.

### Summary

Several prominent classes of guidance cues have been identified: the four families of canonical guidance cues (netrins, semaphorins, slits, and ephrins), whose functions in guidance are widespread and well established; three families of morphogens (Hedgehogs, BMPs, and Wnts), whose functions are just being defined; a growing set of growth factors implicated in select attractive guidance events; and members of the Ig superfamily, which, beyond their roles as receptors for other guidance cues, are implicated in axon fasciculation and, recently, in axonal repulsion. These guidance cues can function in long-range or short-range axon guidance. Many guidance cues are multifunctional and can function in attraction, in repulsion, or in regulating branch formation. Furthermore, many cues are conserved evolutionarily, both in structure and in function, between vertebrates and invertebrates. In addition to these molecules, yet other molecules appear to contribute to guidance in ways that are just being defined; these include other extracellular matrix components, transmembrane phosphatases, and cadherins (Dickson, 2002).

## GUIDANCE CUES AND THE CONTROL OF CYTOSKELETAL DYNAMICS

Guidance cues are signaling molecules that influence the cell biological mechanisms by which growth cones extend, turn, and retract. The forward-crawling motion of a growth cone depends on its own intrinsic motile mechanism interacting with a permissive outside environment. The extension and withdrawal of the leading edge and filopodia are an intrinsic property of a healthy growth cone. Once the leading edge has extended, an appropriate substratum on which it can attach and become stabilized must be present. Once attached, an inherent traction-generating mechanism within the growth cone causes tension to develop. Unattached or poorly attached processes are thereby withdrawn, whereas tension exerted against attached processes helps draw the body of the growth cone forward. The continuous repeated cycling of extension, attachment, retraction of poorly attached processes, and tension generation produces net forward extension. In principle, guidance cues could act at any one of these steps to affect the direction in which growth cones extend.

### Actin Cycle, Microtubules, and Axon Growth

Within growth cones the distribution of actin and microtubules is dramatically segregated, with micro-

**FIGURE 17.10 Distributions of microtubules and fibrillar actin in a neuronal growth cone.** Microtubules and fibrillary actin are highly compartmentalized within growth cones. Microtubules (green) are a key structural component of the axon and though tightly bundled within the axon shaft, a dynamic sub-population of microtubules actively explores the peripheral domain of the growth cone by extending along filopodia. All of the growing ends of microtubules are pointed toward the leading edge. In contrast, actin (red) is highly concentrated in the filopodia and in the leading edges of lamellae. Within filopodia, actin fibrils are oriented with their growing tips pointed distally. The same is true of many fibrils within lamellae, although many additional fibrils are oriented randomly and form a dense meshwork. Modified from Lin *et al.* (1994). (B) The organization of cytoplasmic domains and cytoskeletal components in an *Aplysia* bag cell growth cone. Fluorescent labeling of microtubules (green) and fibrillar actin (red) shows their segregation within the growth cone central and peripheral domains, respectively. Note the extension of a small number of microtubules into the actin-rich peripheral domain. From Suter and Forscher (2000).

tubules primarily occupying the axon shaft and the central domain of the growth cone, and actin residing in the peripheral domain (Fig. 17.10). One way in which guidance cues can affect the direction of growth cone advance is by controlling the actin polymerization that helps drive protrusion of the leading edge of the growth cone. A dense mesh-work of fibrillar actin (F-actin) is concentrated at the leading edge of the growth cone. New actin polymerization just behind the leading edge effectively helps push it forward, while, on average, F-actin is simultaneously depolymerized at an equal rate more centrally. A second important component of growth cone motility is a continuous rearward flow of polymerized actin away from the leading edge toward the central domain. This actin flow can be visualized in cultured growth cones with the aid of a drug that blocks actin polymerization (Forscher and Smith, 1988). Actin monomers generated by depolymerization in the body of the growth cone are recycled to the front, polymerized again at the leading edge, and swept rearward, where they are depolymerized once again. This continuous rearward flow of polymerized actin is called *treadmilling*, and it results from the action of myosin-based motors driving F-actin toward the growth cone central domain (Lin *et al.*, 1996) (Fig. 17.11A). In the absence of adhesive contacts with the substratum, a steady state arises whereby the actin polymerization–depolymerization cycle and treadmilling do not contribute to growth cone advance. If polymerized F-actin is linked to a permissive substratum through cell surface receptors, however, growth cone actin dynamics advance the leading edge and withdraw the trailing edge.

Particular representatives of several families of proteins have been shown to provide permissive substrata for growth cone extension. Among these are extracellular matrix molecules such as laminin-1 and fibronectin, and also specialized cell surface molecules from either the immunoglobulin superfamily or the cadherin family. These molecules are bound by specific cell surface molecules on the growth cone, including members of the integrin, Ig, and cadherin superfamilies. Although these proteins provide potent

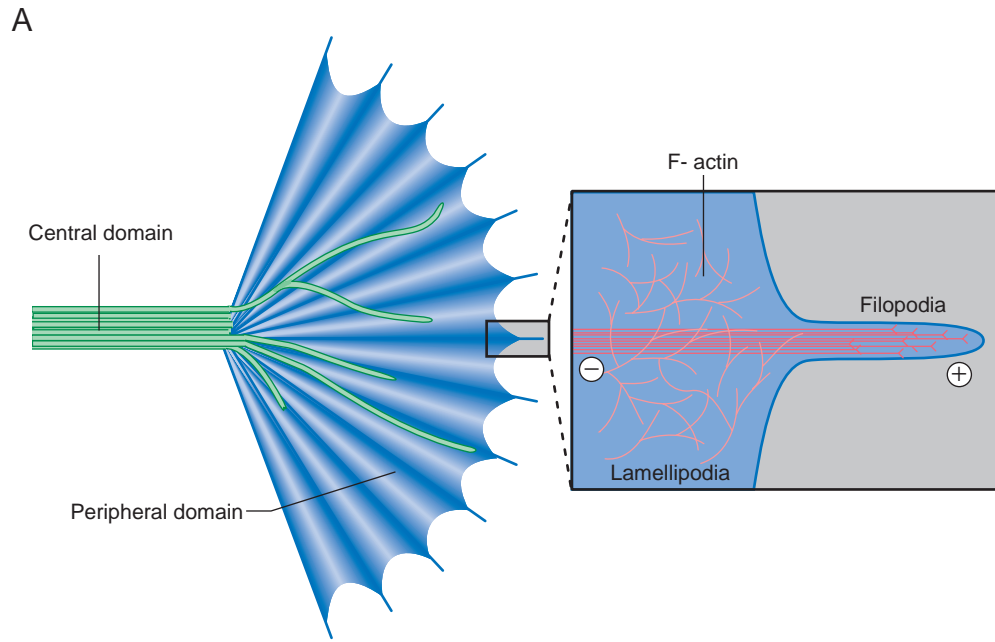

permissive substrates for cultured neurons, it is still unknown whether they or other classes of molecules are the major permissive factors for axon growth *in vivo*. At least two of the sets of canonical guidance cues, the netrins and semaphorins, are known to include members that have a permissive role for axon growth *in vivo*.

Microtubules also play a key role in regulating growth cone advance. In the axon and proximal region of the growth cone's central domain, microtubule polymers are bundled and relatively stable. However, toward the peripheral region a highly dynamic population of microtubule polymers extends individually toward the leading edge along filopodia (Fig. 17.10). Subsequent stabilization and bundling of these dynamic microtubules within the advancing growth cone leads to growth cone advance and defines the location of the newly generated trailing axon shaft.

### Linking Cytoskeleton and Permissive Substratum Molecules

Cell surface receptors that bind permissive substratum molecules must in turn be linked to the cellular cytoskeleton. Indirect linkages between the cytoskeleton and members of the integrin, cadherin, and immunoglobulin families can give the cytoskeleton traction on the substratum and facilitate growth cone advance (Fig. 17.11B). This traction can be modulated by several signaling events, including the phosphorylation of specific cytoplasmic proteins. For example, activity of the nonreceptor tyrosine kinase Src reduces the strength of cadherin and integrin mediated cell adhesion. Localized activation of these kinds of signaling pathways could control the direction of growth cone advance by modulating adhesion to the substratum.

The linkage of F-actin to the substratum generates tension within the growth cone and causes processes that are poorly attached to the substratum to shrink or withdraw. When the retrograde movement of actin is impeded by a relatively strong attachment between the actin cytoskeleton and the surface substratum, not only is the leading edge of the growth cone advanced,

but microtubules tend to be drawn forward. The strong attachment of individual filopodia to appropriate cellular targets induces additional localized actin accumulation in the contacting process, and these processes are preferentially invaded by dynamic microtubules.

In this way, filopodia can act as scouts for less advanced portions of the growth cone, either seizing hold of permissive substrata or avoiding nonpermissive or inhibitory substrata, and thereby reorienting subsequent process extension.

**FIGURE 17.11 Actin dynamics regulate growth cone advance.** (A) A schematic representation of a growth cone filopodium, depicting polarized assembly and disassembly of actin monomers at the distal (red triangles) and proximal (yellow triangles) ends of a fibrillar actin filament. Retrograde flow (large arrow) of fibrillar actin polymers occurs through the action of non-muscle myosin. This can be visualized by the proximal translocation of a particle that is linked to the actin cytoskeleton (sphere), which fails to occur if myosin function is inhibited. Modified from Lin *et al.* (1996). (B) Linkage of the actin cytoskeleton to a permissive surface is required for forward advance. Actin polymerized at the leading edge of the growth cone (right) is swept toward the rear. If the actin meshwork is not linked to cell surface receptors that bind permissive molecules on adjacent cell surfaces, the actin cycles from front to rear but does not advance the growth cone. However, when the actin meshwork becomes attached to these receptors and thereby linked to the substrate, the meshwork remains in place and newly polymerized actin helps advance the leading edge. Modified from Lin *et al.* (1994).

leading edge by increasing the local rate of actin polymerization in the preferred direction or by decreasing its rate of depolymerization in other directions. Guidance cues also could modulate the rate of myosin-mediated F-actin translocation, thereby stimulating or inhibiting filopodia and leading edge retraction. It is therefore reasonable to expect that many signaling pathways activated by guidance cues ultimately converge on actin dynamics. Studies on the receptor mechanisms for the several families of guidance cues described earlier show that activation of these receptors often directly or indirectly alters the activity of small Rho family GTPases such as Rac and Rho, which are key regulators of actin dynamics and impact on cell motility in a large variety of cell types (Dickson, 2001; Huber *et al.*, 2002). For example, the netrin receptor DCC activates Rac, whereas activation of certain semaphorin receptors results in activation of Rho through the action of an adaptor protein that associates with the cytoplasmic domain of Plexin B receptors and stimulates the exchange of GDP for GTP on the Rho GTPase. Activation of both Eph and Robo receptors can also modulate Rho GTPases through the action of distinct adaptor proteins that associate with these receptors and either stimulate or inactivate Rho GTPases. In addition to modulating signaling cascades that regulate actin dynamics, guidance cue receptor activation can also directly regulate microtubule dynamics through activation of microtubule binding proteins that either promote or inhibit microtubule extension (Fig. 17.12).

### Interactions between the Cytoskeleton and Guidance Receptors

How do cues such as semaphorins, netrins, slits, and ephrins tap into these mechanisms for growth cone extension to affect guidance? Attractive and repulsive signals could promote the extension of the

### Summary

Growing axons utilize an intrinsic, actin-based treadmilling mechanism to extend filopodia and

advance the leading edge of the growth cone. Growth cone extension requires an appropriate substratum for attachment and stabilization, which allows an inherent traction-generating mechanism within the growth cone to generate tension. This tension results in the withdrawal of poorly attached processes and the growth of processes that form attachments with the substratum. Net forward extension results from repeated cycles of extension, attachment, and the retraction of poorly attached processes. Cell surface receptors that bind substratum molecules are linked indirectly to the cellular cytoskeleton, and these linkages can be modulated by the activation of signaling pathways. The binding of extracellular guidance cues to receptors on the growth cone surface modulates axon growth through several mechanisms, including regulation of actin polymerization, F-actin treadmilling, linkage between the growth cone cytoskeleton and the substrate, and modulation of microtubule dynamics. Many guidance receptors directly or indirectly modulate the activity of small Rho family GTPases, which are key regulators of actin polymerization.

## GUIDANCE AT THE MIDLINE: CHANGING RESPONSES TO MULTIPLE CUES

How are guidance cues interpreted by growth cones *in vivo* and how do they direct the appropriate wiring together of the nervous system? The guidance of an axon from its inception through its acquisition of a target is a complex process that can be broken down into a series of discrete decisions. This section illustrates how multiple guidance cues and receptors cooperate closely to direct a complex series of guidance events at the nervous system midline.

Single guidance cues probably rarely or never act by themselves, and the integration of several simultaneously active cues is required for most, if not all, guidance decisions. This can be illustrated by interactions between the activities of many different guidance cues at the midline of the developing nervous systems of both invertebrates and vertebrates, which have been elucidated through genetic, biochemical, and embryological studies in rodents, *Drosophila* and *C. elegans*. Focusing on the mammalian spinal cord, we describe four important regulatory mechanisms that are required for reaching, crossing, and leaving the midline: initial attraction, switching on of repulsion, switching off of attraction, and prevention of premature repulsion. These mechanisms involve both canonical guidance cues, illustrated in Figure 17.13, and morphogens, illustrated in Figure 17.14.

**FIGURE 17.12** Microtubule dynamics can be directly regulated by extracellular cues. Two different microtubule binding proteins, CLASP and APC, bind to the distal (+) end of microtubules and are intracellular targets for guidance cue signaling. Slit-mediated repulsion results in activation of CLASP, which in turn stabilizes microtubules and prevents their extension into the growth cone periphery (Lee *et al.* 2004). In contrast, NGF-mediated neurite outgrowth results in promotion of microtubule assembly and extension into the peripheral region of the growth cone (Zhou *et al.* 2004). Modified from Kalil and Dent (2004).

### Initial Attraction

As mentioned earlier, in both vertebrates and invertebrates the so-called commissural axons are attracted to the nervous system midline by members of the netrin family, which activate receptors of the DCC family (Tessier-Lavigne and Goodman, 1996; Chisholm and Tessier-Lavigne, 1999). We also mentioned that netrins do not function alone in guiding commissural axons to the midline. In the mammalian spinal cord, the morphogen sonic hedgehog is also made by floor plate cells at the ventral midline and collaborates with netrin-1 to attract the axons to the midline. In addition, morphogens of the BMP family are made at the dorsal midline (by so-called “roof plate cells”) and function as repellents for commissural axons, providing a “push from behind” to help set them out on their initial ventral trajectory. Thus, even over a relatively simply trajectory, multiple cues collaborate to ensure accurate guidance of axons.

**FIGURE 17.13 A switch from attraction to repulsion allows commissural axons to enter then leave the CNS midline.** (A) Schematic of a cross-section through the mammalian spinal cord (as in Figure 1), illustrating the trajectory of commissural axons from the dorsal spinal cord to, and across, the ventral midline. The axons cross the midline at the floor plate; upon exiting the floor plate, they make a sharp right angle turn and project in a rostral (anterior) direction. A long-range gradient of netrin-1 protein (green dots) and a shorter-range gradient of slit protein (red dots) are shown. Right: Illustration of the “open-book” configuration, in which the spinal cord is opened at the dorsal midline and flattened, which helps to visualize the crossing and turning behavior of the axons at the midline. (B) As the axons project to the midline (“precrossing”), they are attracted by netrin-1 acting on the attractive netrin receptor DCC. They are insensitive to the repulsive action of slit proteins despite expression of the repulsive slit receptors (Robo1 and Robo2) because they also express Robo3, a slit receptor that suppresses the activity of Robo-1 and Robo-2. This enables these axons to enter the midline upon reaching it. However, upon crossing the midline, commissural axons down-regulate expression of Robo3 and increase expression of Robo1 and Robo2 (not shown), which allows them to sense the repulsive action of slits and results in their expulsion from the midline. (C) In *Robo3* mutant mice, the precrossing commissural axons are prematurely sensitive to slits, which prevents them from entering the midline. Shown are cross sections through a normal E11.5 mouse embryo (left) and a stage-matched *Robo3* mutant embryo (right), illustrating the inability of commissural axons in the mutant to cross the midline. (From Sabatier *et al.*, 2004). (D) Human patients with Horizontal Gaze Palsy and Progressive Scoliosis (HGPPS) carry mutations in the human *ROBO3* gene. They are capable of coordinated eye movements along the vertical axis (center), but not along the horizontal axis (left and right panels are attempts by this HGPPS patient to look left and right). The deficits in horizontal gaze result from a defect in neuronal connections across the midline in the hindbrain, which is presumed to arise from aberrant axon guidance during development since a similar defect is observed in *Robo3* mutant mice. (From Jen *et al.*, 2004.)

### Switching on Repulsion

The midline is not, however, the final destination for commissural axons: upon reaching it, axons cross the midline, then they turn at right angles and project alongside the midline to other levels of the embryo, and finally they leave the midline area altogether to reach their eventual targets (Fig. 17.14). This behavior immediately raises a paradox: if the midline is such an attractive environment for the axons, how can they leave it? The answer is that midline cells, in addition to making attractive netrin proteins, also make repellents of the slit family (and, in vertebrates, of the semaphorin family) (Fig. 17.14A) (Kidd *et al.*, 1999; Zou *et al.*, 2000). Axons can approach and then cross the midline a first time because they are initially insensitive to these repellents and thus respond only to the attractive effects of the netrins. However, and quite remarkably, upon crossing the midline the axons become responsive to the repellents by increasing the expression or function of receptors for the repellents, including upregulating expression of the slit receptors of the Robo family on their surfaces (Fig. 17.14A) (Kidd *et al.*, 1998; Zou *et al.*, 2000). What causes this dramatic change in receptor expression and function is not yet known, but its net effect is to make the axons interpret the midline as a repulsive environment, which helps expel the axons from the midline and move on to the next leg of their trajectory.

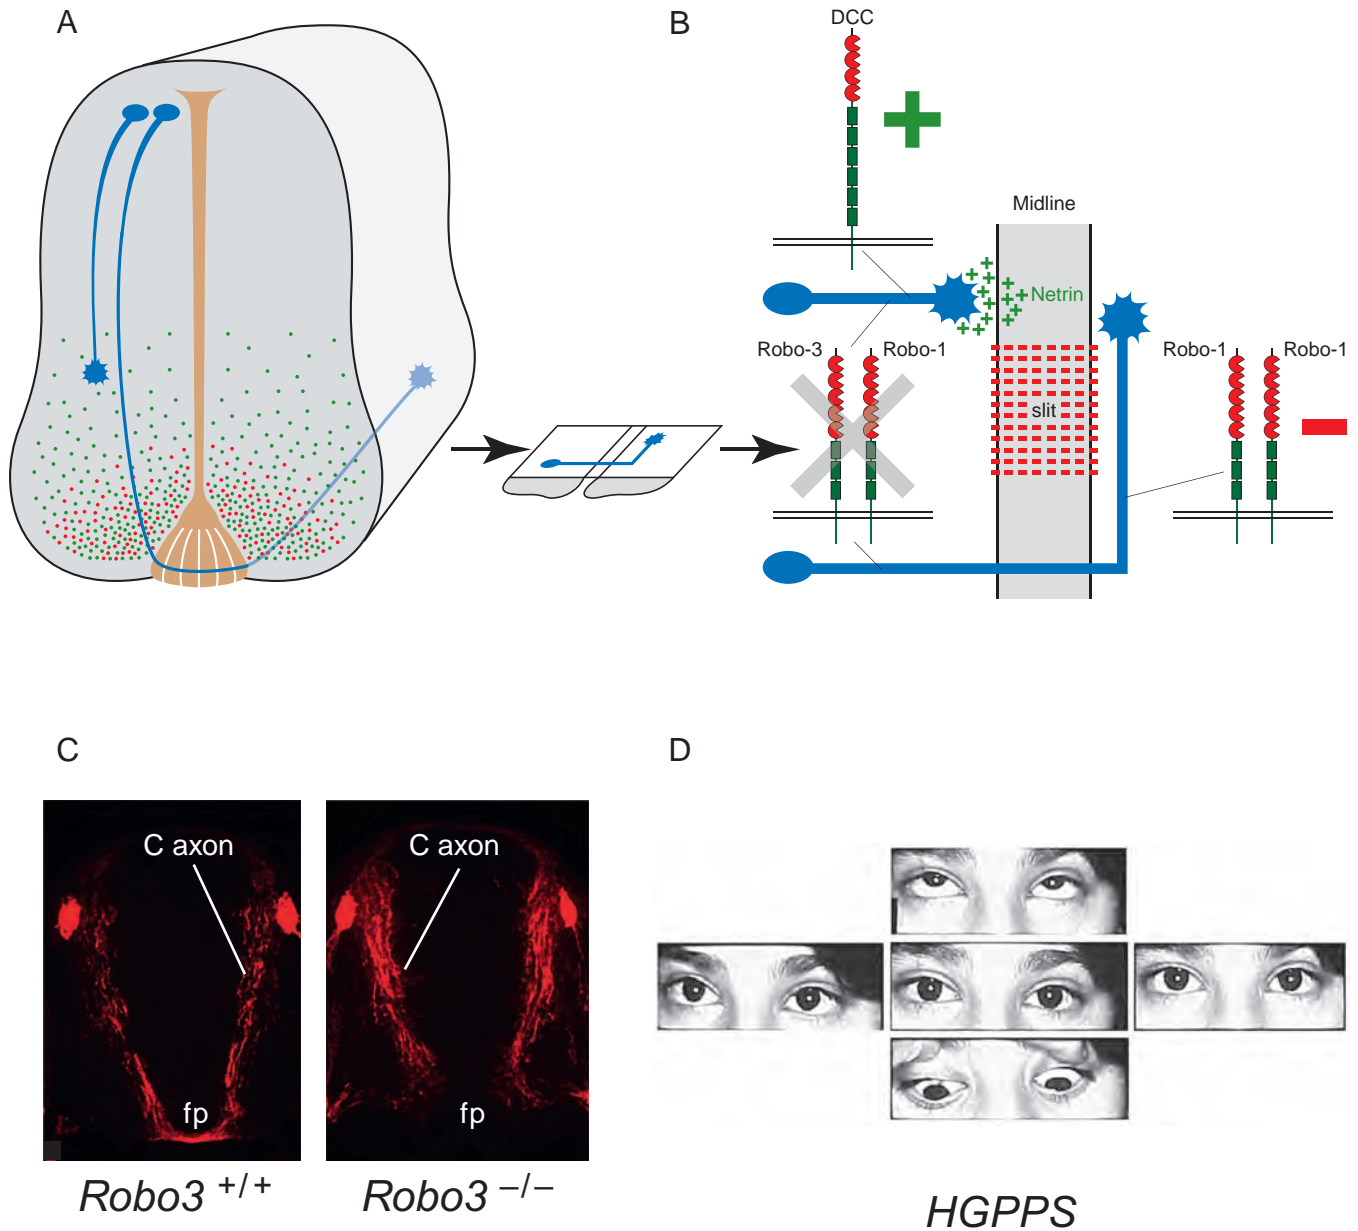

### Switching off Attraction

The upregulation of responsiveness to midline repellents is only half of the equation, however; to be efficiently expelled from the midline, it would be desirable for the axons to stop being attracted. Indeed, the attractive response of these axons to netrins is switched

off (silenced) as the axons cross the midline. There is evidence that the silencing of netrin attraction is caused by activation of the slit receptor Robo: activation of Robo by slit causes a specific region of its cytoplasmic domain to bind a specific region of the cytoplasmic domain of the netrin receptor DCC and to prevent it from transducing an attractive response to netrin (Stein and Tessier-Lavigne, 2001). How silencing of attraction by sonic hedgehog is achieved is not known. Together, these two mechanisms (upregulation of a response to midline repellents and silencing of the attractive receptor) ensure that the growth cones perceive a once attractive environment, the midline, as unambiguously repulsive.

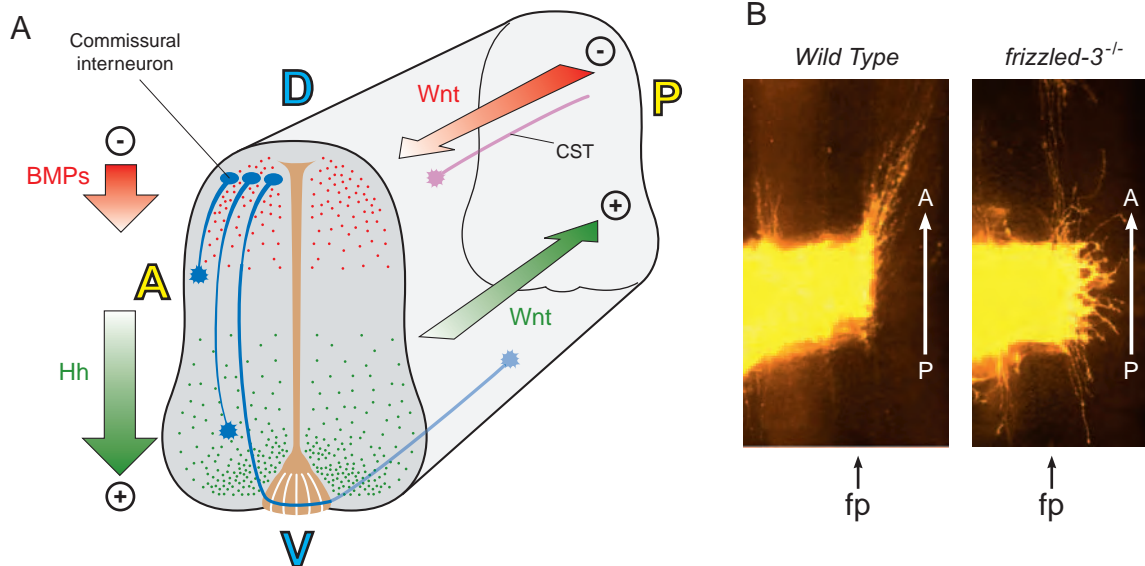

### Preventing Premature Repulsion

For guidance at the midline to occur accurately, it is essential that the switch from attraction to repulsion be carefully choreographed. In particular, it is essential that growth cones upregulate responses to repellents only after crossing the midline, not before, otherwise the axons would not be able to enter the midline. It is perhaps not surprising, then, that there are mechanisms that ensure these axons do not become responsive to repellents too soon. One mechanism that regulates the switch, already mentioned, is that the Robo receptors are expressed only at low levels before crossing, being upregulated only after crossing. How surface expression of these receptors is controlled is poorly understood, although in *Drosophila* this appears to occur at the level of regulated trafficking of the receptor to the neuronal cell surface under the control of a protein called Commissureless. However, the low level of Robo receptor that is present on the axons before crossing appears to be capable nonetheless of transducing a repulsive slit signal that can prevent

midline crossing, and which must be silenced. In vertebrates, this is achieved by a more divergent member of the Robo family called Robo3 (also known as Rig1). Robo3 is expressed on commissural axons before and during crossing, and it silences the repulsive slit signal mediated by other Robo receptors, allowing the axons to cross (Sabatier *et al.*, 2004). Thus, in *Robo3* knock-out mice, which lack Robo3 function, the axons can sense slit repulsion before midline crossing. As a result, commissural axons fail to cross the midline in these mutant mice, resulting in a dramatic “commissure-less” phenotype (Figure 17.13B).

Remarkably, a similar midline crossing defect is caused by mutations in the human *ROBO3* gene, found in patients with a syndrome known as Horizontal Gaze Palsy with Progressive Scoliosis (HGPPS) (Jen *et al.*, 2004). These patients are unable to move their eyes in a coordinated fashion along the horizontal axis (horizontal conjugate gaze), a behavior that requires the function of commissural interneurons linking the two sides of the hindbrain (Fig. 17.13C). Imaging and evoked potential studies have shown that, as in *Robo3* knock-out mice, there is a failure of midline crossing by axons in the hindbrains of these patients. Thus, the

**FIGURE 17.14 Morphogens also help direct pre- and postcrossing commissural axon trajectories.** (A) Diagram of the roles of morphogens in commissural axon guidance to the midline and beyond. BMP proteins made at the dorsal midline repel the axons from the dorsal spinal cord, providing a “push from behind,” whereas Sonic Hedgehog (Shh) made by floor plate cells attracts the axons, providing a “pull from afar” in collaboration with Netrin-1 (see Figure 17.13). After midline crossing, the axons turn in a rostral (anterior) direction in response to an attractive rostral-to-caudal decreasing gradient of Wnt protein. In contrast, cortical spinal tract (CST) axons extending caudally in the dorsal spinal cord are repelled by different Wnt family members. (B) The rostral Wnt signal is mediated by the Frizzled3 (Fz3) receptor. The trajectory of commissural axons at the midline is examined in the “open-book” configuration (Figure 17.13A), with the axons visualized by labeling with the fluorescent dye DiI. In wild-type mice (left), commissural axons cross the midline then turn rostrally (up), whereas in *Frz3* knock-out mice (right) the axons are disorganized after crossing (From Lyuksyutova *et al.*, 2003).

role of Robo3 proteins in allowing midline crossing is conserved in humans.

The ability illustrated here of growth cones to change their responses to guidance cues makes it possible for them to move from one intermediate target (such as the midline) to the next along their often complex and lengthy trajectories. Guidance at the midline also has shed light on the mechanisms involved in longitudinal guidance (i.e., along the anterior-posterior axis). Upon crossing the midline, commissural axons turn either anteriorly or posteriorly; in particular, the earliest born commissural axons in the mammalian spinal cord turn in an anterior direction. This anterior turn appears to be directed by an anterior-to-posterior gradient of Wnt protein in the spinal cord, which the growth cones sense as an attractive cue (Fig. 17.14A). Transduction of the attractive Wnt signal involves a receptor called Frizzled 3 (Fz3), so that loss of Fz3 function in a *Fz3* knock-out mouse causes the growth cones to become misrouted after midline crossing, unable as they are to sense the Wnt gradient (Lyuksyutova *et al.*, 2003). Anterior-posterior gradients of Wnt proteins provide a mechanism conserved between vertebrates and invertebrates to guide a variety of classes of axons along the longitudinal axis.

Some axons, like the spinal commissural axons just described, respond to the Wnts with an attractive response, and extend up the gradient. Others have repulsive responses and therefore grow down gradient. This has been shown, for example, for corticospinal tract axons, which navigate in the opposite direction to commissural axons (Figure 17.14) (Schmitt *et al.*, 2006).

### Summary

The study of the growth of commissural axons to and beyond the midline exemplifies how guidance of axons *in vivo* involves the simultaneous interpretation of multiple cues, including canonical guidance cues and morphogens, and how dynamic changes in axon responsiveness enables axons to navigate successive intermediate targets. Before reaching the midline, commissural axons are guided through the combined actions of repellent BMPs, providing a “push from behind,” and the attractive effects of netrin-1 and sonic hedgehog from the ventral midline. Just as important, these axons are insensitive to midline repellents, which allows them to enter and cross the midline; this is achieved in part by Robo3, expressed on the axons

before crossing, which prevents them from sensing repellent midline slits. Upon reaching the midline, the axons acquire responsiveness to the repellent molecules, including slits, through upregulation of the function of repellent receptors, including Robo receptors for midline slits. They concomitantly lose responsiveness to the midline attractants. The coordinated switch from attraction to repulsion ensures that the axons can move on from the midline. Finally, the precise positioning of the axons in axon tracts after midline crossing involves a code of Robo proteins, and the anterior turn is directed by a Wnt gradient.

# Target Selection, Topographic Maps, and Synapse Formation

A fundamental issue in neurobiology is defining the mechanisms by which neurons recognize and innervate their targets. The formation of a proper functioning nervous system depends on the development of precise connectivity between appropriate sets of neurons or neurons with peripheral targets such as muscles, tendons, skin, and various organs. The development of appropriate synaptic connections requires a series of steps including the specification and generation of neurons and their target cells (Chapters 14, 15, and 16), the guidance of axons to their targets (Chapter 17), the selection of appropriate targets, the formation of orderly specific projections within the target, and ultimately the induction of a specialized presynaptic terminal and postsynaptic membrane (this chapter). The first section of this chapter will focus on the mechanisms and molecules that govern target selection by cortical and retinal axons, and the formation of topographically ordered connections. The second section will focus on the signaling molecules and mechanisms that induce presynaptic and postsynaptic differentiation at the neuromuscular synapse. The third section will summarize current views of how presynaptic and postsynaptic differentiation is initiated in the central nervous system (CNS).

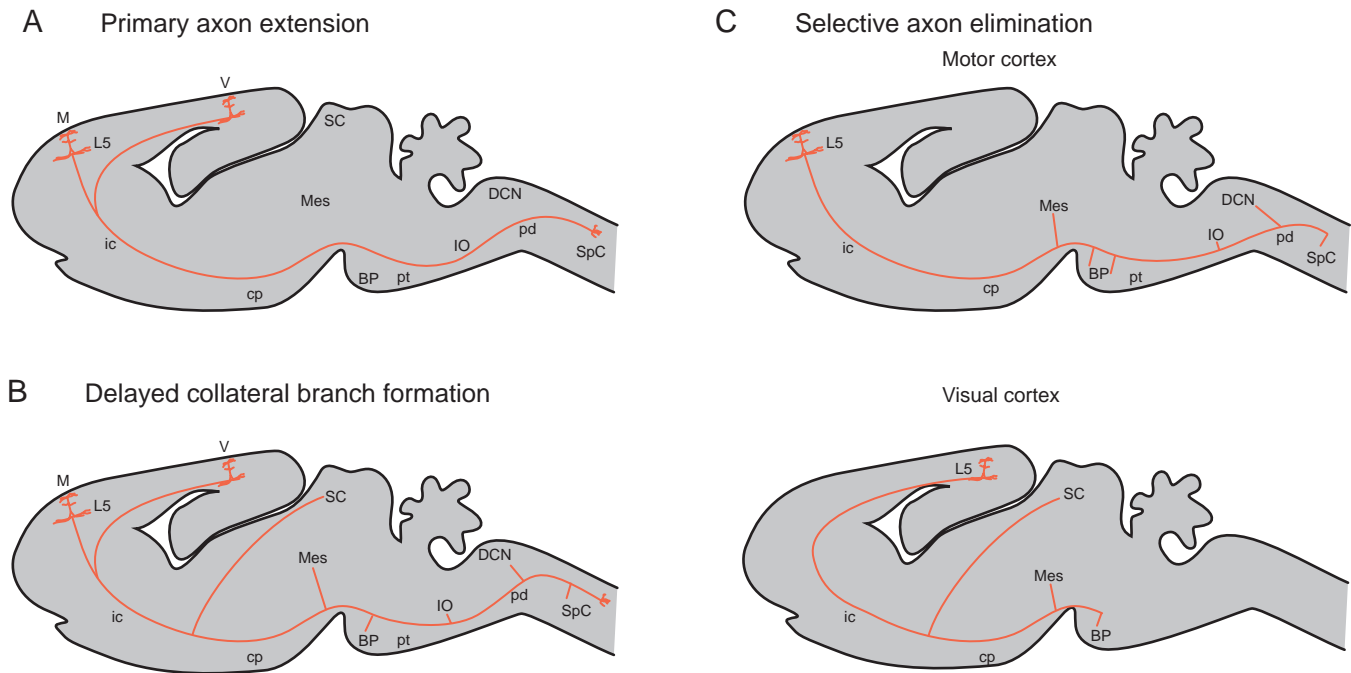

## TARGET SELECTION

### Target Selection by Delayed Interstitial Axon Branching

As discussed in Chapter 17, the growth cone makes navigational decisions in response to axon guidance molecules. This process of pathfinding by the growth

cone is crucial to bring the axon within the vicinity of its targets. The growth cone has also long been considered to be responsible for the process of target selection itself. In some vertebrate systems, and especially in many of the projections studied in *Drosophila* and other invertebrates, the growth cone tipping the primary axon does ultimately select its target. Many neurons, though, in the vertebrate brain innervate multiple, widely separated targets by axon collaterals, and therefore face a unique problem of target selection during development. It has now become clear that in these situations, the process of target selection is accomplished by a distinct mechanism, often referred to as *interstitial axon branching*, a phenomenon first described as a targeting mechanism by Dennis O'Leary and colleagues in mid-late 1980s.

A prominent example of neurons that employ delayed interstitial branching as a mechanism of target selection is layer 5 neurons in the mammalian neocortex (Fig. 18.1). Layer 5 neurons form the major output projection of the cortex and establish connections with several targets in the midbrain, hindbrain, and spinal cord. Studies by O'Leary and colleagues show that during development, layer 5 axons extend out of the cortex along a spinally-directed pathway; their growth cones ignore several potential targets as they grow past them and continue to extend caudally through the corticospinal tract. Axon collaterals extended by layer 5 axons later innervate the brainstem and spinal targets. One of the major brainstem targets is the basilar pons, a prominent nucleus that lies at the ventral surface of the anterior hindbrain, and is particularly well suited for studying this mechanism of target selection. Evidence obtained from the examination of fixed tissue sections suggests that the collaterals to the basilar pons, as well as to the other subcortical targets of layer

**FIGURE 18.1** Area-specific subcortical projections of layer 5 neurons of the neocortex develop by delayed interstitial branching and selective axon elimination. The three main phases of this mechanism is illustrated in schematics of a sagittal view of the developing rat brain. (A) Primary axon extension: Layer 5 neurons (L5) extend a primary axon out of the cortex along a pathway that directs them toward the spinal cord (SpC) passing by their subcortical targets. (B) Delayed collateral branch formation: Subcortical targets are later contacted exclusively by axon collaterals that develop by a delayed extension of collateral branches interstitially along the spinally-directed primary axon. As a population, layer 5 neurons in all areas of rat neocortex develop branches to a common set of targets. (C) Selective axon elimination: As illustrated for visual and motor cortex, specific collateral branches or segments of the primary axon are selectively eliminated to generate the mature projections functionally appropriate for the area of neocortex in which the layer 5 neuron is located. Abbreviations: BP, basilar pons; cp, cerebral peduncle; DCN, dorsal column nuclei; ic, internal capsule; M, motor cortex; Mes, mesencephalon; pd, pyramidal decussation; pt, pyramidal tract; SC, superior colliculus; V, visual cortex. Adapted from O'Leary and Koester (1993).

5 axons, develop by a delayed interstitial branching from the axon shaft millimeters behind the growth cone, often days after the parent axons have grown past the target. Time-lapse imaging in hemi-brain slice preparations from neonatal mice has provided further evidence that the branches form *de novo* along the portion of the axon shaft overlying the target. Evidence from collagen gel assays suggests that the target releases a diffusible activity with chemoattractant properties that induces branching along layer 5 axons, and directs the branches into the target. Thus, the axon shaft millimeters behind the growth cone is actively involved in target selection.

Examples of interstitial branching as the primary mechanism of target selection in vertebrates are accumulating. These examples include the extensive analysis by Katherine Kalil and coworkers on the development of cortical callosal projections, as well as development of axonal projections from the hippocampal formation (i.e., the subiculum) to the mammillary bodies, dorsal root ganglion neurons to the spinal gray matter, the innervation of the cortical plate by thalamic axons and

of the dorsal lateral geniculate nucleus by retinal axons. In addition, as discussed later, the formation of topographic connections by retinal axons in the optic tectum of chicks and superior colliculus of rodents also occurs by interstitial branching along the axon shaft.

### Exuberant Axonal Connections and Collateral Elimination

The development of many axonal projections in the brain is characterized by an initially exuberant, or widespread, growth of axons, followed by the elimination of functionally inappropriate axon segments and branches. For example, this mechanism is used to generate the adult patterns of callosal, intracortical, and subcortical projections of the mammalian neocortex (O'Leary and Koester, 1993). In the adult cortex, neurons that send an axon through the midline corpus callosum to the opposite cortical hemisphere, termed callosal neurons, have a limited, discontinuous distribution. Giorgio Innocenti and colleagues were the first to show that the limited adult distribution of callosal

neurons emerges from an early widespread, continuous distribution of cortical neurons that send an axon through the corpus callosum. Subsequently, Innocenti, O'Leary, and others used fluorescent retrograde tracers as fate markers to show that the developmental restriction in the distribution of callosal neurons is due to the loss of callosal axons rather than to the death of the parent neurons, which maintain an ipsilateral cortical connection. Collateral elimination also has been implicated in establishing the mature connections between cortical areas in the same hemisphere and in the refinement of horizontal connections within an area. For example, in adult visual cortex, layer 2/3 neurons have discrete horizontal projections to groups of other layer 2/3 cells with similar receptive field properties. However, Larry Katz and others have shown that the initial axonal outgrowth from layer 2/3 cells is very widespread in the horizontal plane, and the mature pattern of connections emerges in part through collateral elimination.

The organization of the adult neocortex into functionally specialized areas requires that each area establishes projections to specific subsets of targets in the brainstem and spinal cord. During development, though, layer 5 neurons project more broadly, and form collateral projections to a larger set of layer 5 targets than they will retain in the adult (Fig. 18.1). The functionally appropriate patterns of layer 5 projections characteristic of the adult later are pruned from this initial widespread pattern through selective axon elimination. Depending upon the cortical area in which the layer 5 neuron is located, it will eliminate different subsets of the initial complement of branched projections, and retain only those that are functionally appropriate. For example, layer 5 neurons in motor cortex lose their collateral branch to the superior colliculus, but retain branches to other targets including the basilar pons, inferior olive, dorsal column nuclei, and spinal gray matter. In contrast, layer 5 neurons in visual cortex lose the entire segment of their primary axon and its branches caudal to the basilar pons, and retain branches to the pons and superior colliculus. Although functionally inappropriate for the proper operation of the adult brain, the eliminated collateral branches or axon segments should not be viewed as projection errors, since they seem to be elaborated according to a specific axonal growth program characteristic of that general class of neuron.

The cellular mechanisms that control axon elimination and the final patterning of cortical projections are not well understood. In general, axon elimination occurs through one of two distinct phenomena that relate to the scale of the event: small-scale elimination typically occurs by retraction, whereas large-scale

elimination, as discussed earlier for layer 5 axon patterning, relies primarily on degeneration, which is similar in appearance to Wallerian degeneration but is mechanistically distinct (Hoopfer *et al.*, 2006). The triggers and selection process are also poorly understood, but the available evidence for large-scale cortical pruning indicates a role for neural activity, specifically the sensory information being relayed by thalamocortical input. In contrast, the elimination of callosal axons is perturbed by a variety of peripheral manipulations of either visual or somatosensory input, that alters either patterns of neural activity (e.g., strabismus) or absolute levels of activity (e.g., dark-rearing, eyelid suture, or silencing of retinal activity with the sodium channel blocker, tetrodotoxin). In these instances, callosal axon elimination is abnormal, resulting in the retention of callosal connections in parts of cortex that would normally lose them. Similar findings have been obtained for the development of layer 2/3 horizontal connections. Thus sensory input plays an important role in developing the adult pattern of callosal and intracortical connections by influencing the pattern of axon elimination.

Heterotopic transplant experiments by O'Leary and Brent Stanfield show that collateral elimination by layer 5 neurons is also plastic during development. Developing layer 5 neurons transplanted from visual cortex to motor cortex permanently retain their normally transient spinal axon, whereas layer 5 neurons transplanted from motor cortex to visual cortex lose their normally permanent spinal axon and retain their transient axon collateral to the superior colliculus. Thus, the projections retained by the transplanted layer 5 neurons are appropriate for the cortical area in which the transplanted neurons develop, not where they were born.

## Summary

Most projections in the vertebrate brain are formed by the mechanism of delayed interstitial branching along the length of the axon shaft rather than by direct axon targeting. During development, neurons often project to more targets than in the adult, and generate their adult pattern of connections through a process of selective axon or collateral elimination. This developmental phenomenon of transiently "exuberant" axonal projections may provide a substrate for developmental plasticity. For example, alterations in axon elimination may be a source of functional sparing or recovery following neural insults during development. In addition, this mechanism may contribute to differences between species in axonal connections as suggested by studies of the projection from the subiculum to the

**FIGURE 18.2 Development of topographic order in the retinotectal projection of model species.** (A) Photographs, at critical ages during topographic map formation, of the primary model systems currently used for the examination of retinocollicular/retinotectal map development. All photographs are at the same scale. The mouse superior colliculus (SC), on the dorsal surface of the midbrain (bracket denotes size), is approximately as large as an entire developing zebrafish and the chick optic tectum (ot) is approximately the size of an entire *Xenopus* tadpole at these ages. The *Xenopus* and zebrafish optic tectum sizes are denoted by the small white bars adjacent to the brain. The mouse and zebrafish are used commonly for the potential genetic manipulations available in these organisms. Chick and *Xenopus* are especially useful for overexpression, misexpression, and knock-down studies. Retinal ganglion cells from these organisms can be cultured and manipulated *in vitro*. (B and C) Mechanisms and molecules controlling retinotopic mapping in (B) mouse and chick and (C) frogs and zebrafish. The names and distributions of molecules and activities demonstrated *in vivo* to control, in part, the mapping mechanisms used at each stage are listed. The gradients may represent the consensus distribution for a combination of related molecules (i.e., EphAs), which are not listed individually due to distinctions in the individual members expressed and the precise distributions between species. Molecules and activities other than those listed are likely to participate in topographic mapping. (B) In mouse and chick RGC axons originating from a small focal retinal site enter the OT/SC over a broad L-M extent and significantly overshoot their future termination zone (TZ, circle). Interstitial branches form *de novo* from the axon shaft well behind the primary growth cone; their formation is topographically biased for the anterior-posterior (A-P) position of the future TZ. Branches are directed along the lateral-medial (L-M) axis of the OT/SC toward the position of the future TZ, where they arborize in a domain encompassing the forming TZ. The broad, loose array of arbors is refined to a dense TZ in the topographically appropriate location. (C) In frogs and fish the RGC growth cone extends to the TZ where it forms a terminal arbor through a process of backbranching from the base of the primary growth cone. The tectum expands as terminal arborizations elaborate and refine into a mature TZ. (2003). *Current Opinion in Neurobiology*.

mammillary bodies in mammals ranging from rodents to rabbits to elephants (O'Leary, 1992).

## Topographic Map Development

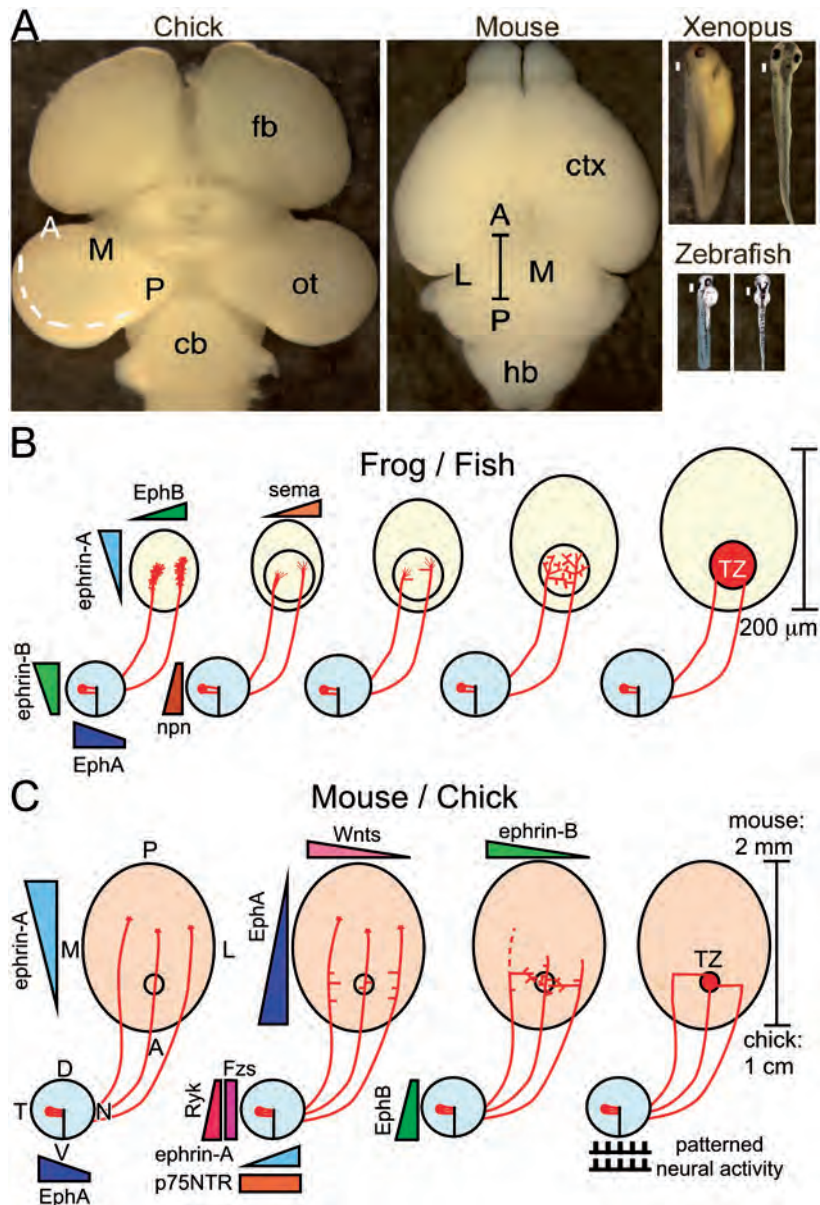

Once axons reach their targets, they must select appropriate target cells with which to form synaptic connections. Many axonal projections within the brain establish an orderly arrangement of connections within their target field, termed a topographic map. These maps are arranged such that the spatial order of the cells of origin is reflected in the order of their axon terminations, thereby neighboring cells project to neighboring parts of the target to form a smooth and continuous map. Topographic projections are especially evident in sensory systems, such as the somatosensory and visual. In the somatosensory system, a map of the sensory receptors distributed on the body is reiterated multiple times at various levels of the neuraxis. In the visual system, the main objective is to represent the visual world in the brain; that is, to reconstruct a topographic representation of the visual world that projects onto the retina and is remapped multiple times in the brain, initially through direct retinal projections to the dorsal thalamus and midbrain, and subsequently by higher order projections. This precise mapping requires the maintenance of the spatial ordering of the axons of retinal ganglion cells (RGCs) within their central targets in a pattern that reflects their origins in the retina. The projection from the retina to its major midbrain target, the superior colliculus (SC) of mammals, or its nonmammalian homologue, the optic tectum (OT), has been the predominant model system for studying the mechanisms that account for the development of topographic axonal connections. The relative size of the OT and SC

in the species predominantly used as models to study the development of topographic maps is shown in Figure 18.2A.

A large body of evidence developed over the past 50 years has shown that the target presents guidance information to incoming axons that controls their development of topographic connections. This work has culminated in the discovery of topographic guidance molecules over the past decade. Further, the development of a fully refined map requires activity-dependent mechanisms that are influenced by retinal waves that correlate the patterns of spiking activity between neighboring RGCs. These molecules and mechanisms will be discussed in detail in the following sections and placed into a historical context.

## The Chemoaffinity Hypothesis

The mechanisms that control the establishment of topographic maps have been intensively studied for many decades, but only in recent years has the molecular control of this process begun to be defined. The chemoaffinity hypothesis, formally proposed by Roger Sperry over 40 years ago (Sperry, 1963), has been a driving force in the field. Sperry designed clever experiments to address earlier theories such as that of Weiss, which posited that the specificity of neuronal connections in an adult resulted from the "functional molding" of circuits formed more or less at random; connections that are functionally appropriate are retained and the others are eliminated. Sperry studied the regeneration of the retinotectal projection in newts and frogs; in these amphibians, unlike in birds or mammals, cut RGC axons are capable of regenerating to reestablish functional connections with target

neurons in the tectum. In one particularly conclusive experiment, Sperry cut the optic nerve, rotated the eye in its orbit by  $180^\circ$ , and allowed the RGC axons to regrow to the tectum. According to earlier theories, one would predict that the axons eventually should form a novel pattern of connections that could generate appropriate behavioral responses to visual stimuli. Instead, Sperry showed that the frogs behaved as if their visual world had been rotated  $180^\circ$ . For instance, when a fly was presented in the upper left-hand quadrant of the visual field of the rotated eye, the frog responded by diving down to the right. This inappropriate response was retained throughout the frog's life, even after attempts to train the animals to compensate

for the rotation. These findings suggested that the regenerated RGC axons had reestablished their original pattern of connections, which was subsequently confirmed by Sperry and others using anatomical and electrophysiological analyses. These findings provided experimental evidence inconsistent with the prevailing theories of the time that the adult pattern of axonal connections is established by the selective retention of functionally appropriate connections, and eventually led to Sperry's chemoaffinity hypothesis.

Sperry proposed that molecular tags on projecting axons and their target cells determine the specificity of axonal connections within a neural map. Further, he suggested that these molecular tags might establish

topography through their distribution in complementary gradients that mark corresponding points in both sensory and target structures. The representation of the retina onto the tectum (or SC) typically is simplified to the mapping of two sets of orthogonally-oriented axes: the temporal (T)-nasal (N) axis of the retina along the anterior (A)-posterior (P) axis of the tectum, and the ventral (V)-dorsal (D) axis of the retina along the medial (M)-lateral (L) axis (also referred to as the D-V axis) of the tectum. Based on the chemoaffinity hypothesis, each point in the tectum would have a unique molecular address determined by the graded distribution of topographic guidance molecules along the two tectal axes, and similarly each RGC would have a unique profile of receptors for those molecules that would result in a position-dependent, differential response to them by RGC axons.

Over the next half century, the specificity of the projections of RGC axons to tectal cells was investigated further by the tracing of axonal projections following experimental manipulations, first in the regenerating retinotectal system and later during the development of the projection. The manipulations included rotations or transplantations of the retina, tectum, and even the optic pathway, using either the whole structure or parts of it. These experiments showed that regenerating and developing RGC axons formed topographically appropriate connections even when they are experimentally deflected within the tectum, or forced to enter the tectum from abnormal positions or with a reversal in the relative time of arrival of populations of RGC axons. Studies of this sort done by Bill Harris and Christine Holt were particularly compelling, and provided a body of evidence supporting the basic tenet of the chemoaffinity hypothesis that the establishment of topographic projections involves the recognition of positional information on the tectum.

Prior to the discovery of the ephrins (described later), the most compelling evidence for topographic guidance molecules came from the work of Friedrich Bonhoeffer and coworkers using several elegant *in vitro* assays, for example the membrane stripe assay, as well as the growth cone collapse assay codeveloped by Jonathon Raper. Using the membrane stripe assay, Bonhoeffer showed that chick temporal RGC axons given a choice between growing on alternating lanes of anterior and posterior tectal membranes, show a strong preference to grow on their topographically appropriate anterior membranes, whereas nasal RGC axons exhibit no preference (Fig. 18.3). A critical finding was that the growth preference of temporal axons was not due to an attractant or growth-promoting activity associated with anterior tectal membranes, but instead to a repellent activity associated with posterior tectal membranes. This was the first demonstration of a role for repellent activities in axon guidance. By taking advantage of the finding that posterior tectal membranes also preferentially collapse the growth cones of temporal axons, the repellent activity was biochemically isolated to a 33kDa, GPI-anchored protein referred to as RGM (Repulsive Guidance Molecule). An interesting twist is that the search for RGM led to the cloning of ephrin-A5 (described later), and only several years after that was RGM itself cloned. However, mice with a targeted deletion of RGM1, one of the members of the RGM family, do not exhibit significant mapping defects in the retinocollicular projection.

### Axonal Behaviors during Development of Topographic Maps and Their Implications for Actions of Topographic Guidance Molecules

Following the pioneering work of Sperry and Bonhoeffer, two major sets of events directly led to the

**FIGURE 18.3** Repellent effects of ephrin-As on retinal axons *in vitro*. (A, B) Summary of use of the membrane stripe assay to analyze the effects of membrane-associated molecules in the optic tectum, such as the ephrin-A ligands, on the guidance of retinal ganglion cell (RGC) axons. This elegant *in vitro* assay, developed by Friedrich Bonhoeffer, has been used extensively by many investigators to characterize repellent versus attractant effects of membrane-associated molecules on axon guidance. A retinal strip oriented along the nasal-temporal axis is explanted on carpets consisting of alternating 90  $\mu\text{m}$  wide lanes of membranes derived from the anterior (A) or posterior (P) third of the tectum, or from heterologous cell lines (e.g., Cos or 293T cells) mock-transfected or transfected with *ephrin-A2* or *ephrin-A5* cDNA. RGC axons growing out of the temporal half of the retinal strip show a strong preference to grow on anterior tectal membranes, whereas those growing out of the nasal half show no preference. In contrast, temporal axons do not show a preference for anterior membranes when posterior membranes are pretreated with heat or proteases, indicating that the preference is due to a repellent in posterior membranes. ephrin-A2 and ephrin-A5 are candidate mediators of this repellent activity, since they are enriched in posterior membranes and repel retinal axons in the stripe assay. Adapted from O'Leary *et al.* (1999). (C, D) Examples of RGC growth preferences in the stripe assay. The lanes containing *ephrin-A2* or *ephrin-A5* transfected cell membranes are labeled with rhodamine isothiocyanate (RITC) fluorescent beads, visualized as red lanes in the lower part of each panel. Temporal RGC axons grow predominantly on membranes from mock transfected cells, while nasal RGCs axons grow equally well on membranes from ephrin-A and mock transfected cells. These growth preferences exhibit an abrupt transition at mid-retina on *ephrin-A2* transfected membranes, similar to the preferences observed on anterior and posterior tectal membranes, and in contrast to the more gradual transition in growth preferences observed on *ephrin-A5* transfected membranes. Adapted from Monschau *et al.* (1997).

current understanding of the development of retinotopic maps. One was the major breakthrough toward understanding the molecular control of topographic mapping that came in the mid-1990s with the cloning of two closely related genes, ephrin-A2 (originally called Eph Ligand Family-1, or ELF-1) by John Flanagan and colleagues, and ephrin-A5 (originally called Repulsive Axon Guidance Signal, or RAGS) by Bonhoeffer, Uwe Drescher, and colleagues. These proteins, like all members of the ephrin-A family, are anchored to the cell membrane by a GPI-linkage and bind with similar affinities and activate the same receptors, members of the EphA subfamily of receptor tyrosine kinases (Fig. 18.4). As discussed in the following sections, these proteins are prominent players in topographic mapping.

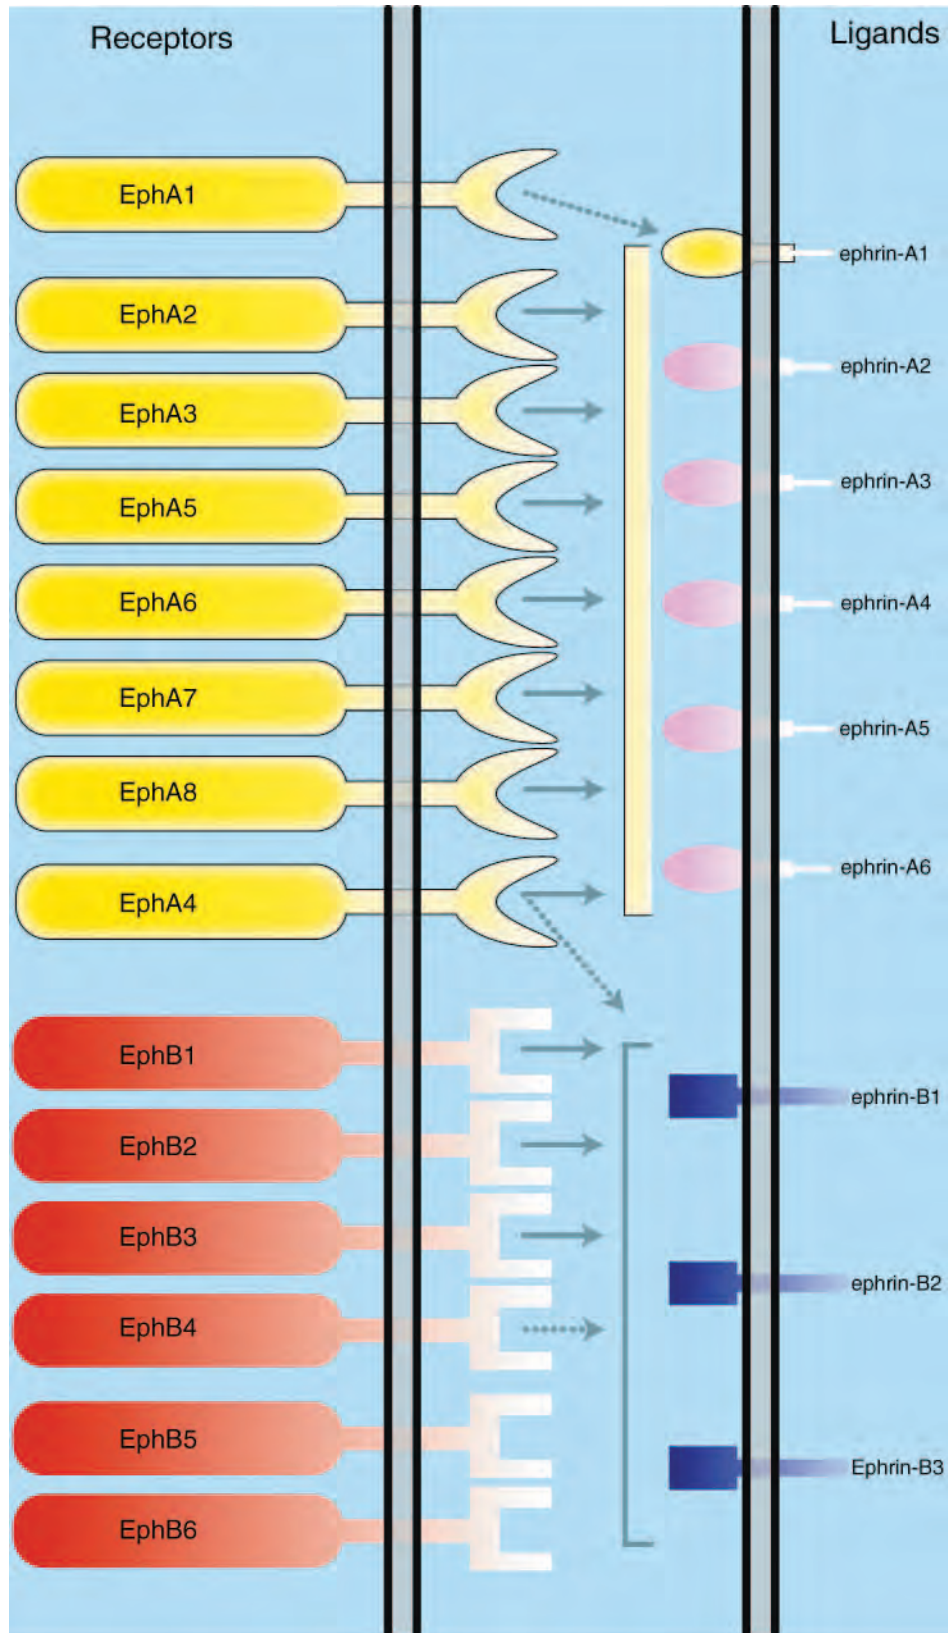

The other major set of events was the result of the introduction of high resolution axon tracers, the lipophilic fluorescent dyes DiI and DiO (and subsequently related molecules such as DiA and DiD), in the late 1980s that allowed for the first time detailed analyses of the morphologies and behaviors exhibited by RGC axons in chicks and rodents as they form topographically ordered projections. This was important for several reasons, including that it allowed for the analysis of chicks and mice, which was critical to take advantage of genetic manipulations, and showed that interstitial axon branching was a key mechanism of map development in warm-blooded vertebrates. Prior to this work, the behavior of RGC axons during map development was based largely upon the studies of amphibians and fish done by many investigators, including Hollis Cline, Martha Constantine-Paton, Scott Fraser, Haijme Fujisawa, Bill Harris, Christine Holt, and Claudia Stuermer. Among the reasons for the initial focus on fish and amphibians is that they were already widely used for studies of retinotopic mapping because of their ability to regenerate retinal connections, the relative ease with which their visual systems could be experimentally studied, but most importantly, preexisting axon tracers (e.g., HRP, cobalt chloride) provided high resolution labeling of RGC

axons in these cold-blooded animals although these and other available tracers did not in developing chicks and rodents. Numerous studies in frogs and fish concluded that topographic retinotectal connections develop by the direct topographic targeting of RGC axon growth cones (Fig. 18.2B); therefore, similar mechanisms were assumed to account for mapping in other vertebrates. These findings and assumptions led to models of mapping and roles for topographic guidance molecules, such as the ephrin-As, to account for a mechanism of direct topographic targeting of the primary growth cone.

Studies by O'Leary and colleagues using the new age high resolution lipophilic tracers, DiI and related compounds, revealed an unexpected and unique picture of the development of topographic retinotectal projections in warm-blooded animals, which in turn required a substantial reassessment of the mechanisms of mapping and roles for topographic guidance molecules in controlling them. They showed that development of retinotectal topography in chicks, rats, and mice is a multistep process that involves axon overshoot of the topographically correct position of the termination zone along the A-P axis of the target followed by topographically appropriate interstitial branching along the axon shaft.

As schematized in Figure 18.2C, in chicks and mice, RGC axons originating from a focal site in the retina enter the chick OT and mouse SC at its anterior edge with an aberrantly broad distribution along its L-M axis, with a peak in their distribution centered on the location of the future termination zone. The axons extend posteriorly across the OT/SC well past the topographically appropriate site for their termination; during this process they form branches *de novo* interstitially from the axon shaft hundreds of microns or even millimeters behind the primary growth cone. Interstitial branching exhibits a significant degree of topographic specificity along the A-P axis, with the highest percentage of branches found near the A-P position of the future termination zone (Yates *et al.*, 2001). The interstitial branches form roughly perpen-

**FIGURE 18.4 Eph and ephrin families.** Eph receptors comprise the largest family of receptor tyrosine kinases, currently numbering 15 members, and are divided into two subfamilies, EphA (A1 to A9; EphA9 is not depicted) and EphB (B1 to B6) with distinct binding specificities that correlate with structural similarities. The nine known ephrins are divided into the ephrin-A (A1–A6) and ephrin-B (B1–B3) subfamilies on the basis of sequence homology and their membrane anchoring: ephrin-As are anchored by a glycosyl phosphatidylinositol (GPI) linkage, and the ephrin-Bs by a transmembrane domain. Within each receptor-ligand subfamily, the ligands bind, albeit with different affinities, and activate, with few exceptions (EphB5 and EphB6), all the receptors, but only very limited interaction occurs between subfamilies (for example, EphA4 interacts with ephrin-As and two ephrin-B proteins; dashed lines indicate relatively weak interactions). Although membrane-anchored ephrins activate Eph receptors, soluble forms of an ephrin can do so only when artificially clustered. Clustered ligand binding results in the formation of receptor multimers and activates the catalytic kinase domain on the cytoplasmic portion of the Eph receptor. In addition, the ephrin-B ligands themselves can also transduce signals; thus receptor-ligand binding can result in bidirectional signaling into the receptor-expressing and ligand-expressing cells. Recent evidence suggests that the ephrin-A ligands are also capable of bidirectional signaling.

dicular to the primary axon shaft and preferentially extend along the L-M axis to their future termination zone where they go on to arborize. These interstitial branches are the exclusive means by which RGCs form permanent, topographically ordered connections (Yates *et al.*, 2001). This mechanism of map development results in an initial map that is very coarse. In mice, for example, these features result in RGC axons originating from a focal source in the retina covering virtually the entire SC at perinatal ages (Fig. 18.8A). The refined topography characteristic of the mature projection finally is achieved through the preferential arborization of appropriately positioned branches and the elimination of the overshooting segments of the primary axons and any ectopic branches and arbors (Fig. 18.8A–C). These analyses of topographic mapping of RGC axons in chicks and mice indicate that a primary role for topographic guidance molecules is to regulate topographic branching along RGC axons, and guide the branches to the correct site in the target: processes that impose unique requirements on the molecular control of map development (Yates *et al.*, 2001).

### Role for Ephrin-A/EphA Forward Signaling in A-P Mapping

Since the discovery of ephrin-As in the mid-1990s, six ephrin-As have been identified, as well as nine EphA receptors (Fig. 18.4). Figure 18.5 illustrates the ephrin-As and EphAs that are expressed by RGCs and in the OT/SC in chicks and mice, as well as an approximation of their expression patterns. In both chicks and mice, multiple ephrin-As are expressed in the OT/SC, but together they form a low-to-high A-P gradient. In addition, RGCs express multiple EphAs that together form a high-to-low T-N gradient of expression.

In chick, ephrin-A2 is expressed in an increasing A-P gradient across the entire OT, and ephrin-A5 is expressed in a steeper A-P gradient largely limited to posterior OT; together they combine to form an increasing gradient of ephrin-As across the A-P axis. RGCs express EphA3, EphA4, and EphA5, but only EphA3 is expressed in a gradient, which is highest in temporal retina and lowest in nasal retina. Because temporal retina with high levels of EphA3 maps to anterior OT with low levels of ephrin-As, and vice versa, ephrin-A2 and ephrin-A5 were predicted to act as axon repellents that more strongly affect temporal axons than nasal axons. This suggestion has been confirmed by *in vitro* and *in vivo* studies (Nakamoto *et al.*, 1996; Monschau *et al.*, 1997). Experiments employing membrane stripe and growth cone collapse assays using membranes from transfected cell lines show that both ephrin-A2 and ephrin-A5 preferentially repel tempo-

ral axons, and that at the appropriate concentrations, retinal axons exhibit a graded temporal-to-nasal response to ephrin-A5 (Fig. 18.3). *In vivo*, temporal axons specifically avoid ectopic patches of ephrin-A2 that were overexpressed in anterior OT following infection with recombinant retrovirus. These studies suggest that the interaction of EphA3 with ephrin-A2 and ephrin-A5 could determine the specificity of RGC projections along the A-P tectal axis.

Although species-specific differences are apparent in the particular EphAs and ephrin-As that are expressed, or in their patterns of expression (Fig. 18.5), the basic theme just described for chicks is constant across all vertebrate species examined. For example, as in chick tectum, ephrin-A2 and ephrin-A5 combine to form a smooth increasing A-P gradient in the mouse SC. However, their pattern of expression in the SC differs substantially from chick tectum: ephrin-A5 is expressed in an increasing A-P gradient across the SC, resembling ephrin-A2 in chick tectum, whereas ephrin-A2 is expressed at high levels in a broad domain centered on mid-posterior SC and shows a graded decline to low or no expression in the anterior third and far-posterior SC (Fig. 18.6). The expression of EphA receptors by RGCs also differs between chick and mouse. In mouse, EphA3 is not expressed by RGCs, EphA4 is expressed uniformly, and both EphA5 and EphA6 are expressed in a high temporal to low nasal gradient.

The graded expression of ephrin-As and their differential repulsion of temporal versus nasal RGC axons strongly implicated them as topographic guidance molecules. The first genetic test of whether they are required for proper topographic mapping came from an analysis of mice with a targeted deletion of ephrin-A5 (Frisen *et al.*, 1998) (Fig. 18.6). The mapping of RGC axons in the SC of ephrin-A5 null mice is topographically aberrant in a manner consistent with the loss of ephrin-A5 and the maintained expression of ephrin-A2. For example, temporal RGC axons form ectopic projections to far-posterior SC and within the anterior third of the SC. As expected, topographic mapping defects in ephrin-A2/A5 double knockout mice are more severe than in either ephrin-A single knockout (Feldheim *et al.*, 2000). Surprisingly, though, in ephrin-A2/A5 double knockout mice, temporal RGC axons form a termination zone, albeit smaller, in anterior SC at approximately the correct position, suggesting the action of other molecules or mechanisms. This led to the finding that ephrin-A3 also is expressed in the mouse SC, although at low levels uniformly across its A-P axis. Mice with a triple knockout of ephrin-A2, -A3, and -A5 exhibit a near complete loss of topography. When this ephrin-A triple knockout is combined with mice that lack patterned RGC activity (see follow-

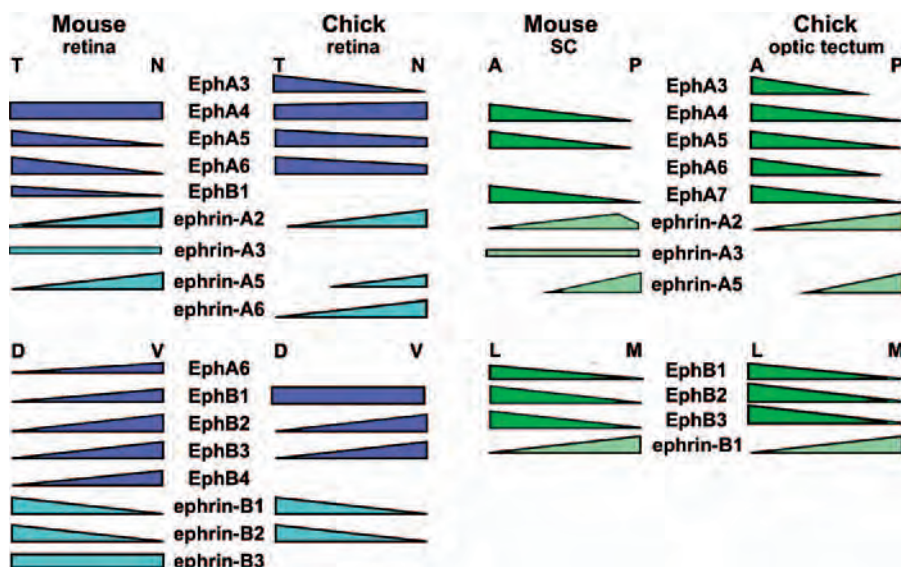

FIGURE 18.5 Distribution of Ephs and ephrins in the retina and optic tectum/superior colliculus (OT/SC) of chick and mouse. The table represents generalized patterns for individual Ephs and ephrins in the retina and OT/SC during critical stages in the development of the retinotopic map (E15-P7 in mouse and E6-E14 in chick). The chart is likely incomplete and the distributions for several molecules is dynamic during development. The sizes and shapes of the gradients are generalized and relative expression levels should not be inferred. ing section), topography is essentially completely lost (Pfeiffenberger *et al.*, 2006).

Although it is well established that ephrin-As mediate the repulsion of RGC axons by forward signaling through EphA receptors, genetic studies showing roles for EphAs have been few. Mice with a targeted deletion of EphA5 have mapping defects consistent with it mediating a repellent activity through forward signaling. A particularly intriguing study of EphA function was a gain-of-function strategy that took advantage of the features that ephrin-As bind and activate with similar efficacy most EphA receptors, and that EphA3 is not expressed by RGCs in mice. Mice were generated in which EphA3 was ectopically expressed in about half of the RGCs uniformly distributed across the retina, thus producing two subpopulations of RGCs, one which has the wild-type gradient of EphA receptors (EphA5 and EphA6), and one with an elevated gradient of overall EphA expression (Brown *et al.*, 2000). In these mice, the projection of the EphA3 RGCs is compressed to the anterior half of the SC, indicating that the level of EphA receptor dictates the degree to which an RGC axon is repelled by ephrin-As. Surprisingly, though, the projection of the wild-type RGCs is compressed to the posterior half of the SC, and is likely excluded from the anterior SC by competitive interactions with the EphA3 RGCs. Thus, the mapping of the two RGC subpopulations is not determined solely by the absolute level of EphA recep-

tor signaling, but instead is plastic and can be strongly influenced by the relative difference in EphA signaling. Importantly, these findings also reveal a hierarchy in the mechanisms for generating topographic maps, showing that molecular axon guidance information, such as that signaled by ephrin-As and EphAs, dominates over activity-dependent patterning mechanisms that are based on near neighbor relationships and correlated activity.

### Countergradients of Repellent Activities in A-P Mapping and Roles for Ephrin-A Reverse Signaling

Historically, models of topographic mapping have been based upon the action of molecular activities that promote axon growth. However, with Bonhoeffer's identification in the late 1980s of repellent activities concentrated in posterior chick OT that preferentially affect temporal RGC axons, it became clear that topographic mapping was controlled in a different fashion than previously recognized. These findings eventually resulted in the incorporation of repellent activities into models of topographic mapping, but until recently these models focused on guiding RGC axons to their correct TZ in the target. These models were based upon a gradient determined repulsion, in which an RGC axon would stop its growth when it reaches a threshold level of repulsion found at the AP position

**FIGURE 18.6 RGC projections in wild-type and *ephrin-A5* knockout mice related to the expression patterns of *ephrin-A5* and *ephrin-A2*.** (A, B) Anterograde DiI labeling of RGC axons from peripheral temporal retina in wild-type and *ephrin-A5* knockout mice. Dorsal views of whole mounts of the superior colliculus (SC) are shown; midline is to the right, dashed lines indicate the posterior SC border. (A) In wild-type mice, temporal RGC axons end and arborize in a densely labeled termination zone (TZ) in anterior SC. The RGC projection to optic tract nuclei is also evident (OT). (B) In *ephrin-A5* null mutant mice, temporal RGC axons also end and arborize in a densely labeled TZ at the topographically appropriate site in anterior SC, but in addition temporal axons project to and arborize at topographically inappropriate sites in posterior-most SC (e1) and anterior SC (e2). (C, D) Schematic representations summarizing temporal RGC axon mapping in wild-type and *ephrin-A5* mutant mice in relationship to the expression of *ephrin-A5* and *ephrin-A2*. (C) In wild-type mice, a focal DiI injection in peripheral temporal retina labels axons (red lines) that form a dense TZ (red oval) in the topographically correct anterior SC. *Ephrin-A5* (blue shading) is expressed in a low anterior (A) to high posterior (P) gradient across the SC. *Ephrin-A2* (orange shading) is expressed highest in mid-posterior parts of the SC, and declines to low levels in more anterior and far-posterior SC. Together, ephrin-A5 and ephrin-A2 form a smooth gradient of repellent activity across the SC. EphA receptors are expressed in a high temporal (T) to low nasal (N) gradient by RGCs. (D) In *ephrin-A5* mutant mice, *ephrin-A2* (orange shading) is expressed in the same pattern as in wild-type. A focal DiI injection in temporal retina labels axons that form a dense TZ in topographically correct anterior SC, but in addition, aberrant terminations (e1, e2) form at topographically incorrect locations. The pattern of ectopic arbors relates to the maintained expression pattern of *ephrin-A2*: ectopic arbors are typically present in far-posterior and anterior SC where *ephrin-A2* expression is low, but are rare in mid-SC where *ephrin-A2* expression is highest. This distribution suggests that in the absence of ephrin-A5, ectopic arbors are present where the levels of repellent activity due to ephrin-A2 are too low to prevent their formation and stabilization. Abbreviations: D, dorsal; L, lateral; M, medial; V, ventral. Adapted from Frisén *et al.* (1998). *Neuron*.

of the future TZ (Fig. 18.7). Although such models could explain retinotectal map development in amphibians and fish, they cannot account for aspects of map development along the A-P axis in chick OT and mouse SC, including the initial A-P overshoot of RGC axons and the subsequent topographic interstitial branching along RGC axons.

Models for A-P mapping in mouse SC and chick OT must explain the topographic bias in the formation of

interstitial branches, which arguably is the key feature of A-P map development in warm-blooded vertebrates. Such a model must be able to account for the paucity of branching both posterior and anterior to the appropriate A-P location of the termination zone along each axon. Models that in principle can account for topographic branching have been recently proposed; for example models based upon parallel gradients of a branch repellent (or inhibitory) activity and a branch

promoting activity (Fig. 18.7). However, the field has moved toward favoring a model based upon opposing gradients along the A-P axis, each of which inhibits branching. As described in the preceding section, the low-to-high A-P repellent gradient is due to EphA forward signaling, which acts to inhibit interstitial branching posterior to the correct termination zone along the A-P axis. Indeed, use of a modified membrane stripe assay shows that temporal axons preferentially branch on their topographically-appropriate anterior tectal membranes, and that this branching specificity is due to the inhibition of branching on posterior tectal membranes by ephrin-As.

Emerging evidence indicates that the opposing high-to-low A-P repellent gradient, which would serve to prevent branching anterior to the correct termination zone (Fig. 18.7), is due to ephrin-A reverse signaling. A key feature of the countergradients of ephrin-A/EphA mediated repellent activities is that EphAs and ephrin-As both are expressed by RGCs and in the OT/SC, and exhibit opposing gradients of expression along both the T-N retinal axis and the A-P OT/SC axis (Figs. 18.2, 18.5). Recent experimental data has shown that ephrin-As can reverse signal, and that this reverse signaling has a repellent effect on RGC axons. The critical findings, which come from the work of Uwe Drescher, show that RGC axons are repelled by EphA7 in the “Bonhoeffer” stripe assay, a repulsion blocked by ephrin-A5-fc that blocks EphA function, and that EphA7 knockout mice have retinocollicular mapping defects consistent with the loss of the high-to-low AP graded expression of EphA7 in the SC (EphA7 is not expressed by RGCs; Fig. 18.5). Thus, the low-to-high T-N gradient of ephrin-As on RGC axons and a high-to-low A-P gradient of EphAs expressed in the SC generates through reverse signaling a high-to-low A-P gradient of repellent activity.

Because ephrin-As are anchored to the cell membrane by a GPI linkage and lack an intracellular domain, to reverse signal they must associate with transmembrane proteins capable of activating intracellular signaling pathways. Such “coreceptors” that mediate the repellent effect of ephrin-A reverse signaling on RGC axons upon binding EphAs are being studied.

### **Molecular Control of Mapping along D-V (M-L) Axis of the Target**

As described previously, RGC axons enter the OT/SC with an aberrantly broad distribution along the L-M axis; topographic specificity along the L-M axis emerges

through the bidirectional guidance of interstitial branches that form along RGC axons with an A-P topographic bias (Fig. 18.2C). Branches that extend from RGC axons located lateral to their future termination zone grow medially whereas branches that extend from RGC axons located medial to their future termination zone grow laterally. Branches that reach the vicinity of the nascent termination zone selectively form complex arbors. Therefore, not only is the directed guidance of interstitial branches a critical feature for D-V retinotopic mapping, but the molecular mechanisms that control it must account for the bidirectional guidance of branches along the L-M axis of branches formed by RGC axons that have the same retinal origin, and presumably express the same set of receptors at similar levels.

Studies of the molecular control of D-V mapping in multiple species (chick, mouse, and frog) independently by the O’Leary and Holt labs have shown roles for EphBs and ephrin-Bs (Fig. 18.3), and that they exhibit bidirectional signaling (forward and reverse) as well as bifunctional action (acting as repellents and attractants). In addition, Wnts and their receptors also have been implicated in D-V mapping based on studies in chick. In retina, EphB receptors are expressed by RGCs during map development in an overall low-to-high D-V gradient, complemented by an overall high-to-low D-V gradient of ephrin-B1. In both chick OT and mouse SC, ephrin-B1 is expressed in a low-to-high L-M gradient, complemented by an overall high-to-low L-M EphB gradient (Figs. 18.2, 18.5). Analyses of mice with targeted deletions of EphB2 and EphB3, with and without reverse signaling intact, show aberrant L-M mapping due to defects in the guidance of interstitial branches (Hindges *et al.*, 2002). Other analyses show that for a given population of RGC axons, ephrin-B1 acts via EphB2/B3 forward signaling as a branch attractant at lower levels of ephrin-B1 expression and as a branch repellent at higher levels of expression (McLaughlin *et al.*, 2003a). Thus, an interstitial branch that forms lateral to its appropriate termination zone is attracted up the gradient of ephrin-B1 to its termination zone, whereas a branch located medial to its nascent termination zone is repelled down the ephrin-B1 gradient to its termination zone. The primary RGC axons are not influenced by ephrin-B1, but instead the effects of ephrin-B1 are specific to interstitial branches and is context dependent—the location of the branch on the ephrin-B1 gradient in relation to the location of its future termination zone and its EphB level determine its response (McLaughlin *et al.*, 2003a). In frogs, ephrin-B reverse signaling also has been implicated in retinotopic mapping (Mann *et al.*, 2002), but such a role has yet to be shown in mice and chicks.

**FIGURE 18.7 Actions and limitations of ephrin-As in retinotectal map development.** (A) The top panel schematizes the approximate gradient profiles for EphA receptors and ephrin-A ligands in the chick retina and optic tectum, respectively. RGCs show a high temporal (T) to low nasal (N) gradient of EphA receptor expression, due mainly to EphA3. Ephrin-A2 and ephrin-A5 combine to form a low anterior (A) to high posterior (P) gradient of expression across the tectum. Panels A1–A3 schematize observed and theoretical behaviors of RGC axons. Growth cones stop at A-P positions in the tectum where they reach a threshold level of repellent activation following a mass action law of receptor-ligand interactions. Temporal growth cones, which have high levels of EphA receptors, reach threshold levels of repellent at anterior (A) positions in the tectum, with low levels of ephrin-A ligand. Growth cones from nasal retina (N), which have low levels of EphA receptors, will reach threshold levels of activation at more posterior (P) positions in the tectum. This mechanism can account for the guidance of RGC growth cones to their topographically correct TZ, as is observed in amphibians and fish (A1), as well as the position-dependent overshoot of RGC axons, as observed in chicks (A2). However, a single repellent gradient, such as that formed by ephrin-A ligands in the tectum, alone is insufficient to generate topographic branching along RGC axons observed in chick (A2). The ephrin-As can inhibit branching along the segment of the overshooting axons posterior to their correct TZ, but anterior to the correct TZ, the level of ephrin-A repellent signal would be below the threshold required to inhibit branching. Thus, if only the tectal ephrin-As regulated branching, all RGC axons should exhibit increased branching at more anterior positions in the tectum, which have the lowest levels of ephrin-A repellent signal (A3). (B) Illustrated are two potential models, among many, that can account for topographic branching along RGC axons. Both models incorporate the graded ephrin-A repellent, and a distinct graded activity that cooperates with it to generate topographic branching. In each case, the ephrin-A repellent prevents branching along the axon shaft posterior to the TZ and the distinct graded activity regulates branching along axons anterior to their TZ. One model includes a distinct repellent in a gradient that opposes the ephrin-A gradient, and acts by inhibiting branching along the axon shaft anterior to the TZ. Thus, branching along the axon shaft occurs at an A-P tectal position below threshold for branch inhibition for both of the repellent signals. Recent findings have indicated that ephrin-A reverse signaling may account for the distinct opposing repellent gradient: ephrin-As expressed by RGCs are the “Distinct receptors” and EphAs expressed in the chick tectum, or mouse superior colliculus, are the “Distinct repellent ligands” depicted in panel B (see text for details). The other model includes a branch promoting activity in a gradient that roughly parallels the ephrin-A gradient. In this model, branching along the axon shaft occurs at an A-P tectal position above threshold for the branch promoting signal, but below threshold for branch inhibition by the ephrin-A repellent signal. Adapted from O’Leary, D. D. M., Yates, P., McLaughlin, T. *Cell* 96, 255–269.

In principle, EphBs and ephrin-B1 could account for D-V mapping through their actions as bifunctional and bidirectional topographic guidance molecules. However, Yimin Zhou has reported that Wnt signaling also is involved in D-V mapping (Schmitt *et al.*, 2006). Wnt3 is expressed in a high-to-low M-L gradient in chick OT and mouse SC, and Wnt receptors, Ryk and Frizzled family members, are expressed in an overall high-to-low V-D gradient by RGCs (Fig. 18.2). Functional studies show that Ryk mediates RGC axon repulsion by higher levels of Wnt3, whereas Frizzled receptors mediate an attractant effect of lower levels of Wnt3 on dorsal RGC axons. Thus, Wnt3, which is classically known as a secreted, diffusible signaling molecule, appears to act as a topographic guidance molecule in the OT and cooperate with EphB-ephrin-B1 to regulate D-V mapping.

### Role for Patterned Activity in Map Refinement

It is well established that neural activity plays an important role in the development of axonal connections in many neural systems including the segregation of RGC axons into eye-specific laminae in the lateral geniculate nucleus or eye-specific stripes in experimentally created three-eyed frogs (see Chapters 20 and 22). In addition, correlated activity has long been postulated to refine topographic connections by strengthening coordinated inputs and weakening

uncorrelated inputs. However, for the development of retinotopic projections, roles for neural activity appear to vary considerably depending upon the species. Among the first studies to address this issue were those done by Bill Harris, who homotopically transplanted axolotl eyes into the California newt, a species that produces endogenous tetrodotoxin (TTX), a neurotoxin that blocks Na<sup>+</sup> channels. The transplanted axolotl RGCs were silenced by the TTX, but their projection to the tectum developed an appropriately ordered topographic map.

Similarly, in other species in which the map develops by the direct topographic targeting of RGC axons, such as fish and frogs, activity blockade has little effect on topography. For example, RGC axonal arbors are reportedly unaffected in zebrafish bathed in either TTX or AP5, and blocking the NMDA class of glutamate receptors in *Xenopus* results only in a slowing of map development. Even in chicks and rats, in which the early retinotectal projection is topographically very diffuse, a considerable degree of order emerges under pharmacological activity blockade. In chick, TTX and grayanotoxin, which interfere with Na<sup>+</sup> currents, prevent the elimination of only a small proportion of overshooting axon segments and aberrant branches and arbors. Similarly, in rats, chronic application to the SC of AP5, an antagonist of the NMDA receptor, at levels that block the activation of SC neurons by RGCs (which use glutamate as their neurotransmitter), also results in the abnormal retention of only a small pro-

portion of topographically aberrant axons and arbors. These studies, though, have caveats associated with them, including questions about the effectiveness of the block and potential side effects of activity block on gene expression. However, recent analyses of mice lacking cholinergic-mediated retinal waves has circumvented these problems and show that correlated patterns of RGC activity are required for the large-scale remodeling of the retinocollicular projection into a refined map.

Interestingly, the large-scale remodeling of the retinocollicular projection required to generate refined topography in the mouse SC occurs well before the onset of visually evoked activity and eye opening. However, this remodeling is coincident with a period of correlated waves of spontaneous neural activity that propagate across the retina, a phenomenon first described by Carla Shatz. These waves are mediated by a network of cholinergic amacrine cells and correlate the activity of neighboring RGCs, thereby relating an RGC's position to its pattern of activity. Mice lacking the  $\beta 2$  subunit of the nicotinic acetylcholine receptor maintain normal levels of spontaneous activity, but the correlation in activity patterns among neighboring RGCs is lost. The topographic projection in  $\beta 2$  mutant mice fails to properly refine and RGC axons from a given retinal location do not form a dense termination zone but rather maintain a loose collection of diffuse arborizations around the appropriate location of their termination zone (Fig. 18.8) (McLaughlin *et al.*, 2003b). However, some remodeling does occur and may be driven by the same EphA-ephrin-A mediated repellent activities that establish the initial coarse map. In  $\beta 2$  mutant mice, correlated RGC activity does resume during the second postnatal week through a glutamatergic process, and patterned visually evoked activity begins soon thereafter, but neither process leads to proper map refinement, indicating a brief early critical period for activity-dependent map remodeling in the mouse retinocollicular projection (McLaughlin *et al.*, 2003b).

### Summary

The formation of topographic maps involves the establishment of an initial, coarse map that subsequently is refined. Analysis of the retinotectal system in amphibians, fish, birds, and mammals shows that the initial map is formed based on positional information present in the tectum. In birds and mammals, a critical mechanism in map development is the topographic specific branching of RGC axons that overshoot their correct termination zone. Topographic guidance information is encoded in the form of gradients of signaling molecules, Ephs and ephrins, along

both the A-P and D-V axes of the tectum. Other receptor-ligands systems, as well as patterned RGC activity, are also involved in map development.

## DEVELOPMENT OF THE NEUROMUSCULAR SYNAPSE

Once axons have arrived at their appropriate target destination, synapse formation ensues. Much of our understanding about the mechanisms of synapse formation arises from studies of the neuromuscular synapse. These studies have benefited from (1) the relative ease of experimentally manipulating developing and regenerating neuromuscular synapses *in vivo*, (2) cell culture systems for both motor neurons and skeletal muscle cells, (3) the *Torpedo* electric organ, an abundant and homogeneous source of neuromuscular-like synapses (see Box 18.1), and (4) transgenic and mutant mice for studying and altering gene expression. Consequently, we have a good, although incomplete, understanding of the mechanisms that lead to the formation of the neuromuscular synapse.

### Substructural Organization of the Neuromuscular Synapse

An adult myofiber, a syncytial cell containing several hundred to several thousand nuclei, is innervated by a single motor axon that terminates and arborizes over approximately 0.1% of the muscle fiber's cell surface. The neurotransmitter receptor, acetylcholine receptors (AChRs), is localized to this small patch of the muscle fiber membrane, and its precise localization to synaptic sites during development is a hallmark of the inductive events of synapse formation. Although other proteins are likewise concentrated at synaptic sites, much of our knowledge about synaptic differentiation has come from studies aimed at understanding how AChRs accumulate at synaptic sites.

Nerve terminals are situated in shallow depressions of the muscle cell membrane, which is invaginated further into deep and regular folds, termed postjunctional folds (Fig. 18.9). AChRs and additional proteins (see later) are localized to the crests of these postjunctional folds, whereas other proteins, including sodium channels, are enriched in the troughs of the postjunctional folds. The nerve terminal likewise is organized spatially, and its substructural organization reflects that of the postsynaptic membrane. Synaptic vesicles are sparse in the region of the nerve terminal underlying Schwann cells and are abundant in the region of the nerve terminal facing the muscle fiber. Moreover,

**FIGURE 18.8 Normal development of the topographic retinocollicular map requires large-scale remodeling mediated by retinal waves that correlate RGC activity patterns.** (A–C) Normal development of the topographic retinocollicular map requires large-scale remodeling. Focal injection of the fluorescent lipophilic tracer DiI into temporal retina of WT mice labels RGC axons from a single retinal location. Shown are fluorescence images of DiI labeled RGC axons in WT SC at the ages indicated. (A) At P1 RGC axons are dispersed across the entire lateral-medial (L–M) and anterior (arrowheads)–posterior (P) axes of the SC. Essentially all RGC axons extend well posterior to the location of their future TZ (circle). Branches form *de novo* from the axon shaft in a distribution biased for the A–P location of the future TZ. In addition, branches are directed toward their future TZ along the L–M axis. (B) At P4 RGC axons with branches near the future TZ preferentially elaborate arbors. Note that many RGC axons have eliminated their initial posterior overshoot. (C) At P8, a dense focal TZ is labeled at the topographically appropriate location in the SC. The initial axon overshoot is eliminated and no arbors persist outside the TZ. At P8 the retinocollicular map resembles its mature form. (D–F)  $\beta 2$   $-/-$  mice that lack retinal waves have defective topographic remodeling of the retinocollicular projection. Fluorescence images of DiI labeled RGC axons in SC of P8  $\beta 2$   $+/+$  (D) and  $\beta 2$   $-/-$  (E and F) mice. (D) Focal injection of DiI into temporal retina of a P7  $\beta 2$   $+/+$  mouse reveals a single, densely labeled TZ in anterior SC at P8 (arrowheads mark anterior border of SC) characteristic of refined topographic organization of the mature retinocollicular projection in WT. (E and F) Focal DiI injections, similar in size to that in panels A–D, made into temporal retina of P7  $\beta 2$   $-/-$  mice reveal at P8, TZs characterized by aberrantly large domains of loosely organized arborizations in the vicinity of the appropriate topographic position but have not refined into a single dense TZ characteristic of WT mice at this age. Large arrows point to black circles that indicate the approximate size and position of the appropriate TZ predicted by the injection site. Many RGC axons persist in mid-SC with elaborate arbors (small arrows). The inset in each panel is a tracing of the flat-mounted retina and injection site (black spot) for each case. The cases shown in panels A–C have an injection similar to that in panel D. Temporal is to the right and dorsal is to the top for each retinal tracing. L, lateral; M, medial; P, posterior. Scale bar = 250  $\mu$ m. Adapted from McLaughlin, T., Torborg, C. L., Feller, M. B., and O’Leary, D. D. M. (2003). *Neuron* 40, 1147–1146.

synaptic vesicles are clustered adjacent to a poorly characterized specialization of the presynaptic membrane, termed active zones, which are the sites of synaptic vesicle fusion. Active zones are organized at regular intervals and are aligned precisely with the mouths of the postjunctional folds. This precise registration of active zones and postjunctional folds ensures that acetylcholine encounters a high concentration of

AChRs within microseconds after release, thereby facilitating synaptic transmission. The alignment of structural specializations in pre- and postsynaptic membranes, separated by a 500-Å synaptic cleft, suggests that spatially restricted signaling between pre- and postsynaptic cells is important to coordinate pre- and postsynaptic differentiation. The mechanisms that align active zones and postjunctional folds are

not understood, but  $\alpha 3 / \beta 1$  integrin is concentrated at active zones and several laminins are found in the synaptic basal lamina, raising the possibility that laminin/integrin interactions have a role in positioning and organizing active zones (see later).

The precise organization of molecules in pre- and postsynaptic membranes belies the concept that the neuromuscular synapse is a simple synapse. Rather, the substructure of pre- and postsynaptic membranes, together with the faithful registration of pre- and postsynaptic specializations, suggests that complex mecha-

nisms are required to assemble the synapse and to coordinate pre- and postsynaptic differentiation.

### Muscle-Autonomous Patterning of AChR Expression

As motor axons extend toward developing muscle, muscle cells are themselves undergoing differentiation. Myotubes, formed by fusion of precursor myoblasts, develop prior to innervation and continue to grow after innervation by further myoblast fusion.

**FIGURE 18.9 Pre- and postsynaptic membranes at the neuromuscular synapse are highly specialized.** (A) An electron micrograph of a neuromuscular synapse shows that the nerve terminal is capped by a Schwann cell and is situated in a shallow depression of the muscle cell membrane, which is invaginated further into deep and regular folds, termed postjunctional folds (arrows). AChRs, labeled with  $\alpha$ -bungarotoxin coupled to horseradish peroxidase, are concentrated at the synaptic site. (B) A higher magnification view shows that AChRs are concentrated at the crests and along the sides of the postjunctional folds (white arrow). Rapsyn, NRG receptors, and MuSK are also concentrated in the postsynaptic membrane, whereas Agrin, NRG-1, acetylcholinesterase, S-laminin, and certain isoforms of collagen are localized to the synaptic basal lamina. The postjunctional folds of the myofiber are spaced at regular intervals and are situated directly across from active zones and clusters of synaptic vesicles in the nerve terminal (arrows).

Because myoblasts fuse to developing myotubes at their growing ends, the central region of the muscle is more mature than the distal ends of the muscle. Recent studies have shown that the central region of muscle is regionally specialized prior to innervation. For example, AChRs are already clustered in the central region of the muscle prior to and independent of innervation (Yang *et al.*, 2000, 2001; Lin *et al.*, 2001). As such, motor axons approach muscles that are regionally specialized, or prepatterned, prior to innervation, in a manner that preconfigures the prospective zone of innervation (Fig. 18.10).

How the prospective synaptic region of the muscle becomes prepatterned is not well understood, but muscle pre-patterning restricts motor axon growth and promotes synapse formation in the central region of mammalian muscle (Kim and Burden, 2008).

### The Synaptic Basal Lamina Contains Signals for Synaptic Differentiation

Following contact with the growth cone of a developing motor neuron, developing muscle fibers undergo a still further complex differentiation program in the synaptic region, which is dependent upon motor neuron-derived signals. In addition, signals from the muscle further regulate differentiation of presynaptic nerve terminals. The idea that signals for regulating both presynaptic and postsynaptic differentiation are contained in the synaptic basal lamina arose from studies of regenerating neuromuscular synapses. Following damage to a motor axon, the distal portion of the motor axon degenerates, and the proximal end regenerates to muscle. The regenerated axon precisely reinnervates the original synaptic site and forms a synapse that is indistinguishable from the original synapse. Original synaptic sites are not thought to provide guidance cues to motor axons; rather, it is believed that the vacated perineurial tubes, containing Schwann cells and their basal lamina, provide a favorable substrate for motor axons and have a role in directing regenerating motor axons to original synaptic sites (Son and Thompson, 1995). Although motor axons precisely reinnervate original synaptic sites, there appears to be little, if any, selectivity among motor neurons or among Schwann cells in assuring accurate regeneration; indeed, both original and foreign motor neurons can accurately and functionally reinnervate original synaptic sites in denervated muscle.

Following damage to motor axons and muscle, nerve terminals and muscle fibers degenerate and are phagocytized, but the basal lamina of the muscle fiber remains intact. Even in the absence of nerve terminals

**FIGURE 18.10 Muscle pre-patterning.** (A) Motor axons approach muscles that already express *MuSK* and *acetylcholine receptor (AChR)* genes (green) in the central, prospective synaptic region of the muscle. (B) This aspect of muscle pre-patterning requires *MuSK*. Following innervation, this zone of *AChR* expression is refined and sharpened, so that *AChR* expression and *AChR* clustering is restricted to nascent synaptic sites. Two neural signals refine *AChR* expression: *Agrin/MuSK* signaling stabilizes and stimulates *AChR* clustering, whereas *acetylcholine (ACh)* disperses *AChR* clusters. As a consequence of these two signals, *AChR* clusters are maintained only at nascent synaptic sites.

and muscle fibers, several structures, including the terminal Schwann cells, the basal lamina of the postjunctional folds, and AChE, remain at the original synaptic site and allow for its identification.

Axons eventually regenerate into the muscle, and new myofibers regenerate within the basal lamina of the original myofiber. The regenerated motor axons form synapses with the regenerated myofibers precisely at the original synaptic sites. If axons regenerate into muscle, but muscle regeneration is prevented,

## BOX 18.1

## TORPEDO ELECTRIC ORGAN

The majority of proteins known to be localized to neuromuscular synapses were first identified in postsynaptic membranes isolated from the electric organ of the marine ray *Torpedo*. Indeed, this specialized tissue has been essential for the identification and purification of the AChR, AChE, Rapsyn, Syntrophin, Agrin, MuSK and several synaptic vesicle proteins. The electric organ is a particularly homogeneous and abundant source of pre- and postsynaptic membranes that are similar in structure and function to those at neuromuscular synapses. The biochemical advantages of the electric organ are evident from its anatomy. The postsynaptic cell, which differentiates initially as a syncytial skeletal muscle fiber but subsequently loses its contractile machinery, is termed an electroplaque. Each electroplaque is a thin, elongated cell (1 cm × 1 cm × 10 mm) that is so densely innervated that nearly one-half of the electrocyte membrane is studded by nerve terminals. In contrast, nerve terminals occupy less than 0.1% of the cell surface of a skeletal myofiber.

Because of this dense innervation and because the electric organ from a moderate size ray weighs several kilograms, it is possible to obtain several mg of purified postsynaptic proteins from a single electric organ.

Innervation is restricted to the ventral surface of the electroplaque, whereas the dorsal surface is enriched for the sodium/potassium ATPase which maintains the resting potential. Because the electroplaque lacks action potentials, activation of AChRs on the innervated ventral surface results in a voltage drop across the innervated but not the non-innervated membrane of the electrocyte. Since thousands of electroplaques are stacked closely one upon another, the potential difference across a single electrocyte is summated by the stack of electroplaques, resulting in a several thousand volt potential difference across the entire electric organ, a voltage that is sufficient to stun prey.

*Steven J. Burden, Dennis D. M. O'Leary and Peter Scheiffele*

axons still unerringly reinnervate the original synaptic site on the basal lamina, and active zones form in register with the basal lamina of the original postjunctional folds (Fig. 18.11) (Sanes *et al.*, 1978). Thus, the presence of the myofiber is necessary neither for precise reinnervation nor for the morphological differentiation of regenerated nerve terminals. The vacated perineurial tubes, containing Schwann cells and their basal lamina, may direct regenerating motor axons to original synaptic sites, but the induction of active zones suggests that cues in the synaptic basal lamina have a role in organizing the presynaptic terminal. Notably, laminin  $\beta 2$ , which is expressed by muscle and found in the synaptic basal lamina, binds presynaptic calcium channels, and this interaction has a role in anchoring active zones and coordinating pre- and postsynaptic differentiation (Nisimune *et al.*, 2004).

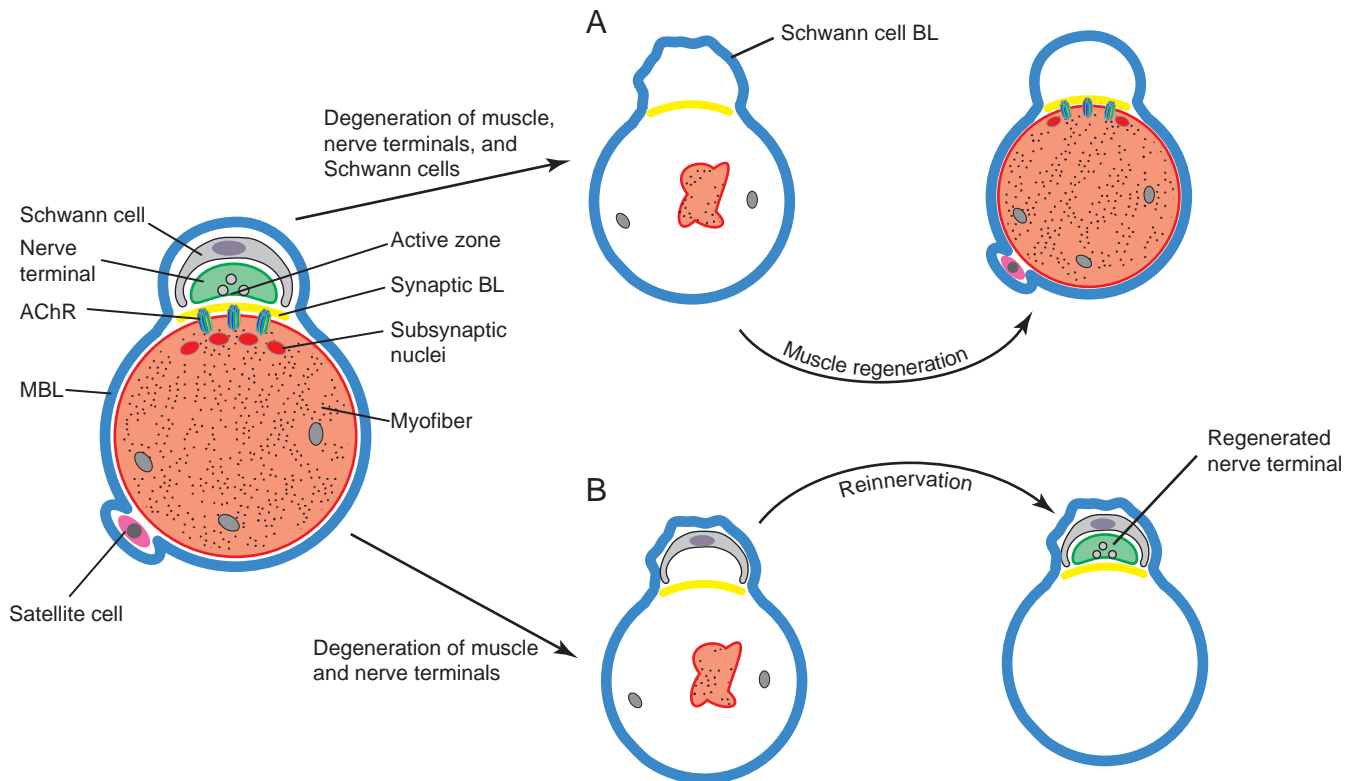

If regeneration of motor axons is prevented, but myofibers are allowed to regenerate, AChRs accumulate and membrane folds form in the regenerated myofiber precisely at the original synaptic site on the basal lamina (Burden *et al.*, 1979). Thus, in the absence of nerve terminals, myofibers, and terminal Schwann cells, information that remains at the original synaptic site instructs both presynaptic and postsynaptic differentiation (Fig. 18.11). Because the synaptic basal lamina is the most prominent extracellular structure

remaining at neuromuscular synapses following removal of all cells, these results indicate that the synaptic basal lamina contains signals that can induce differentiation of both nerve terminals and myofibers.

### Agrin Is a Signal for Postsynaptic Differentiation

Because clustering of AChRs, unlike the formation of active zones, can be studied readily in cell culture, it has been far simpler to identify the basal lamina signals that induce postsynaptic rather than presynaptic differentiation. Extracellular matrix from the *Torpedo* electric organ, a tissue that is homologous to muscle but more densely innervated, contains an activity that stimulates AChR clustering in cultured myotubes (see Box 18.1). McMahan and colleagues purified the electric organ activity, which they termed Agrin, and showed that Agrin is synthesized by motor neurons, transported in motor axons to synaptic sites, and deposited in the synaptic basal lamina. Agrin also stimulates the clustering of other synaptic proteins (see later), including AChE, Rapsyn and Utrophin (see later), indicating that Agrin has a central role in synaptic differentiation.

Agrin is a ~200-kDa protein containing multiple epidermal growth factor (EGF)-like signaling domains,

**FIGURE 18.11 The synaptic basal lamina contains signals for presynaptic and postsynaptic differentiation.** A cross-section of normal muscle containing a nerve terminal, Schwann cell, and myofiber is shown at the far left. *AChR* genes are induced in synaptic nuclei (red) and AChRs (green) are concentrated at synaptic sites. Active zones and clusters of synaptic vesicles in the nerve terminal are aligned with post-junctional folds in the myofiber. Each myofiber is ensheathed by a basal lamina (MBL), which is specialized at the synaptic site (synaptic BL) and which remains intact following degeneration of the original myofiber. The MBL serves as a scaffold for regenerating myofibers, which form from the fusion of satellite cells that proliferate following damage to the original myofiber. (A) Experiments showing that the synaptic basal lamina contains signals for clustering AChRs and activating *AChR* genes in synaptic nuclei. Following damage and degeneration of axons, Schwann cells and myofibers, new myofibers regenerate within the basal lamina of the original myofiber in the absence of the nerve. AChRs cluster and *AChR* gene expression is reinduced at original synaptic sites in myofibers that regenerate in the absence of the nerve and other original presynaptic cells. (B) Experiments showing that the synaptic basal lamina contains signals for inducing presynaptic differentiation. Following damage and degeneration of axons and myofibers, motor axons regenerate to original synaptic sites in the absence of the myofiber and accumulate synaptic vesicles precisely across from the sites of the original postjunctional folds.

two different laminin-like domains, and multiple follistatin-like repeats. The four EGF-like domains and three laminin G domains are contained in the carboxyl-terminal region, which is sufficient for inducing AChR clusters in cultured myotubes; sequences in the amino-terminal region are responsible for the association of Agrin with the extracellular matrix.

The *agrin* gene is expressed in a variety of cell types. Alternative splicing results in multiple Agrin isoforms that differ in their AChR clustering efficiency. The isoform that is most active in clustering AChRs is expressed in neurons, including motor neurons, whereas other Agrin isoforms are expressed in additional cell types, including skeletal muscle cells. The active, neuronal-specific isoforms of Agrin contain 8, 11, or 19 amino acids at a splice site, referred to as the Z site in rat Agrin and the B site in chick Agrin.

The *agrin* gene contains multiple promoters. Although the promoter used in motor neurons leads to expression of isoforms that are associated with the extracellular matrix, the promoter used in the CNS leads to expression of membrane-bound isoforms (Burgess *et al.*, 2000).

In mice lacking Agrin, AChRs are initially prepatterned, and synapses appear to form, but only transiently (Lin *et al.*, 2001). Over the course of several days, the AChR prepatter is dispersed, synapses are lost, and motor axons begin to grow throughout the muscle. Thus, Agrin is necessary to stabilize the AChR prepatter and nascent synapses. Because the AChR prepatter is stable in the absence of innervation but dispersed by motor axons lacking Agrin, neural signals, other than Agrin, extinguish the AChR prepatter (Yang *et al.*, 2001; Lin *et al.*, 2001). Genetic evidence

indicates that acetylcholine is a key neural signal that disperses AChR clusters (Lin *et al.*, 2005; Misgeld *et al.*, 2005). Thus, during normal development, Agrin counteracts acetylcholine-mediated dispersion, thereby stabilizing AChR clusters selectively at nascent synapses.

### MuSK Is Required for Agrin-Mediated Signaling and Synapse Formation

The mechanisms of Agrin-mediated AChR clustering are not known, but a receptor tyrosine kinase, termed MuSK, is a critical component of an Agrin receptor complex. MuSK is expressed in *Torpedo* electric organ and in skeletal muscle, where it is concentrated in the postsynaptic membrane. Mice deficient in MuSK (DeChiara *et al.*, 1996), like *agrin* mutant mice, lack normal neuromuscular synapses. Both *agrin* and *MuSK* mutant mice are immobile, cannot breathe, and die at birth. Muscle differentiation is normal in *agrin* and *MuSK* mutant mice, but muscle fibers in *MuSK* mutant mice lack all known features of postsynaptic differentiation. Muscle-derived proteins, including AChRs and AChE, which are concentrated at synapses in normal mice, are distributed uniformly in *MuSK* mutant myofibers (Fig. 18.12). In addition, *AChR* genes, which normally are transcribed selectively in synaptic nuclei of normal muscle fibers (see later), are transcribed at similar rates in synaptic and nonsynaptic nuclei of muscle fibers from *MuSK* mutant mice. Unlike *agrin* mutant mice, the AChR prepatterning is absent from *MuSK* mutant mice at all stages, indicating that MuSK is essential not only for synapse formation but also to establish muscle prepatterning.

Five lines of evidence indicate that MuSK is required for Agrin-mediated signaling and is a component of the Agrin receptor complex: (1) Agrin can be chemically cross-linked to MuSK in cultured myotubes; (2) Agrin induces rapid tyrosine phosphorylation of MuSK in cultured myotubes; (3) a recombinant, soluble extracellular fragment of MuSK inhibits Agrin-induced AChR clustering in cultured muscle cells; (4) cultured *MuSK* mutant muscle cells, unlike normal muscle cells, do not cluster AChRs in response to Agrin; and (5) dominant-negative forms of MuSK inhibit Agrin-induced AChR clustering in cultured myotubes. MuSK itself, however, does not bind Agrin, indicating that other activities or additional proteins are required for Agrin to activate MuSK. The additional activities in muscle that are required for Agrin to activate MuSK are not known, but Lrp4, a member of the low density lipoprotein receptor family, is essential for synapse formation, and the synaptic defects in *lrp4* mutant mice appear identical to those in *MuSK* mutant mice

(Weatherbee *et al.*, 2006). Thus, Lrp4 may be a component of a MuSK protein complex.

Interestingly, a pair of proteins with homology to MuSK and Lrp4 are required for clustering AChRs at *C. elegans* neuromuscular synapses: CAM-1, a receptor tyrosine kinase that shares homology with MuSK, and LEV-10, a transmembrane protein that contains a LDLa domain (Gally *et al.*, 2004; Francis *et al.*, 2005). However, the kinase activity of CAM-1 is dispensable for synaptic differentiation, pointing to a different mechanism of action than MuSK at vertebrate neuromuscular synapses.

The signaling mechanisms that regulate neuromuscular synapse formation during embryogenesis in *Drosophila* are poorly understood, but two ligands, Wingless and TGF- $\beta$ , unrelated to Agrin, are involved in the growth of *Drosophila* neuromuscular synapses during larval development. Wingless is secreted by motor neurons and thought to activate Frizzled-2, a Wingless receptor expressed in muscle (Packard *et al.*, 2002); Glass bottom boat, a ligand from the TGF- $\beta$  family, is synthesized by muscle and thought to activate Wishful thinking, a type II receptor, in motor neurons (Aberle *et al.*, 2002).

How does MuSK activation lead to postsynaptic differentiation? Agrin stimulates the rapid phosphorylation of MuSK, and the kinase activity of MuSK is essential for Agrin to stimulate clustering and tyrosine phosphorylation of AChRs. Signaling downstream from MuSK depends on phosphorylation of a tyrosine residue (Y553) in the juxtamembrane region of MuSK (Herbst *et al.*, 2002). Phosphorylation of this tyrosine leads to recruitment of Dok-7 (Okada *et al.*, 2006), which engages additional, but unknown downstream signaling pathways essential for synapse formation. Mice lacking Dok-7 have defects identical to *MuSK* mutant mice (Okada *et al.*, 2006), and mutations in human Dok-7 are a cause of congenital myasthenic syndromes with defects in neuromuscular synapses (Beeson *et al.*, 2006). Rac and Rho, small GTP-binding proteins that regulate actin organization, are activated by Agrin and required for Agrin to stimulate AChR clustering (Weston *et al.*, 2000, 2003). Rac acts early and is important for the formation of AChR microclusters, whereas Rho is activated more slowly and is important for the consolidation of microclusters into larger AChR clusters. Moreover, at least one kinase acts downstream from MuSK and is recruited and/or activated by Agrin-activated MuSK, as staurosporine, a protein kinase inhibitor, inhibits Agrin-induced AChR tyrosine phosphorylation and clustering without blocking tyrosine phosphorylation of MuSK.

Following the recruitment of Dok-7 to phosphorylated MuSK, the signaling pathways downstream from

**FIGURE 18.12 Presynaptic and postsynaptic differentiation are defective in mice lacking MuSK.** Whole mounts of muscle from wild-type and *MuSK* mutant mice were stained with antibodies to neurofilament (NF) and synaptophysin (Syn) to label motor axons and nerve terminals (green), respectively, and with  $\alpha$ -bungarotoxin to label acetylcholine receptors (AChRs) (red). In *MuSK* mutant mice, motor axons fail to stop and differentiate adjacent to the main intramuscular nerve and instead wander aimlessly over the muscle; AChRs, as well as other postsynaptic proteins, are expressed at normal levels but they fail to cluster.

MuSK are poorly understood. Abl 1/2, Src-family kinases and Pak have been proposed to act downstream from MuSK, but functional evidence for Abl and Pak in forming synapses *in vivo* is currently lacking. Genetics studies point to a role for Src-family kinases, as well as dystrobrevin, in stabilizing rather than forming neuromuscular synapses, but how these kinases stabilize synapses is not known (Smith *et al.*, 2001).

### Muscle-Autonomous and Neural-Dependent Patterning of AChR Expression

The preceding sections have emphasized the role of muscle prepatterning and motor neuron-derived signals in regulating the distribution of AChR expression. Taken together, these findings suggest a model for the sequential steps involved in establishing the pattern of AChR expression on developing skeletal muscle fibers (Arber *et al.*, 2002; Kummer *et al.*, 2006). An initial, spatially restricted pattern of AChR expression is generated in muscle independent of neurally derived Agrin, or indeed of any other neural signal (Fig. 18.10). Because this prepattern is not observed in mice lacking MuSK, the emergence of this muscle AChR prepattern, nonetheless, coopts at least some of the same molecules used during normal synaptogenesis. Arrival of the nerve, and its attendant signals, converts the AChR prepattern into the more refined pattern of AChR transcription and AChR clustering characteristic of mature synapses. This conversion appears to be dependent on two separable nerve-

dependent programs: one program appears to utilize neurally derived Agrin to maintain AChR expression at nascent synaptic sites and a second program, which appears to be triggered by acetylcholine, extinguishes AChR clustering at sites that are not stabilized by Agrin/MuSK signaling (Fig. 18.10). These two programs thus ensure the stable expression of AChR clusters selectively at nascent synapses. The mechanisms that are intrinsic to muscle and responsible for establishing regional differences in muscle in the absence of innervation are not well understood but appear to depend upon the pattern of muscle growth and positive feedback loops that sustain MuSK activation (Kim and Burden, 2008).

### Rapsyn Is Required for Postsynaptic Differentiation and Is Downstream of Agrin and MuSK

A 43-kDa protein, termed Rapsyn, has an important role in Agrin-mediated signaling. Rapsyn is a myristoylated, peripheral membrane protein that is present at 1:1 stoichiometry with AChRs at synaptic sites and interacts directly with AChRs and potentially other synaptic proteins, including Dystroglycan and Dystrophin, Utrophin, Syntrophin, and Dystrobrevin, proteins that are components of a subsynaptic, cytoskeletal complex.

Agrin stimulates the clustering of Rapsyn in myotubes grown in cell culture, and clustering of Rapsyn and AChRs occurs coincidentally at developing synapses. Rapsyn is critical for synapse formation, as mice

lacking Rapsyn die within hours after birth and have difficulty moving and breathing (Gautam *et al.*, 1995). Mutations in human Rapsyn are a cause of congenital myasthenic syndromes with defects in AChR clustering that lead to muscle weakness (Engel *et al.*, 2003). Although the mechanisms by which Rapsyn regulates the clustering of synaptic proteins is poorly understood, the clustering of most synaptic proteins, including AChRs, Utrophin and Dystroglycan, depends upon Rapsyn. Nonetheless, MuSK is clustered at synapses in rapsyn mutant mice, raising the possibility that engagement with Agrin is sufficient to stabilize MuSK at rapsyn mutant synapses. Synapse-specific gene expression (see below) is also normal in rapsyn mutant mice, suggesting that MuSK may trigger this pathway independent of Rapsyn.

### Agrin and MuSK Are Required for Retrograde Signaling and Presynaptic Differentiation

Although pathfinding of motor axons to muscle is normal in mice lacking Agrin or MuSK, *agrin* and *MuSK* mutant mice lack normal nerve terminals. In the mutant mice, branches of the main intramuscular nerve fail to stop and differentiate and instead wander aimlessly across the muscle (Fig. 18.12). Because MuSK is expressed in skeletal muscle and not in motor neurons, it seems likely that the aberrant behavior of presynaptic terminals in *MuSK* mutant mice is due to indirect actions of the Agrin/MuSK signaling system. Indeed, restoring MuSK expression selectively in muscle of *MuSK* mutant mice rescues synapse formation and neonatal lethality (Herbst *et al.*, 2002). These results indicate that Agrin, released from nerve terminals, causes the muscle cell, via MuSK activation, to reciprocally release a recognition signal back to the nerve to indicate that a functional contact has occurred. In response to this putative muscle-derived recognition or adhesion signal, the nerve undergoes presynaptic differentiation and stops growing.

### Certain Genes Are Expressed Selectively in Synaptic Nuclei of Myofibers

Like AChR protein, mRNAs encoding the different AChR subunits ( $\alpha$ ,  $\beta$ ,  $\gamma$ , or  $\epsilon$  and  $\delta$ ) are concentrated at synaptic sites. Studies with transgenic mice that harbor gene fusions between regulatory regions of AChR subunit genes and reporter genes have shown that AChR genes are transcribed selectively in myofiber nuclei near the synaptic site (Fig. 18.13). Thus, localized transcription of AChR genes in synaptic nuclei is responsible, at least in part, for the accumulation of

AChR mRNA at synaptic sites. This pathway is important for ensuring that AChRs are expressed at the required density in the postsynaptic membrane, as defects in synapse-specific gene expression of the AChR  $\epsilon$  subunit gene are the cause of a congenital myaesthesia (see later).

Like AChR subunit genes, the *utrophin* gene is transcribed selectively in synaptic nuclei, resulting in an accumulation of *utrophin* mRNA and protein at synaptic sites. mRNAs encoding *Rapsyn*, NCAM, MuSK, sodium channels, the catalytic subunit of AChE, LL5beta and CD24 are also concentrated in the synaptic region of skeletal myofibers, raising the possibility that these genes are likewise transcribed preferentially in synaptic nuclei. Thus, synapse-specific transcription may be a common and important mechanism for expressing and localizing a variety of gene products at high levels at the neuromuscular synapse.

The neural signals that regulate synapse-specific transcription remain elusive. Until recently, Neuregulin-1, which stimulates tyrosine phosphorylation of ErbB2, a member of the EGF receptor family, was considered the best candidate. However, neuromuscular synapses appear normal in mice lacking ErbBs in skeletal mice as well as in mice lacking Neuregulin-1 in motor neurons and skeletal muscle (Escher *et al.*, 2005; Jaworski and Burden, 2006). Synapse-specific transcription, however, requires Agrin and MuSK, indicating that this signaling pathway has a critical role in regulating synaptic gene expression.

### Ets Domain Transcription Factors Regulate Synapse-Specific Transcription

A binding site for Ets domain proteins in the AChR  $\delta$  subunit gene is critical for synapse-specific gene expression in mice. Importantly, mutation of an Ets-binding site in the human AChR  $\epsilon$  subunit gene leads to a myopathy, termed congenital myasthenic syndrome, due to decreased AChR expression. This Ets site can bind GABP, a complex containing GABP $\alpha$ , an Ets protein, and GABP $\beta$ , a protein that lacks an Ets domain but dimerizes with GABP $\alpha$ , suggesting that GABP may be a transcriptional regulator that stimulates transcription of AChR genes in synaptic nuclei. In addition, the gene encoding another Ets domain protein, Erm, is expressed selectively by myofiber synaptic nuclei (Hippenmeyer *et al.*, 2002), suggesting that Erm may also have a role in synapse-specific expression. Genetic analysis of GABP and *erm* mutant mice indicates that Erm has a critical role, whereas GABP has a more subsidiary role in synapse-specific transcription.

**FIGURE 18.13** *Acetylcholine receptor (AChR) genes are expressed selectively by myofiber synaptic nuclei, leading to enrichment of AChR mRNA in the central, synaptic region of the muscle.* (A) Muscle from transgenic mice harboring a gene fusion between the regulatory region from the *AChR*  $\delta$  subunit gene and *human growth hormone (hGH)* gene were stained with  $\alpha$ -bungarotoxin ( $\alpha$ -BGT) to label AChRs and with antibodies to hGH. Intracellular hGH is concentrated in the ER/Golgi apparatus near myofiber synaptic nuclei of *AChR*  $\delta$  transgenic mice but expressed uniformly in muscle from control transgenic mice carrying a gene fusion between the regulatory region of the *muscle creatine kinase (MCK)* gene and *hGH*. (B) A whole mount of a mouse diaphragm muscle was processed for *in situ* hybridization to reveal the pattern of *AChR*  $\delta$  mRNA expression. *AChR*  $\delta$  mRNA expression is concentrated in a narrow band in the central, synaptic region of the muscle.

### Electrical Activity Regulates Gene Expression

Changes in the pattern of muscle electrical activity have an important role in regulating the electrophysiological and structural properties of muscle, as well as the ability of motor axons to innervate muscle. The expression of several genes, including *AChR* genes, is repressed by electrical activity, and this repression, together with focal activation in synaptic nuclei, as described earlier, contributes to the disparate levels of AChR expression in synaptic and nonsynaptic regions of the muscle. A binding site for myogenic bHLH transcription factors, or E box, in the proximal promoter of *AChR* subunit genes is essential for electrical activity-dependent transcription, as transgenes containing a mutation in this E box, unlike wild-type transgenes, are not induced following denervation. These results

suggest that electrical activity decreases the level and/or activity of E box binding proteins, notably Myogenin, leading to decreased *AChR* expression. The transcriptional mechanisms that control expression of *myogenin* in an activity-dependent manner are just beginning to be explored. Electrical activity induces expression of two transcriptional repressors, HDAC-9 (aka MITR) and *Dach2*, which act to repress *myogenin* expression (Schaeffer *et al.*, 2004; Tang and Goldman, 2006). A reduction in myofiber electrical activity leads to a reduction in HDAC-9 and *Dach2* expression, causing an elevation in *myogenin* expression. Thus, the mechanisms that couple changes in electrical activity to changes in HDAC-9 and *Dach2* expression are critical to regulating genes, such as *AChR* genes, which are dependent upon Myogenin. The mechanisms that regulate HDAC-9 and *Dach2* expression are not under-

stood, but the involvement of multiple protein kinases, including PKA, CAM kinase II, and PKC, has been suggested.

### Summary

Signals exchanged at nascent synaptic sites ensure that differentiated presynaptic terminals are aligned precisely with a highly specialized postsynaptic membrane. Analysis of mice lacking innervation demonstrates that a coarse pattern of postsynaptic differentiation is present prior to innervation and that neuronal signals, including Agrin, selectively maintain, rather than induce, postsynaptic differentiation at sites of nerve–muscle contact (Fig. 18.10). MuSK, a receptor tyrosine kinase expressed by muscle and activated by Agrin, has a key role in establishing muscle prepatterning and in stabilizing nascent synapses in response to Agrin.

## SYNAPSE FORMATION IN THE CENTRAL NERVOUS SYSTEM

Compared to synapse formation between neurons and muscle cells, we know only relatively little about how neuron–neuron synapses in the central nervous system are put together. The reason for this lack of knowledge is the complexity of the problem. CNS synapses are much smaller (about one hundredths of a neuromuscular junction), a single neuron typically receives hundreds to thousands of synapses and the synaptic inputs are derived from multiple different synaptic partners. Finally, these synapses employ not just one but a variety of neurotransmitters, some excitatory that depolarize the postsynaptic partner, and some that are inhibitory and lead to hyper-polarization. The placement of excitatory and inhibitory synapses on the postsynaptic cell is a critical parameter for integration of these counteracting inputs. Another complicating factor is that the synaptic connectivity in the central nervous system is not static but undergoes extensive plastic changes that modify the function of neuronal circuits in response to experience. All of these properties pose intriguing challenges regarding the synthesis of synaptic components, their targeting and assembly at functionally distinct synaptic sites, and the recognition of the appropriate synaptic partners in a sea of candidate partners within the target area.

While the assembly of the vertebrate neuromuscular junction represents a much simpler problem there are several principles discovered in work on the NMJ that appear to apply to CNS synapse formation: (1) Cells express most synaptic components before synapse

formation, (2) bi-directional signaling organizes synaptic components at emerging synaptic contacts, (3) synapses undergo extensive functional maturation, (4) during development an exuberant number of synaptic contacts is formed, some of which later undergo elimination.

Building on these parallels to NMJ formation significant progress in understanding CNS synapse formation has been made. Other invaluable information for these studies has come from the previous elucidation of the molecular composition of pre- and postsynaptic structures (Chapters 8 and 9) and the recent advances in understanding the mechanisms of synaptic plasticity of mature synapses (Chapters 50 and 51), some of which are likely to be also important for their initial formation. This section focuses on the formation of chemical synapses between neurons in the central nervous system of vertebrates. It examines emerging evidence on the mechanisms controlling recruitment and assembly of pre- and postsynaptic components and discusses some candidate molecules that may contribute to the selectivity of synaptic wiring in development.

### The First Contact between Axons and Their Neuronal Targets

Neurons express both pre- and postsynaptic components prior to synapse formation. For example, growing axons and growth cones contain synaptic vesicles and release neurotransmitter before interacting with a postsynaptic target cell. Similarly, target cells express functional neurotransmitter receptors on their surface before synapse formation. Cell–cell contact, however, is essential for the concentration and juxtaposition of pre- and postsynaptic components in opposing membranes and for achieving the mature complement of both pre- and postsynaptic proteins.

Many initial contacts between synaptic partners are established through filopodia, tiny membrane extensions that rapidly extend and retract from a cell (Chapter 17). Importantly, filopodia extend from both, axons and dendrites and increase the extracellular space sampled by a cell during development (Jontes and Smith, 2000). Imaging studies, both in culture and *in vivo* indicate that when filopodia contact potential synaptic partners, they can lose their motility and become stabilized. These contacts are then thought to transform into synaptic structures (McAllister, 2007). Indeed, synaptic specializations have been seen on filopodia themselves and neurotransmitter release from axons is likely to play an important role for the regulation of filopodial dynamics (Tashiro *et al.*, 2003).

A second important realization from imaging studies has been that the assembly of synapses occurs very rapidly. The time required from initial contact to establishment of a functional synapse is only in the range of 1–2 hours, with the formation of a presynaptic terminal occurring in only 10–20 minutes and the recruitment of postsynaptic neurotransmitter receptors lagging somewhat behind (Friedman *et al.*, 2000) (Fig. 18.14). This rapid timecourse is plausible if one considers that most synaptic components are “ready-to-go” before contact and primarily need to be redistributed in response to a cell surface signal. The key molecules mediating stabilization of filopodial contacts between pre- and postsynaptic partners and rapid assembly of synaptic structures are not known but recent studies identified several candidate proteins for these events.

### Target-derived Signals for Presynaptic Development

What are the trans-synaptic interactions that mediate the stabilization of filopodial contacts and rapid recruitment of presynaptic components? A striking realization emerging during the past years has been that single target-derived signals are sufficient to induce a substantial degree of presynaptic organization. The first proteins with such an activity to be identified were the neuroligins. Neuroligins are a small family of postsynaptic adhesion molecules that can bind to neurexins, a second family of neuronal receptors, that is present on axons (Brose, 1999). Neuroligins and neurexins are expressed in the nervous system at the right time and place to influence synaptogenesis. Work in cultured cerebellar and hippocampal neurons demonstrated that the heterologous expression of neuroligin in nonneuronal cells induces focal accumulations of neurexins and synaptic vesicle proteins such as synapsin, synaptotagmin, and synaptophysin in axons (Dean *et al.* 2003; Scheiffele *et al.*, 2000) (Fig. 18.15). These presynaptic structures were capable of vesicle exocytosis upon depolarization indicating that the machinery for regulated exocytosis had been recruited to the neuroligin-induced presynaptic terminals. Subsequent studies identified additional synaptic adhesion molecules with similar “synaptogenic” or “synapse-organizing” functions (Biederer *et al.*, 2002; Kim *et al.*, 2006). These include the Ig-domain protein SynCAM and Netrin-G-ligand, both of which have similar activities as neuroligins with respect to the induction of presynaptic structures. While these studies provided convincing evidence that each of these molecules is sufficient to induce presynaptic specializations, it is not clear how these multiple trans-synaptic systems cooperate during development in

vivo and whether any one of these systems is absolutely essential for the assembly of synapses in vivo.

How might adhesion molecules on the postsynaptic cell induce presynaptic development? For neuroligins, presynaptic induction is mediated by recruitment and local aggregation of neurexins that act as a neuroligin receptor. Neurexins bind intracellularly to several cytoplasmic scaffolding molecules including Mint/Lin-10 and CASK/Lin-2, which may couple neurexins to voltage-gated calcium channels at the active zone (Maximov *et al.*, 1999; Missler *et al.*, 2003). Consistent with such a model, voltage-gated calcium channel function is perturbed in knock-out mice lacking a subset of neurexin isoforms. Despite these advances, it remains a major question how the enormous number of presynaptic active zone components required for regulated vesicular release (discussed in Chapter 8) can be recruited by an adhesion complex within the 10–20 minute timeframe that has been observed in imaging studies. One intriguing model for this rapid assembly of functional presynaptic terminals is that presynaptic components are recruited in pre-assembled units. Morphological and imaging experiments revealed that synaptic vesicles move in axons before synapse formation in grape-like clusters (Kraszewski *et al.*, 1995). Also active zone components can be found pre-complexed in so-called “active zone precursor vesicles” (Garner *et al.*, 2002). These vesicles could be rapidly captured and inserted in response to a target-derived signal, thereby greatly simplifying the process of presynaptic assembly (Fig. 18.14). However, whether any of the identified “synaptogenic” signals such as the neuroligins, SynCAM, or netrin-G-ligands specifically defines the insertion site of these vesicles remains to be shown.

Additional studies identified secreted growth factors that might act as target-derived signals upstream of synaptogenic cell-adhesion molecules. Using the cerebellar mossy fiber-granule cell synapse as a model system, Salinas and co-workers showed that WNT-7a derived from granule cells can induce the characteristic spreading of pontine mossy fiber axon terminals in vitro (Hall *et al.*, 2000). Normal presynaptic development is delayed in WNT-7a knockout mice, resulting in reduced synapsin clustering and simplified presynaptic membrane structures. Sanes and colleagues discovered that fibroblast growth factor 22 (FGF22) is a second granule cell-derived growth factor that contributes to mossy fiber development (Umemori *et al.*, 2004). Suppression of FGF signaling by injection of blocking proteins into the cerebellar cortex or ablation of FGF signaling receptors results in a profound reduction of presynaptic vesicles clustering in mossy fiber axons. Similar to WNT-7a, also FGF22 alters cytoskeletal

**FIGURE 18.14 Model for the assembly of central synapses.** Before synapses formation, axons and dendrites contain synaptic vesicles, active zone components, and neurotransmitter receptors, respectively. Cell-cell contact is initiated via cell surface adhesion and/or signaling molecules (red,  $t = 0$  min). Contact triggers fusion of active-zone precursor vesicles (APV, green) with the plasma membrane ( $t = 15$  min), which leads to the deposition of active zone material (black spikes). Subsequently, synaptic vesicles (clear circles) are recruited to the cell-cell contact sites ( $t = 30$  min), and postsynaptic scaffolding molecules (black), NMDA-type (blue), and AMPA-type neurotransmitter receptors (red) are delivered to the maturing postsynaptic membrane. The surface molecules that mark the insertion sites for APVs are not known and further work will be needed to confirm whether APV fusion represents the main mechanism for active zone assembly. Adapted from Garner *et al.* (2002).

**FIGURE 18.15 Synapse-organizing function of the postsynaptic adhesion molecule neuroigin.** When HEK293 cell fibroblasts overexpressing neuroigin (green) are brought into contact with pontine axons, synaptic vesicles (vesicle protein synapsin, red) accumulate at the contact sites in punctate structures in the axon. Electron microscopy of the axon-HEK293 cell contacts shows clusters of synaptic vesicles (sv) and electron-dense material (\*). The right panel shows a cartoon of the transcellular arrangement of the neuroigin-neurexin complex, with cytoplasmic scaffolding molecules CASK and Mint attached to the neurexin cytoplasmic tail. In this cell culture assay, the proteins SynCAM and Netrin-G-ligand have activities that are similar to neuroigin. How the synapse-organizing function of all three proteins is used in the intact brain *in vivo* is still an area of active studies. Adapted from Scheiffele *et al.* (2000).

properties and promotes axonal branching. These morphological rearrangements could shape the pre-synaptic partner and facilitate the recruitment of appropriate organelles in response to trans-synaptic adhesion molecules.

### Control of Postsynaptic Development

NMJs and central synapses differ most dramatically in their postsynaptic structures. This is not surprising considering the difference in cell type of the postsynaptic cell, neurons in the CNS *versus* muscle cells at the NMJ. While the cleft of neuron-neuron synapses is filled with proteinaceous and carbohydrate material it does not contain a thick basal lamina like the one seen at the NMJ. With 20nm, the width of the synaptic cleft is much narrower and the postsynaptic membrane is closely apposed to the presynaptic active zone, lacking the junctional infoldings of the NMJ. Despite these substantial differences, both synapses share the accumulation of postsynaptic neurotransmitter receptors as the hallmark of postsynaptic differentiation.

Excitatory neuron-neuron synapses using the transmitter glutamate contain multiple types of neurotransmitter receptors. So-called metabotropic glutamate receptors (mGluRs) that couple to G-proteins and modulate synaptic function and the ionotropic NMDA- and AMPA-type receptors that carry ion currents for synaptic transmission which depolarize and excite the postsynaptic cell. During development NMDA- and AMPA-receptors are thought to be recruited to synapses in a stepwise manner, with an initial accumulation of NMDA receptors at postsynaptic sites and the subsequent addition of AMPA receptors. This view is supported both by electron microscopy using immu-

nogold labeling and by electrophysiology in which NMDA receptor-rich “silent synapses” are identified initially in development and the AMPA-receptor content increases at later stages.

How can postsynaptic neurotransmitter receptors be recruited to a newly forming neuron-neuron contact? One model for neurotransmitter recruitment in analogy to the NMJ is that trans-synaptic signals could recruit a rapsyn-like cytoplasmic protein that provides a scaffold underneath the postsynaptic membrane. This scaffold would then also interact with postsynaptic neurotransmitter receptors and selectively retain receptor molecules at the appropriate sites. Biochemical studies have identified a vast array of such scaffolding proteins, many of which contain multiple protein-protein interaction domains and are ideally suited to cross-link multiple postsynaptic membrane proteins into a larger macro-molecular complex (Kim and Sheng, 2004) (Fig. 18.16). Interestingly, neuroigins, SynCAM and Netrin-G-ligands all interact with such scaffolding proteins via their cytoplasmic tail. For example neuroigins and Netrin-G-ligand bind via PDZ-domain interactions to PSD-95, a major component of the glutamatergic postsynaptic scaffold. Overexpression or aggregation of neuroigins with recombinant neurexins results in the recruitment of the scaffolding proteins PSD-95, Homer, GKAP and NMDA-type glutamate receptors (Chih *et al.*, 2005; Graf *et al.*, 2004). An important role for neuroigin in neurotransmitter receptor recruitment is also supported by knock-out mice. Mice lacking most neuroigin proteins show a 20% reduction in synapse density and a significant loss of postsynaptic neurotransmitter receptor proteins from synapses (Varoqueaux *et al.*, 2006). Mouse knockouts lacking the scaffolding protein

**FIGURE 18.16** A simplified model for transsynaptic interactions that may coordinate assembly of presynaptic and postsynaptic elements of glutamatergic synapses and recruitment of NMDA- and AMPA-type glutamate receptors. Neurexin-neuroigin interactions can organize pre- and postsynaptic structures. In this process presynaptic neurexin might couple to voltage-gated calcium channels (VGCC) through the scaffolding molecule CASK. Postsynaptic neuroigin binds via PDZ-domain interactions to PSD95, which itself can directly interact with NMDA-receptors. Heterophilic interactions through Netrin-G–Netrin-G-ligand and homophilic interactions via SynCAM–SynCAM pairs provide two additional transsynaptic links that organize pre- and postsynaptic sites (note that Netrin-G is a glycosyl-phosphatidylinositol-anchored protein that does not have an intracellular domain). Presynaptic EphrinB binding to postsynaptic EphB-receptors can regulate the clustering of NMDA receptors through interactions via the extracellular domains of the proteins. The secreted protein Narp provides a second example for an extracellular mechanism for clustering of certain populations of AMPA receptors at synapses. Another critical mechanism for synaptic trafficking of AMPA-receptors is via the Stargazin (blue)/PSD95 complex. This cartoon provides only a working model for how transsynaptic adhesion molecules might be coupling to neurotransmitter receptors. The importance of some of these interactions for synapse formation *in vivo* remains to be determined.

PSD95, however, indicate that PSD-95 is not essential for NMDA receptor localization at synapses. This means, either there are other scaffolding molecules that are more important with respect to NMDA-receptor recruitment or perhaps multiple PDZ-containing proteins have overlapping functions in this process and can substitute for the loss of PSD-95 in the mutant mice.

In a complex with another postsynaptic protein called stargazin, PSD-95 has also been implicated in synaptic recruitment of AMPA-type glutamate receptors. Mice lacking the stargazin protein have severely reduced AMPA-receptor currents in cerebellar granule cells (Chen *et al.*, 2000). Stargazin itself is a membrane protein that co-assembles with AMPA-receptors in the endoplasmic reticulum. Upon transport to the cell surface, PSD-95 might then capture these AMPA-receptor-stargazin complexes at glutamatergic synapses.

The concept that scaffolding molecules contribute to the clustering of postsynaptic neurotransmitter receptors applies to both, excitatory and inhibitory synapses. Importantly, these synapses differ not only in their neurotransmitter receptors but also in their scaffolding proteins. In fact, the scaffolding molecules

may ensure that the appropriate neurotransmitter receptors are selectively recruited to excitatory and inhibitory synapses, respectively. The scaffolding protein gephyrin represents one of the best-understood examples for the scaffold-mediated postsynaptic receptor clustering at inhibitory synapses. A host of studies, including mouse knockouts, demonstrates that gephyrin, a cytoplasmic protein associated with the glycine receptor, is essential for receptor clustering at synaptic sites (Kneussel and Betz, 2000b). Gephyrin is also concentrated at GABAergic postsynaptic sites but there it might not be absolutely essential for the recruitment of GABA receptors. Notably, gephyrin is well equipped to serve as a scaffolding protein that links receptors to the cytoskeleton; it binds with high affinity to polymerized tubulin, the actin-binding protein profilin, and the lipid-binding protein collybistin. Thereby, gephyrin may link membrane lipids, neurotransmitter receptors and cytoskeletal elements to stabilize postsynaptic specializations.

Work on glycine receptor transport also uncovered another key mechanism for regulating neurotransmitter receptor recruitment to synapses, namely that the function of the receptor itself can regulate its concentration at synapses. Pharmacological blockade

of glycine receptors with strychnine or the blockade of sodium channel dependent action potentials with tetrodotoxin (TTX) prevents postsynaptic accumulation of the receptors. Further studies on the activity-dependent glycine receptor clustering at synapses indicate that calcium influx is essential for clustering, possibly by initiating a calcium-activated signaling cascade in the cytoplasm (Kneussel and Betz, 2000a). These mechanisms may ensure the accumulation of glycine receptors only at active synapses or at synapses that release the appropriate neurotransmitter.

A second mechanism for the recruitment of postsynaptic neurotransmitter receptors that is independent of scaffolding molecules is the direct interaction of membrane and secreted proteins with the extracellular domain of neurotransmitter receptors. Receptor tyrosine kinases of the EphB-family and their cognate ligands, called ephrinB proteins, were shown to form a tripartite complex with NMDA receptors (Dalva *et al.*, 2000) (see Fig. 18.4 for more detail on Eph receptors). EphrinB-EphB interactions trigger the clustering of NMDA receptors and stimulation of EphB-receptors increases density of glutamatergic synapses in cultured neurons. The coclustering depends only on the extracellular portions of the NMDA and EphB receptors and may reflect a direct interaction between them. In addition, EphB-receptor kinase activation initiates a cytoplasmic signaling cascade which leads to phosphorylation of NMDA-receptors and increases calcium flux through these receptors (Takasu *et al.*, 2002). Studies on EphB-receptor knock-out mice support an important role in the synaptic recruitment and function of NMDA-receptors as well for the structural assembly of synapses (Pasquale, 2005). This synaptic role for the Eph-receptor tyrosine kinases provides an interesting mechanistic parallel to the role of the receptor tyrosine kinase MuSK in AChR recruitment at the NMJ.

Notably, EphB-receptors had been initially recognized for their critical roles in axon guidance and topographic mapping and in the past years novel synaptic functions have also emerged for other axon guidance receptors. This suggests that many of the proteins that function in axon guidance also contribute to synapse formation. Notably, in many cases the signaling read-out downstream of these receptors differs at the different steps of neural development: many receptors that mediate repulsive signaling during axon guidance have adhesive and stabilizing functions at synapses. How this functional switch is achieved is an important focus of ongoing work.

Besides Eph-receptors there are additional proteins that contribute to the synaptic clustering neurotransmitter receptors through extracellular interactions. One of these factors is the protein Narp (O'Brien

*et al.*, 2002). Narp is a member of the pentraxin family, extracellular components capable of head-to-head aggregation. O'Brien and colleagues discovered that Narp can interact directly with the extracellular domain of AMPA-type glutamate receptors resulting in their clustering at synapses. Because patterned electrical activity upregulates Narp expression, it may contribute to activity-dependent synapse maturation.

### Role of Neuronal Activity in Synapse Formation

Understanding how synaptic activity influences the formation and stabilization of synapses is an area of intense study. During development, each axon comes into contact with a large number of potential synaptic partners but the final connectivity pattern is remarkably selective. In the section on topographic mapping above we already discussed two principle mechanisms that might underlie selective interactions during development: Sperry's chemo-affinity hypothesis which suggested that molecular recognition labels specify the positioning and connectivity of neurons and Paul Weiss' hypothesis that neuronal activity would provide instructive information on which neurons are wired into a functional circuit. The essence of both of these hypotheses, put forward more than 50 years ago, is still very much alive and ongoing studies continue to identify wiring decisions that require synaptic activity or cell surface recognition molecules that might act as chemoaffinity tags.

It should be noted that there is evidence that synaptic activity is not absolutely required for the formation of synaptic structures during development. Ablation of Munc18-1, a key component of the presynaptic release machinery results in a complete loss of synaptic transmission but Munc18-1 knock-out mice form synaptic structures. Neurons of the null mutants fail to display evoked and spontaneous transmitter release, thereby resulting in a complete loss of synaptic transmission. Munc18-1 null mutants display apparently normal brain development during embryonic stages (Verhage *et al.*, 2000). Due to the complete loss of synaptic transmission, the mutant animals can not breathe and die at birth. This precludes an analysis of more mature synaptic networks. Nonetheless, morphological development of synaptic connections appears normal, though at later stages of embryonic development many neurons undergo apoptosis. It will be informative to examine more mature synaptic networks in conditional Munc18-1 mutants where the protein is only ablated in small populations of cells. This should clarify how far synaptic development can proceed in the absence of synaptic transmission.

Another approach to understanding activity-dependent mechanisms of synapse formation has been to search for proteins that are specifically up- or down-regulated by synaptic activity. In fact, NARP, the secreted protein discussed above that clusters AMPA receptors was originally identified in such a screen based on its upregulation with strong synaptic stimulation. Another particularly intriguing example of an activity-induced gene is CGP15, a small cell surface protein that is upregulated by activity in adult hippocampus (Nedivi *et al.*, 1998). *In vivo* expression of CPG15 increases axonal arborization by stabilizing branches and promotes the maturation of synapses, as evidenced by a precocious increase in the ratio of AMPA/NMDA-mediated currents. Moreover, CPG15 expression decreases the number of silent synapses, consistent with an early acquisition of AMPA receptors at such sites (Cantalallops *et al.*, 2000).

Many additional activity-induced genes have been identified and the analysis of their regulation and function is likely to yield important new insights into the mechanisms of synapse formation.

### Surface Recognition Molecules in the Synaptic Specificity

Understanding the molecular mechanisms of synaptic specificity is arguably the most exciting and important unresolved question in the field of CNS synaptogenesis. A leading model is that selective trans-synaptic interactions are achieved by an adhesive code. Such a code could be generated by matching expression of adhesion molecules in the pre- and postsynaptic partners that underlie a key-lock mechanism for selective interactions. The first proteins for which such a function was proposed are the cadherins, a family of homophilic adhesion molecules (Fannon and Colman, 1996). Cadherins are concentrated at CNS synapses and pre- and postsynaptic partners often contain the same cadherin family member, suggesting that the homophilic cadherin interactions may specifically link them together. Since there are 20 different ("classical") cadherin isoforms expressed in different neuronal populations these proteins could encode a number of different synaptic interactions. Recent work in the *Drosophila* visual system provided evidence for this hypothesis. Zipursky and colleagues demonstrated an important role for N-cadherin in selection of the appropriate target layer of photoreceptor axons *in vivo* (Clandinin and Zipursky, 2002). However, direct evidence for a role for cadherins in synaptic specificity in vertebrates is still lacking.

The laminar organization of the visual system has also lent itself for studies on synaptic specificity in

vertebrates. Sanes and colleagues discovered a family of proteins called Sidekicks which mediate homophilic binding (Yamagata *et al.*, 2002). As seen for the cadherins, Sidekick proteins show matching expression in pre- and postsynaptic partners and concentrate at synapses (Fig. 18.17). Misexpression of a Sidekick protein in a cell that normally does not express it is sufficient to stabilize ectopic axonal arborization on the misexpressing cells strongly suggesting that Sidekick-mediated adhesion can alter the outcome of innervation.

Another recent exciting discovery with potentially important implications for synaptic specificity was the identification of several neuronal cell surface protein families that encode hundreds or even thousands of different isoforms. The best characterized of these polymorphic surface molecules in vertebrates are related to cadherins and were initially named cadherin-related neuronal receptors (CNRs) but are now primarily referred to as protocadherins (Kohmura *et al.*, 1998). The human genome contains 52 protocadherins genes. These genes are arranged into gene clusters that are reminiscent of the immunoglobulin family (Wu and Maniatis, 1999). By alternative splicing variable exons which encode unique extracellular domains are joined to exons encoding a common intracellular domain. Thereby each protocadherin gene can give rise to numerous different recognition molecules and this molecular diversity encouraged speculations that protocadherins may encode distinct recognition events that specify synaptic connections. Ablation of a large number of protocadherin isoforms results in apoptotic cell death of neurons and a loss of synapses (Wang *et al.*, 2002; Weiner *et al.*, 2005). While it is clear that protocadherin isoforms are selectively expressed in neuronal populations, cell- and isoform-specific functions have not been identified yet.

Two families with even higher molecular diversity than protocadherins are DSCAM and the neuroligins. Like for the protocadherins, diversity is generated through a combination of expression from multiple genes and alternative splicing. In *Drosophila*, alternative splicing generates 38,016 DSCAM variants. Remarkably, all variants tested so far engage in exclusively homophilic binding, that means the DSCAM variants theoretically have the ability to encode thousands of specific cell recognition events (Schmucker *et al.*, 2000; Wojtowicz *et al.*, 2004). The functional relevance of DSCAM molecules is beginning to emerge and recent experiments suggest that DSCAM-mediated interactions in the *Drosophila* nervous system allow a cell to distinguish its own axonal and dendritic processes from those of a neighboring cell (Matthews *et al.*, 2007). While there are vertebrate homologues of

**FIGURE 18.17** Model for lamina-specific synaptic connectivity through homophilic adhesion molecules. Pre- and postsynaptic partners express the same homophilic adhesion molecules and thereby preferentially form synapses with each other. In this example, subsets of amacrine and bipolar cells in the inner nuclear layer express different isoforms of the protein Sidekick (sdk-1 or sdk-2) and form lamina-specific synaptic connections on the dendrites of sdk-1 or sdk-2-positive ganglion cells, respectively. The layered organization of the inner plexiform layer (sublaminae S1-S5) is an excellent system for the analysis of this type of synaptic specificity. In principle, other homophilic adhesion molecules such as cadherins with corresponding expression in pre- and postsynaptic partners may function in a similar manner. Adapted from Yamagata *et al.* (2002).

DSCAM, these homologues do not show a comparable diversity and it remains to be shown what aspects of DSCAM function are conserved in higher organisms.

Vertebrate neurexins encode nearly 4,000 isoforms and as observed for protocadherins and DSCAM the sequence diversity of neurexins is primarily found in their extracellular domains (Ushkaryov *et al.*, 1992). The previously characterized functions of neurexins in the organization and function of synapses (see above) make these proteins excellent candidates for synapse-specific recognition events. However, understanding the selective biochemical interactions of these proteins and their function in recognition events at synapses remains a challenge for the future.

An important conclusion derived from the characterization of the protocadherin, DSCAM, and neurexin gene families is that anatomically apparently identical cells often express different cell surface recognition molecules. This implies that within one anatomically defined cell population there might be subpopulations containing different cell surface recognition markers. While we are only beginning to understand the functional relevance of these highly diverse gene families their analysis should provide important new insights into the organization and function of neuronal networks.

### Summary

The diversity of synapses found in the nervous system is likely to be matched by an equally diverse array of mechanisms producing the synapses. These mechanisms are only now beginning to be elucidated. Prime candidates at present for synaptogenic roles include transmembrane proteins interacting with cognate receptors on the apposing cell surface (e.g., neuroligin/ $\beta$ -neurexin; SynCAM; ephrinB/EphB receptors), diffusible molecules that instruct synaptic development in target cells (e.g., FGF22, WNT-7a) or interact directly with synaptic components (e.g., Narp), membrane-attached components that act to promote maturation both pre- and postsynaptically (e.g., CPG15), and intracellular components that act locally to organize synaptic constituents (e.g., gephyrin). Testing the effects of such components *in vivo* will be a high priority in the near term. Neuronal activity is also important for certain aspects of synapse formation, but exactly how it participates and whether it employs mechanisms shared with those governing synaptic plasticity remain intriguing questions. Finally, we are beginning to identify molecular families (e.g., protocadherins and neurexins) that may contribute to

achieving the remarkable synaptic specificity found in the nervous system. Determining how specific components participate in and direct the continuing “handshake” of trans-synaptic signals governing synapse formation is one of the many challenges for the future.

## Programmed Cell Death and Neurotrophic Factors

One of the hallmarks of embryonic development is the enormous production of new cells and the acquisition of new cellular and morphological properties (phenotypes). Accordingly, in the past, a major focus of developmental neurobiologists has been the study of these progressive events, including proliferation and migration (Chapter 15), determination and differentiation (Chapter 16), pathway formation (Chapter 17), and synaptogenesis (Chapter 18). In this context, the concept of significant regressive events, such as programmed cell death (PCD), occurring during development, initially was considered counterintuitive (Oppenheim, 1981, 1991). Subsequently, however, it has been demonstrated that cell loss and other regressive events, including synapse elimination (Chapter 20) are the rule rather than the exception. In most developing tissues that have been examined in multicellular organisms, substantial cell loss occurs (Buss *et al.*, 2006). As we discuss later, even a proportion of adult-generated neurons in the hippocampus and olfactory system undergo normal PCD (Kempermann, 2006). Genetic programs that result in cell death have been suggested to be a default pathway for all cells (Raff, 1992). In this view neurons would escape this default fate only by receiving the appropriate survival signals (e.g., neurotrophic factors, NTFs) that induce changes in the molecular and biochemical events required for cell survival and neuronal differentiation. If the notion that cells are “born to die” is correct, then understanding the cellular and molecular mechanisms regulating cell death programs is critical. Aberrations in the mechanisms regulating the balance between cell proliferation and cell elimination can lead to pathologies of tissue growth and differentiation (i.e., cancer) or pathological neuronal death (e.g., neurodegenerative disease). Mechanisms that regulate the balance

between cell production and death also serve to determine the ultimate number and maintenance of neurons in the nervous system. Genes regulating these mechanisms provide an underlying substrate for evolutionary changes in brain size and structure and ultimately in adaptive behavior (Buss *et al.*, 2006; von Bartheld and Fritzsche, 2006).

Both progressive and regressive events during development are regulated by intercellular signals. Somewhat surprisingly, many of the same intercellular signals (e.g., NTFs) that contribute to the regulation of progressive events during nervous system development (cell proliferation, migration, differentiation, axonal and dendritic growth, synaptogenesis, synaptic plasticity) also contribute to the control of regressive events (cell death/survival, axon collateral and synapse elimination, dendritic pruning). Neurotrophic factors are now appreciated for their role in survival- as well as nonsurvival-related activities in both developing and mature nervous systems where they play important roles in the regulation of activity-dependent anatomical and functional plasticity of the nervous system. Accordingly, we include here a review of both survival and nonsurvival functions of NTFs.

Because neurons may die for a variety of reasons and in many different situations, it is important to describe the type of cell death observed most often in the developing nervous system. Although the loss of cells during normal development has been called by many different names (normal cell death, spontaneous cell death, naturally occurring cell death, and developmental cell death), this chapter uses the term programmed cell death (PCD). PCD is defined as the spatially and temporally reproducible and species-specific loss of large numbers of individual cells during development. Accidental, injury-induced,

pathological, and disease-related forms of cell death are not included even though we recognize that the biochemical and molecular mechanisms used to kill cells in these situations may overlap with those involved in developmental PCD. This definition of PCD also makes no *a priori* assumptions about either the morphological or the biochemical pathways by which cells die or the stimuli that trigger cell death. The use of the word “programmed” refers to the reproducible, spatiotemporally specific occurrence of cell loss and is not meant to imply that the cell loss is genetically predetermined, inherited from precursor cells, or inevitable. In fact, PCD is clearly not predetermined in most cases, but instead is critically dependent on extrinsic signals arising from diverse kinds of cellular interactions. Finally, and as we discuss in more detail later, the term PCD is not synonymous with the term apoptosis, which refers only to one specific, albeit common, mode of cell death.

### CELL DEATH AND THE NEUROTROPHIC HYPOTHESIS

Early embryological studies of the interactions between developing neurons and their peripheral targets laid the foundation for the discovery of cell death and NTFs (Cowan, 2001). These studies formed the conceptual framework for the neurotrophic (“nerve feeding”) hypothesis (Fig. 19.1). There is general consensus that the neurotrophic hypothesis and the modern history of cell death research began together in the mid-1930s (Table 19.1 and Box 19.1).

By 1949, Viktor Hamburger and Rita Levi-Montalcini had provided compelling evidence to support the significance of normal embryonic neuronal death and postulated that target-derived signals act to regulate the number of neurons that survive

embryonic development. In subsequent studies, they and their colleagues identified a specific protein, nerve growth factor (NGF), that influenced development of the same populations of neurons (sensory and sympathetic) that their earlier studies had suggested were regulated by target-derived signals (Table 19.1).

By 1960, the preparation of specific antibodies that block NGF activity allowed Stanley Cohen, Levi-Montalcini, and coinvestigators to demonstrate the almost total degeneration of sympathetic ganglia *in vivo* following the specific deprivation of NGF activity (Fig. 19.2; Table 19.1). Only with the evidence from this “immunosympathectomy” (the deletion of the sympathetic system by antibody treatment) was NGF considered to be an endogenous survival or maintenance factor for these neurons. Three decades after the original discovery that an unknown chemical substance produced by tumor cells affects the development of sensory and sympathetic neurons, it was finally recognized that NGF was the hypothetical target-derived trophic signal first postulated by Hamburger and Levi-Montalcini in 1949 to be involved in regulating the number of surviving neurons in these populations during normal development (Oppenheim, 1996). Historically then, the appreciation of the role of PCD in the developing nervous system and the discovery of the first target-derived NTF (NGF) were inextricably linked.

### THE ORIGINS OF PROGRAMMED CELL DEATH AND ITS WIDESPREAD OCCURRENCE IN THE DEVELOPING NERVOUS SYSTEM

PCD has been identified in several species of unicellular eukaryotes, including yeast, as well as in prokaryotes such as bacteria, one of the oldest forms of life on

**FIGURE 19.1** The neurotrophic hypothesis postulates that developing neurons survive (green neurons) only when they successfully compete for target-derived trophic molecules (blue) that are internalized at the nerve terminal and are transported retrogradely along the axon (arrow) to the cell body. Neurons that fail to obtain a sufficient flow of trophic molecules from the target die by programmed cell death (black neurons with condensed chromatin). Modified from Barde, 1989.

TABLE 19.1 Major Events in the Discovery and Characterization of Neurotrophins\*

1934	<i>Hamburger</i> discovered that removal of the limb bud in the chick embryo resulted in reduced numbers of sensory and motor neurons in the spinal cord and suggested that targets in the limb are the source of signals that control neuronal development and that travel retrogradely in axons to their respective centers.
1942	<i>Levi-Montalcini</i> and <i>Levi</i> showed that early limb bud removal reduced the number of sensory and motor neurons and proposed that the hypothetical target-derived signals act to maintain the survival of differentiating neurons.
1953	<i>Levi-Montalcini</i> and <i>Hamburger</i> carried out transplantation experiments with a tumor, sarcoma 180, and discovered that sympathetic and sensory ganglia remote from the tumor and not connected with it by nerve fibers were also enlarged greatly. This suggested involvement of a diffusible factor.
1954	<i>Levi-Montalcini</i> , <i>Meyer</i> , and <i>Hamburger</i> developed an <i>in vitro</i> assay that used explanted sympathetic ganglia. Ganglia cocultured with fragments of tumor cells lacking any physical contacts between the two exhibited massive outgrowth of nerve fibers (Fig. 19.2). The extent and density of outgrowth provided a rapid quantitative bioassay for subsequent attempts to isolate and purify the tumor factor.
1960	<i>Cohen</i> discovered that the salivary gland of male mice was an extremely rich source of the same growth-promoting activity found in the sarcoma 180. When an antiserum to the mouse factor was injected into newborn mice, all sympathetic neurons were lost.
1969	<i>Bocchini</i> and <i>P. Angeletti</i> described a method for the purification of biologically active NGF from male mouse submaxillary glands. This activity is the $\beta$ subunit of NGF, also known as 2.5S NGF. It has been estimated that to purify NGF from relevant target organs would have required a purification factor of 100 million, whereas a purification factor of only 100–200 was sufficient to purify NGF from the mouse salivary gland. Salivary glands from female mice or other mammals do not contain this extremely high concentration of NGF.
1971	<i>P. Angeletti</i> and <i>Bradshaw</i> identified the amino acid sequence of 2.5S NGF purified from the mouse submaxillary gland.
1982	<i>Barde</i> and colleagues isolated a novel neurotrophic factor from the mammalian brain (brain-derived neurotrophic factor) (BDNF). Unlike the original purification of NGF from a fortuitous rich source—the salivary gland—this factor was isolated from many brains by an amazing purification factor of several millionfold. BDNF was identified and isolated using an <i>in vitro</i> survival assay with sensory neurons.
1983	<i>Korsching</i> and <i>Thoenen</i> developed a sensitive two-site immunoassay, allowing for the first time the detection of NGF in target organs. With this method it was possible to demonstrate a strong correlation between the density of sympathetic innervation and target levels of NGF, a finding consistent with the neurotrophic theory.
1986	<i>Chao</i> and his colleagues identified the first neurotrophin receptor, at the time believed to be a receptor specific for NGF. The Nobel Prize in medicine was awarded to <i>Levi-Montalcini</i> and <i>Cohen</i> for the discovery of NGF and EGF.
1989	The sequencing and molecular cloning of BDNF by <i>Barde</i> and colleagues revealed a high degree of sequence homology between the new factor and NGF. This finding enabled the rapid molecular cloning and sequencing of other related <i>neurotrophins</i> containing the conserved regions without prior protein purification. These and related studies on the characterization of neurotrophins were carried out by several prominent researchers trained in Eric Shooter's lab or in Hans Thoenen's lab during the 1980s.
1990/1991	<i>Several groups</i> discovered additional members of the “neurotrophin” family by molecular cloning, including NT-3 (in several species), NT-4 (in <i>Xenopus</i> ), and NT-5 (in mammals). Research by <i>Kaplan</i> , <i>Parada</i> , and colleagues identified the trk receptor (an “orphan” receptor) as a member of a family of tyrosine kinase receptors that are specific for neurotrophins, rapidly leading to the identification of the three members trkA (for NGF), trkB (for BDNF and NT-4), and trkC (for NT-3).
1993	<i>Poo</i> and his colleagues discovered that the neurotrophins BDNF and NT-3 have rapid and substantial effects on the strength of synapses, showing for the first time that neurotrophins have important effects in regulating synaptic plasticity.
1996	Work by <i>Barde</i> and his colleagues revealed that neurotrophins can induce cell death (apoptosis) by binding to the “common” neurotrophin receptor, p75NTR.
2001	<i>Hempstead</i> and her colleagues discovered that proneurotrophins, the larger precursor forms believed to have no significant biological function, have important physiological effects.

earth (Ameisen, 2004). One likely explanation for the evolutionary origins of PCD in eukaryotes was the appropriation of cell death associated genes from bacterial mitochondria by a process of endosymbiosis. After being incorporated into the eukaryotic genome this core cell death machinery expanded in complexity

over time to include the diversity found in extant multicellular organisms (Buss *et al.*, 2006). Once the pro- and anti-apoptotic machinery was in place in the genome of multicellular animals, it could then be coopted to mediate the many diverse roles now served by PCD, including the PCD of developing neurons.

## BOX 19.1

LEVI-MONTALCINI, HAMBURGER, AND THE  
NEUROTROPHIC HYPOTHESIS<sup>1</sup>

In the early 1930s Rita Levi-Montalcini was a research associate working in the laboratory of the eminent neuroanatomist Giuseppe Levi in Turin, Italy. Viktor Hamburger sent a personal copy of his 1934 paper on wing removal to his acquaintance Levi, who shared it with Levi-Montalcini. She was inspired by the results but was dubious about the validity of the recruitment hypothesis. Together with Levi, she reexamined the effects of limb bud removal on spinal ganglia in the chick embryo. By examining embryos at regular intervals after limb removal, she showed that neuron numbers develop normally up to a certain stage, after which a gradual neuron loss ensues—a finding incompatible with Hamburger's recruitment hypothesis, which predicted a deficit of neurons immediately after limb removal. Levi-Montalcini and Levi postulated that after the loss of peripheral targets, neurons develop normally but then later regress or degenerate. In other words, peripheral targets were apparently regulating the *survival* or *maintenance*, rather than the recruitment, proliferation, or differentiation of innervating populations of neurons. That targets might act to keep neurons alive was a novel perspective that ushered in a fundamentally new line of investigation of cell death and neurotrophic factors.

Although this important paper by Levi-Montalcini and Levi was published in 1942, Hamburger first saw it after World War II. Intrigued by the novel interpretation, in 1946 he invited Levi-Montalcini to join him in St. Louis to resolve their differences. She accepted and by 1947 they had begun experiments that resulted in their first joint publication in 1949. This paper, which soon became a landmark in the history of this field, fully vindicated the original conclusion of Levi-Montalcini and Levi that regression and cell death, not the failure of recruitment, correctly explained the results of the limb removal experiments. More importantly, this same paper showed that many neurons normally die during development and that a major effect of altering target size is the perturbation of this normal regressive process. They proposed that both normal cell death and death following limb removal result from a lack of target-derived substances necessary for growth and survival. A year later, they used the term trophic or neurotrophic to designate these hypothetical signals or substances. In this context, "trophic" and "neurotrophic" refer to signals

that mediate long-term dependencies between neurons and the cells they innervate (e.g., survival) and are distinct from "tropic" and "neurotropic," which refer to diffusible chemoattractant signals derived from target cells that guide or orient the migration of other cells or cell processes (e.g., axons) toward the target. By 1950, therefore, the basic tenets of what was subsequently called the *trophic theory* were established: developing neurons are overproduced and compete for limiting amounts of target-derived molecules that provide retrograde signal(s) for their survival. Despite this early conceptual breakthrough it would be more than 30 years before convincing evidence in support of all the tenets of the trophic theory was available.

Historically, the prospect of large losses of cells during normal development was conceptually unpalatable to most biologists. Early in the 20<sup>th</sup> century, German anatomists M. Ernst and A. Glücksmann and the French anatomist R. Collin described widespread cell death in the nervous system, but their observations either went unrecognized or were ignored by other investigators of this period. For this reason, the description of normal neuronal death and its proposed role in neuron-target interactions by Hamburger and Levi-Montalcini marked a watershed in the history of this field. Although it would be many more years before cell death was fully accepted as a fundamental process in nervous system development, after 1949 it was no longer possible to exclude it completely from consideration in discussions of the development of neuron-target interactions. Additionally, for the first time it also became possible to conceive of chemical substances (trophic factors) as the source of signals that regulate developmental events in the nervous system such as neuronal survival. Therefore, although Hamburger and Levi-Montalcini were not the first to observe normal cell death in the nervous system, they were the first to draw attention to its significance; they were the first to provide a plausible explanation for its occurrence; and they were the first to postulate a possible mechanism for its regulation. For these reasons, they deserve equal credit along with Collin, Ernst, and Glücksmann as pioneers in the history of this field.

**FIGURE 19.2** Biological activity of nerve growth factor (NGF). Explanted sensory and sympathetic ganglia or dissociated neurons were used in bioassays detecting neurotrophic activity. (A) Control ganglion 24h in culture without NGF and (B) experimental ganglion 24h after NGF treatment. Treatment with NGF (100 ng/ml) causes the formation of a "halo" of axonal growth from sensory neurons in the ganglion. Why the factor was named NGF is obvious. Reprinted with permission from Levi-Montalcini. (C and D) Experimental immunosympathectomy. Antibodies that selectively block NGF activity were administered to newborn mice to deprive the developing animals of endogenous factor. Sympathetic ganglia were examined several weeks after the treatment. Note the marked atrophy of the entire sympathetic chain ganglia (lower in C) and the almost complete loss of sympathetic neurons in a histological section of a single ganglion (right side in D) after antibody treatment. Controls are in the upper part of C and on the left in D. Photographs kindly provided by Viktor Hamburger and Rita Levi-Montalcini.

Although a systematic taxonomic survey of all representative species with a nervous system has not been done, nonetheless, the available evidence is consistent with the idea that some PCD of developing neurons occurs in all such organisms (Buss *et al.*, 2006). For many invertebrate and vertebrate species, the PCD of neurons involves virtually all regions and cell types in the central and peripheral nervous system. Motoneurons, sensory neurons, autonomic neurons, and both long projection and local circuit interneurons in the brain and spinal cord all undergo restricted periods of PCD (Buss *et al.*, 2006). Although the magnitude of neuronal cell death varies from population to population, as many as one-half or more of all cells in a population will die during development (Fig. 19.3). In some special cases, such as the loss of transient neuronal structures during insect and amphibian metamorpho-

**FIGURE 19.3** Changes in the number of developing lumbar spinal motoneurons in the chick embryo (in red) compared to the number of dying motoneurons (in blue) during the first half of the 21 day incubation period. Approximately 50–60% of these motoneurons undergo PCD between Embryonic day (E)6 and E12.

**FIGURE 19.4** Schematic illustration of some key steps in neuronal development. Neurons undergoing PCD (●) are observed during neurogenesis in the ventricular zone, during migration and while establishing synaptic contacts. Schwann cells in developing nerves also undergo PCD. ♯ Represents peripheral glial (Schwann) cells; ● represents CNS glia (astrocytes, oligodendrocytes); ⊕ represents surviving, differentiating neurons (e.g., motoneurons whose targets are skeletal muscle and other neurons in the CNS, with neuronal targets).

sis (e.g., the Rohon-Beard sensory neurons in fish and frogs), most or all cells die. Cell death in the nervous system thus clearly occurs on a very large scale, indicating that it plays a fundamental and essential role in normal development.

Studies of cell death in the nervous system have focused on the loss of developing postmitotic neurons as they form synaptic connections with targets and afferents. However, extensive PCD also occurs during neurulation and in mitotically active progenitor cells, as well as in postmitotic but undifferentiated neurons in the early neural tube (Fig. 19.4). Accordingly, PCD in the nervous system is not limited to any particular stage of development. The loss of cells at different

FIGURE 19.5 The PCD of glial cells is regulated by axonally derived signals. Glial cells that fail to compete successfully for these signals undergo PCD.

developmental stages probably serves distinct functions and may be mediated by different mechanisms (Oppenheim *et al.*, 2001). PCD also occurs in central and peripheral glial cells. For example, many myelin-forming oligodendrocytes in the optic nerve and Schwann cells in peripheral nerves die by PCD. Their loss is thought to reflect a competition for axon-derived trophic signals, the end result of which is the survival of an appropriate number of glial cells for optimum myelination of the available axons (Fig. 19.5). Because glial PCD has been studied much less extensively, it is not known whether the death of other nonneuronal cells in the nervous system (e.g., astrocytes or microglia) is as common as the death of neurons.

Because PCD is the normal differentiated or terminal fate of many developing cells, commitment to this fate occurs in much the same way as the phenotypic fate of cells destined to survive in the embryo. Developmental biologists have identified two major ways in which the commitment of a cell to a particular differentiated phenotype occurs (Gilbert, 2006). The first mechanism, intrinsic or *autonomous specification*, involves the segregation of critical cytoplasmic molecules by asymmetric cell division (Fig. 19.6); cell death thus is programmed into the lineages that generate somatic cells. The second mechanism of commitment involves extrinsic signals from other cells and is called *conditional specification*. Initially, the cells have the potential to follow more than one path of differentiation. As development proceeds, however, signals from

FIGURE 19.6 Schematic illustration of the phenotypic determination of the progeny of dividing precursor cells by autonomous vs. conditional specification. The red and green symbols represent hypothetical cytoplasmic molecules (e.g., mRNAs) whose relative expression in this example specifies survival or death.

other cells act to gradually limit and specify cell fate. Although all organisms use a combination of autonomous and conditional developmental strategies, as a general rule invertebrates are more likely to utilize autonomous specification, whereas most vertebrates exhibit conditional specification. Despite this distinction, as described later, many of the genetic and molecular pathways for PCD are remarkably similar in invertebrates and vertebrates.

### Summary

The PCD of developing neurons appears to occur in virtually all vertebrate and invertebrate species. More generally, PCD also occurs in many different cells and tissues of unicellular and multicellular organisms and thus may have arisen very early during evolution. With few exceptions, PCD occurs in virtually all types of developing neurons and can take place at stages of development from the time of proliferation until the establishment of synaptic connections. Developing glial cells also exhibit PCD. Cell death is the terminal phenotypic fate of subpopulations of developing neuronal and glial cells and, like other cell fate decisions, is controlled by both intrinsic and extrinsic signals.

## FUNCTIONS OF NEURONAL PROGRAMMED CELL DEATH

Why does PCD occur? This is a reasonable question to ask because the loss of large numbers of developing neurons is counterintuitive. Why should embryos invest precious resources in generating cells and tissues only to later cast many of these aside? A satisfactory answer to this apparent paradox requires an evolutionary perspective that addresses two central aspects of the problem. First, how did the biochemical machinery (the cell death program) needed to actively kill cells arise? Second, why, in many developing tissues, are more cells generated than are apparently needed? Because PCD acts to delete these excess cells, an understanding of the overproduction is critical if one is ever to understand cell death from an evolutionary perspective. The first question was addressed in the previous section; however, understanding the evolution of the biochemical cell death program does not help answer the second question of why there is often a massive overproduction of neurons during development that are later eliminated by PCD. Two explanations have been offered (Oppenheim, 1991). First, each case of PCD may have evolved to serve a distinct biological function. For example, according to this view,

in the case of spinal motoneurons, natural selection is thought to be directly responsible for both the overproduction and the subsequent death of neurons as a means for creating an optimal (adaptive) level of functional muscle innervation (e.g., systems-matching).

The second view is that the overproduction of neurons (or other cells) is an inevitable outcome of the imprecise kinetics of proliferation of precursor cells. Once excess cells are available and the pro- and anti-apoptotic machinery is in place, however, natural selection then acts via regulated cell survival and death to mediate a variety of different adaptive needs. For example, following the loss or absence of essential survival signals, the death of excess cells could be accomplished easily by coopting the cell death machinery that evolved to kill cells in early eukaryotes. In reality, both of the proposed mechanisms may occur. For example, it seems highly likely that the creation of transient structures that function at one stage of development but later regress and are discarded (e.g., the tail of tadpoles, larval muscles of insects, and transient neuronal structures such as sensory Rohon-Beard cells in frogs and fish) reflects the direct selection of PCD as a means for mediating adaptive life history transitions (e.g., metamorphosis). In contrast, the presence of increased numbers of neurons in limb versus nonlimb spinal segments of vertebrates may result from the unselected outcome of an overproduction (proliferation) of neurons at all spinal levels, followed by increased survival in limb compared to nonlimb regions.

Many of the circumstances in which the PCD of neurons occurs are thought to mediate distinct adaptive functions, as summarized in Table 19.2. In many of these examples, the production of excess neurons provides a substrate on which differential survival or PCD can then act to meet a variety of adaptive needs. Although the biological functions attributed to PCD in these situations are quite plausible, some of them have not been directly demonstrated experimentally to serve a specific adaptive role. As new genes are identified that regulate PCD, and as we gain a better understanding of how cellular and molecular signals control cell death and survival, there will be increased opportunities for preventing PCD in select neuronal populations *in vivo* and directly assessing whether its occurrence is, in fact, adaptive (Buss *et al.*, 2006).

### Summary

The biochemical and molecular pathways that regulate cell death and survival arose early in the evolution of animal life. Once this cellular capacity arose, however, it is likely that it was coopted to serve a variety of biological functions. In the nervous system,

TABLE 19.2 Some Possible Functions of Developmental PCD in the Nervous System\*

1. Differential removal of cells in males and females (sexually dimorphic spinal motor nucleus in many mammals).
2. Deletion of some of the progeny of a specific sublineage that are not needed (loss of specific progeny of the AB blastomere that is involved in generating ring ganglia in *C. elegans*).
3. Negative selection of cells of an inappropriate phenotype (ligand/receptor-induced cell death in the early chick embryo retina?).
4. Pattern formation and morphogenesis (neurulation/neural tube closure; differential thickness of cortical layers).
5. Deletion of cells that act as transient targets or that provide transient guidance cues for axon projections (death of pioneer neurons/glia in insects).
6. Removal of cells and tissues that serve a transient physiological or behavioral function (loss of Roh-Beard sensory neurons during metamorphosis in frogs).
7. "Systems"-matching by creating optimal quantitative innervation between interconnected groups of neurons and between neurons and their targets (see text and Fig. 19.4).
8. Systems-matching between neurons and their glial partners by regulated glial PCD (Schwann cells and peripheral axons; see Figs. 19.5 and 19.15).
9. Error correction by the removal of ectopically positioned neurons or of neurons with misguided axons or inappropriate synaptic connections (loss of ipsilaterally projecting retinal ganglion cells).
10. Removal of damaged or harmful cells (death of cells with DNA damage).
11. Regulation of the size of mitotically active neural progenitor populations (see text and Fig. 19.4).
12. The production of excess neurons may serve as an ontogenetic buffer for accommodating mutations that require changes in neuronal numbers in order to be evolutionary adaptive (evolutionary increases in limb size may require increased sensory and motoneuron survival).
13. Regulated survival of subpopulations of adult-generated neurons as a means of experience-dependent plasticity (see text and Fig. 19.18).

\*For references see Buss *et al.*, 2006; Oppenheim *et al.*, 2001.

some major functions include establishing optimal levels of connectivity between neuronal populations, eliminating aberrant cells or connections, regulating the size of progenitor populations, and serving transient functional or other needs of immature animals.

### MODES OF CELL DEATH IN DEVELOPING NEURONS

The specific morphological appearance exhibited by degenerating neurons can provide insight into the cellular and molecular mechanisms by which the cells are destroyed. Historically, pathologists were the first to be interested in this issue, and they focused on distinguishing different kinds of cell and tissue degeneration following disease, injury, and trauma (Clarke and Clarke, 1996). Over 125 years ago, the term necrosis was coined to describe what today comprises the major form of accidental or pathological degeneration. The pathological necrotic death of neurons following injury usually involves the degeneration of groups of contiguous cells in a region that initiates an inflammatory response that can be discerned easily in tissue sections (Fig. 19.7). At about the same time that necrosis was first described, however, another form of cell degeneration, called spontaneous cell death, was observed

in normal adult mammals. Spontaneous cell death (now called PCD) was thought to provide a means for counterbalancing mitosis in adult tissues in which the turnover of cells normally occurs. PCD typically involves the sporadic loss of individual cells in a population that often degenerate by a different mode from necrosis, one that does not involve inflammation. Early steps in the spontaneous PCD cascade leading up to when histological signs of frank degeneration first occur may take many hours or days. Once that point is reached, however, the degenerative process is rapid, with individual cells dying and being removed in minutes or a few hours. The loss of thousands of neurons over several days is the consequence of many rapid individual cell deaths that at any moment in time represent only a small minority (~1%) of all the cells in the population. For this reason, historically, the occurrence and magnitude of even massive PCD can (and often did) go unnoticed.

Two different strategies can be used to quantify neuron death: One can determine the total number of neurons at different stages and quantify the decrease (Fig. 19.3), or one can determine an increase in the number of dying (pyknotic) cells during the period of PCD and determine the timing and (with less precision) the extent of cell death (Fig. 19.7). The counting of neurons originally was done by counting profiles in thin sections and application of correction factors to

**FIGURE 19.7** Spinal motoneurons in the chick embryo. (A) Ventral horn from a control embryo. Note that only two cells (asterisks) are undergoing apoptotic PCD; the others appear normal (arrows). (B) Ventral horn from an embryo following treatment with an excitotoxin. Most neurons are undergoing a necrotic type of cell death (asterisks) whereas some appear normal (arrows). Apoptotic (C) and necrotic motoneurons (D) in the chick embryo spinal cord as seen with an electron microscope.

account for multiple profiles per particle (Clarke and Oppenheim, 1995); such counting is now increasingly replaced by stereological methods that count particles in thicker sections, a method that is less affected by confounding changes in particle size but that still presents challenges due to other sources of potential errors if not executed properly (Schmitz and Hof, 2005).

Until quite recently, cell degeneration in adult and developing tissues generally has been dichotomized into death by either apoptosis or necrosis, a distinction based initially on morphological differences and later on other apparent differences between the two (Fig. 19.8). *Apoptosis* is a Greek word indicating the seasonal piecemeal dropping of leaves from a tree and originally was coined to describe all forms of PCD that share certain morphological characteristics. Cells dying by apoptosis shrink in size and the nuclear chromatin condenses and becomes pyknotic, whereas the cell membrane and cytoplasmic organelles tend to remain relatively intact. Eventually the cytoplasm and nucleus break up into membrane-bound apoptotic bodies that

are phagocytized either by professional phagocytes (macrophages) or by healthy adjacent cells (e.g., glia that serve as transient phagocytes). In contrast, necrosis involves an initial swelling of the cell, only modest condensation of chromatin, cytoplasmic vacuolization, breakdown of organelles, and rupture of the cell membrane allowing the release of cellular contents (causing inflammation), followed by shrinkage and loss of nuclear chromatin. Because necrotic cell death elicits an inflammatory response in adjacent tissue, macrophages derived from the immune system attack and phagocytize cellular debris. In contrast, cell death by apoptosis usually involves individual cells that are engulfed and phagocytized before they can release their cellular contents or induce an inflammatory response in adjacent tissue. Phagocytes recognize dying cells by their expression of death-related cell surface signals.

Another feature that has been used to distinguish between apoptotic and necrotic cell death is the occurrence during apoptosis of a specific form of chromosomal DNA fragmentation and degradation that is

**FIGURE 19.8** Schematic representation of cellular changes during necrotic cell death and during three of the most common types of PCD observed at the ultrastructural level. Only type 1 PCD meets most of the criteria for defining apoptosis. The cells on the right marked P represent phagocytic cells engulfing necrotic cell corpses and apoptotic bodies. Phagocytosis also occurs in the other types of PCD but is not shown.

mediated by DNA-specific proteases. DNA digestion occurs at internucleosomal sites, producing small, double-stranded fragments of DNA that migrate in a ladder pattern in multiples of 180–200bp after electrophoresis in agarose gels. This form of DNA fragmentation can also be visualized in tissue sections by a technique that labels the double-stranded DNA breaks associated with apoptosis.

It is widely believed that apoptosis and necrosis reflect mechanically distinct cell death pathways that are triggered by different stimuli. However, our basic understanding of these pathways is still limited, and caution should be exercised in drawing too fine of a distinction between them. For example, a variety of toxic and traumatic stimuli, previously thought to induce necrosis, can also induce morphological signs of apoptosis and may be associated with changes in PCD- or apoptosis-associated genes (Bredesen *et al.*, 2006). Necrotic cell death may also occur by a distinct molecular pathway that involves endogenous release of calcium. The PCD of developing vertebrate neurons provides a striking example of the problems encountered in attempting to rigidly classify the pathway of degeneration as being either necrotic or apoptotic (Clarke, 1990; Bredesen *et al.*, 2006). Developing neurons may adopt one of at least three different

morphological modes during PCD: (1) apoptotic, (2) autophagic, and (3) cytoplasmic (Fig. 19.8). Only the first fits the classic morphological definition of apoptosis. Inhibition of the apoptotic mode of PCD often results in death of cells by alternative pathways (e.g., autophagic). Despite the occurrence of these different morphological types of death, it is clear that they all reflect normal PCD, as they involve the stereotypic loss of individual cells at specific times during development in the absence of injury or inflammation. Within the context of the developing nervous system, the dichotomy of apoptosis versus necrosis is an oversimplification that should be abandoned. Instead, developing cells undergoing normal PCD as well as neurons dying following injury should be categorized by operational definitions that use morphological, genetic, and biochemical criteria (Bredesen *et al.*, 2006; Blomgren *et al.*, 2007). As described in the following section, one of the major success stories begun in the early 1990s has been the remarkable progress made in understanding the biochemical pathways of PCD and identifying the specific genes involved.

## Summary

Historically, degenerating cells have been categorized into two classes: death by apoptosis or death by necrosis. Although the situation is more complex than is reflected in this simple dichotomy, apoptosis in general is more characteristic of PCD, whereas necrosis is more characteristic of cells that die following injury or trauma. A variety of morphological, biochemical, and molecular features have been used to distinguish between these two types of cell death. However, the occurrence of certain features of apoptosis in neurons following injury and the occurrence of several types of PCD other than apoptosis indicates that a more accurate means of identifying and defining distinct forms of cell death should now be employed.

## THE MODE OF NEURONAL CELL DEATH REFLECTS THE ACTIVATION OF DISTINCT BIOCHEMICAL AND MOLECULAR MECHANISMS

As described previously, the normal death of cells in the developing nervous system has long been thought to be regulated by competition for NTFs (the Neurotrophic Hypothesis). Until quite recently, investigators agreed that the doomed neurons, lacking sufficient amounts of a NTF to sustain normal metabolic events, passively degenerated by a process analogous

to starvation. However, PCD of some nonneuronal cells was known previously to be a metabolically active, ATP-dependent process. For example, it had been shown that RNA or protein synthesis inhibitors prevent the programmed death of muscle cells in metamorphic insects and amphibians and also block the hormone-induced death of thymocytes in the mammalian immune system. Additionally, in the early 1980s, genetic mutations in the nematode worm *Caenorhabditis elegans* that prevent PCD had been described, thereby providing further evidence that neuronal death is a genetically regulated, metabolically active process. Beginning in the late 1980s, these various lines of evidence forced a reappraisal of the view that cell death in the nervous system is a passive process and led to the demonstration that for many types of neurons, PCD is regulated by the interaction of specific genetic programs that either inhibit or induce degeneration. Neurotrophic survival molecules are thought to act as extracellular signals that when present in sufficient amounts result in intracellular signaling that either inhibits the expression or activity of pro-apoptotic genes or induces the expression or activity of anti-apoptotic gene products. Considerable progress has been made since the early 1990s in identifying cell death-associated genes and their pathways of action. Due to historical precedent, these have been classified as pro- and anti-apoptotic genes. Although we retain this terminology, in some instances the genes involved may actually induce both apoptotic and non-apoptotic modes of degeneration (see the previous section).

Although early genetic studies of cell death in *C. elegans* demonstrated that PCD is regulated by specific genes, the first indication that the PCD of developing vertebrate neurons may also be controlled by similar so-called “killer” or “death” genes appeared in 1988 (Johnson and Deckwerth, 1993). Cultured neonatal rat sympathetic neurons, which normally require NGF for survival, remain viable following NGF removal if mRNA or protein synthesis inhibitors were added to the cultures. Subsequently, other types of developing neurons also were shown to be rescued by these drugs both *in vitro* and *in vivo* following trophic factor deprivation. These findings were interpreted as evidence that one or more steps in the neuronal PCD pathway requires the *de novo* transcription of genes and the regulated expression of proteins that actively destroy the cell. Because the genetics, morphology, and cell lineages in *C. elegans* have been so well defined, this organism provides a particularly informative and powerful model for analyzing the molecular genetics of PCD (Horvitz, 2003). Of the approximately 1000 somatic cells generated (of which 302 are neurons and

56 are glial cells), 131 undergo embryonic PCD and many of these are neuron precursors. In each individual, the same cells die at specific times in development and these corpses are then engulfed and degraded by neighboring cells. Despite the enormous evolutionary gap that separates the appearance of worms, flies, and vertebrates, significant homology exists in the structure and function of specific cell death pathways between these taxonomic groups.

As summarized in Figure 19.9, there is a sequential cascade of genetically regulated steps involved in PCD. Upstream of the actual execution of the death process, transcription factors specify certain cell types for death while sparing others. In *C. elegans*, manifestation of the death fate requires expression of two pro-apoptotic genes, *ced-3* and *ced-4* (*ced*, cell death), which together mediate the actual breakdown of cellular constituents. Prevention of cell death induced by *ced-3* and *ced-4* can occur by activation of the anti-apoptotic gene *ced-9*. Separate genes, such as nuclease-1 (*nuc-1*), are required for the degradation of DNA in dying cells, and several additional genes are involved in the recognition and engulfment of dead cellular corpses by phagocytes. Evidence for the involvement of this genetic cascade in cell death and survival in *C. elegans* comes from several different approaches, most notably from genetic studies of loss-of-function mutants. For example, in the absence of *ced-9*, many cells that normally survive die, whereas in the absence of *ced-3* or *ced-4*, all PCD is prevented.

Identification of the DNA sequences of the major cell death genes *ced-3*, *ced-4*, and *ced-9* in the worm in the 1980s and early 1990s resulted in the subsequent discovery of vertebrate and insect homologues that serve similar functions (Kornbluth and White, 2005; Johnson and Deckwerth, 1993) (Fig. 19.9). In mammals, *ced-3* is represented by a large family of related cysteine proteases called caspases, whereas *ced-4* is represented by a single vertebrate homologue, Apaf-1 (apoptosis protease activating factor), that is required for caspase activation. The survival-promoting function of *ced-9* originally was represented by a single vertebrate homologue, *bcl-2* (B-cell lymphoma-related gene), but subsequently other *bcl-2* family members have been identified with similar anti-apoptotic functions (e.g., *bcl-x*) as well as other *bcl-2* family members that are pro-apoptotic (e.g., *bax*, *bak*, *bim*). Loss-of-function mutations in mice by targeted gene deletion (gene knockout) of many of these vertebrate homologues have confirmed their role as important regulators of PCD.

This increased genetic complexity in vertebrates in general and in neurons in particular probably reflects a need for multiple levels of control of death and sur-

**FIGURE 19.9** (A) Schematic representation of the major steps in the developmental PCD pathway of neurons in the nematode worm *C. elegans*. (B) The evolutionary conserved core cell death pathway in three diverse species. The role of structurally or functionally homologous genes in the three species are indicated by color coding. Transcription factors such as *ces-1*, *ces-2*, and *tra-1* that specify cell fate in worms have not yet been identified in developing fly or vertebrate neurons. In the worm, these act upstream of *Egl-1* but only on specific, not all, cells that die. *Ces-1* directly represses *ces-2* and thereby blocks *ces-1* from preventing *Egl-1* activation. *Tra-1* can also prevent *Egl-1* activation. *Egl-1* is pro-apoptotic by its role in preventing *ced-9* from preventing *ced-4* from inducing the killing activity of *ced-3*. In the mouse, once neurons are selected to undergo PCD (e.g., by failure to obtain NTF support), the pro-apoptotic gene *Bax* interacts with and inhibits the anti-apoptotic gene *Bcl-2* in mitochondria. This results in the release from mitochondria of cytochrome-c, which forms a complex with *Apaf-1* and *caspase-9* that in turn activates downstream caspases such as *caspase-3* that ultimately directly or indirectly degrade both the nucleus and diverse cytoplasmic targets. These degradative changes are what define apoptosis and that result in eventual engulfment and phagocytosis of the apoptotic cell. In some situations two additional molecules released from mitochondria (along with cytochrome-c) are the pro-apoptotic proteins *AIF*, that can degrade the nucleus independent of caspases, and *Smac*, which can inhibit *IAP* and promote the apoptotic pathway via *caspase-9* and *caspase-3*. Although not shown here, in some situations developing neurons undergoing PCD activate cell cycle proteins that also serve a signaling function required for apoptosis (Copani *et al.*, 2001). Part A modified and redrawn from Horvitz (2003). Part B modified and redrawn from Sanes *et al.* (2006). For additional details including definitions of abbreviations see Bredesen *et al.* (2006), Horvitz (2003), Kornbluth and White (2005), and Johnson and Deckworth (1993).

vival at the cellular level. It also provides for diverse pathways of PCD in different cells and tissues, at different stages of development, and in response to different death and survival signals. In some neurons, NTFs and other extracellular signals may induce death rather than promote survival by binding to so-called death receptors. For example, immature cells in the retina may be induced to die following activation of the common neurotrophin receptor (p75NTR) by NGF, and PCD in this situation involves intracellular pathways partly distinct from those used when neurons die following the loss of neurotrophic support. Additionally, although apparently not a common occurrence, neighboring nonneuronal cells (e.g., microglia) may actively participate in the PCD of developing neurons.

A central integrator of cell death in vertebrates is the mitochondrion (Fig. 19.9). By monitoring the relative expression and activation of pro- and anti-apoptotic family members (e.g., bcl-2, bax), the mitochondrion modulates cell survival by the regulated release of molecules (e.g., cytochrome c) that activates the downstream cell death machinery (e.g., caspases). Although the evidence for the role of mitochondria in regulating PCD in flies and worms is less clear than for vertebrates, it seems likely that mitochondria or other intracellular organelles (e.g., the endoplasmic reticulum) are involved as key control points for death or survival. Most developing neurons appear to share a core cell death program, but there is also increasing evidence that alternative, mitochondrial-independent and caspase-independent pathways may exist for mediating the normal PCD of some neurons. In addition to the increased complexity in vertebrates of the core pro- and anti-apoptotic machinery, a variety of additional biochemical and molecular mechanisms have been described that are involved in pathological, injury-induced forms of PCD/necrosis in the vertebrate nervous system (Bredesen *et al.*, 2006; Blomgren *et al.*, 2007; Vila and Przedborski, 2003).

### Summary

PCD is a metabolically active process that involves specific genetic pathways necessary for the cascade of events leading to degeneration. Several genes in the PCD pathway were first identified in *C. elegans* and homologues have been found in insects and vertebrates. The mitochondrion is a central integrator of cell death signaling. Although most developing neurons appear to share a common core PCD pathway, morphological and biochemical evidence also indicates the presence of alternatives to the core PCD machinery. One goal of the increased evolutionary

complexity in the regulation of neuronal PCD is the need for additional checks and balances before a cell passes the irreversible point of commitment to die. Because virtually all neurons are postmitotic and neuron numbers finite, multiple, relatively fail-safe, mechanisms are required so that accidental death occurs only as a last resort.

### NERVE GROWTH FACTOR: THE PROTOTYPE TARGET-DERIVED NEURONAL SURVIVAL FACTOR

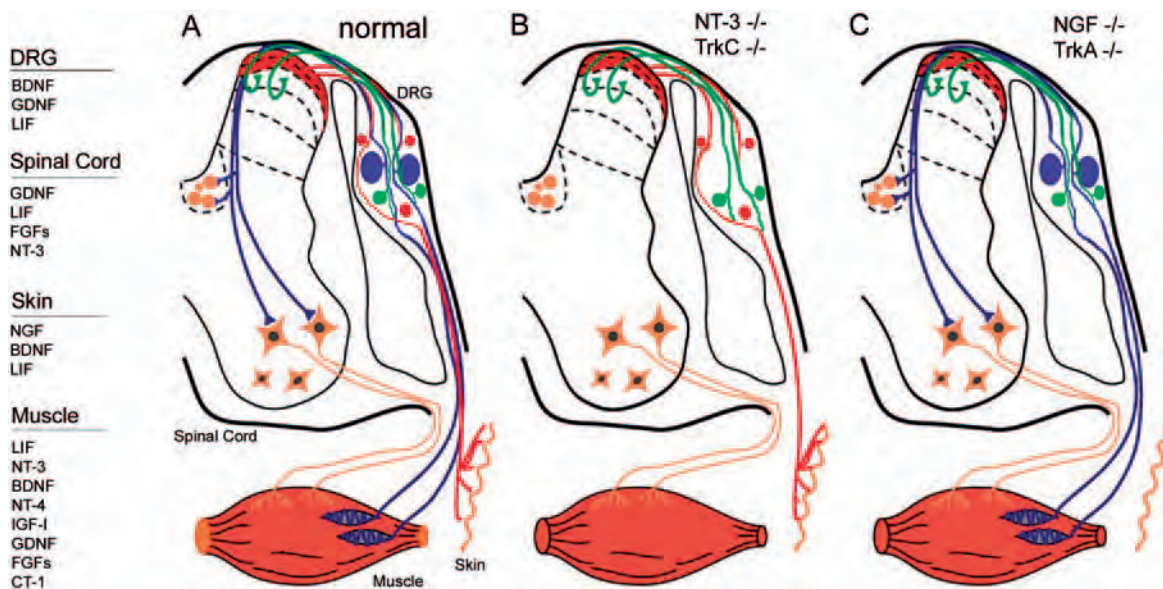

Following the discovery of NGF by Levi-Montalcini, Cohen and Hamburger in the 1950s and 1960s, and its possible role in the survival of developing sympathetic neurons (Table 19.1, Box 19.1), the characterization of the functional role of NGF became the archetypical model for the investigation of other putative NTFs—but other NTF families are also important as discussed later. Analysis of the function(s) of a putative NTF involved several steps. Typically, the biological activities and target cell specificity of putative factors were first investigated *in vitro*. Primary cultures of neurons dissociated from peripheral ganglia were ideal for these early assays. Analysis of the developmental expression of specific NTFs and their corresponding receptors has been used to determine if both the ligand and the receptor are normally present at the appropriate time and place for the putative factor to serve in the regulation of a specific subpopulation of neurons. In gain-of-function approaches, treatment of embryos with excess exogenous NTF has been used to determine if the survival or differentiation of responsive neurons is restricted by either the production or the access to a limited quantity of endogenous factor. Finally, in loss-of-function approaches, methods that inhibit or prevent the function of specific NTFs or their receptors have allowed investigators to determine whether the perturbation of endogenous NTF signaling alters normal development. These factor/receptor deprivation experiments have included treatment with activity-blocking antibodies that prevent trophic signaling, treatment with soluble receptor-derived antagonists that compete for and adsorb endogenous ligands, and the generation of transgenic mice with null mutations of either the factors or their receptors.

Sympathetic and sensory ganglia removed from developing animals have been shown to produce a dense halo of axonal outgrowth when treated with NGF (Fig. 19.2). In fact, this “axonal halo” assay—not a neuronal survival assay—was the original biological activity first used to purify and characterize NGF as a

NTF. NGF was shown to be required for the survival of dissociated sympathetic and some sensory neurons when they were grown in the absence of nonneuronal cells. This demonstrated that NGF could prevent cell death by the direct activation of receptors on isolated neurons. When developing embryos were treated with excess exogenous NGF, sympathetic and sensory ganglia were enlarged significantly, and axonal growth from these neurons increased markedly. In addition, ganglia in NGF-treated embryos contain many more neurons than normal, because naturally occurring cell death had been prevented. The soma was enlarged significantly by NGF treatment, and the dendritic arbors of sympathetic neurons were more complex. These studies indicated that the supply or access to endogenous NGF in sympathetic and sensory targets was likely to be rate limiting for the survival and growth of these dependent populations. The most convincing evidence that NGF is required for neuron survival has been gained from NGF deprivation experiments. Embryos treated with antibodies that selectively block NGF activity as well as the null mutation of either NGF or its *trkA* receptor in transgenic mice have both confirmed that sympathetic as well as some sensory neurons require NGF for survival (Fig. 19.10). NGF was localized to the peripheral targets of these neurons at the time of their normal innervation, con-

sistent with its role as a target-derived survival factor. Further, the level of NGF synthesis was correlated with the density of target innervation, and the NGF receptor, *trkA*, was localized to dependent afferent neurons at the times and places appropriate for regulating normal PCD. The localization of NGF synthesis in sympathetic targets and the loss of these afferent neurons with NGF deprivation firmly established NGF as a prototype target-derived NTF required for the survival of sympathetic neurons and a subset of sensory neurons.

One prediction of the neurotrophic hypothesis is that access to NGF in only the distant target region is adequate to support the survival of the remote cell body. This idea has been tested by Robert Campenot and colleagues *in vitro*. NGF has been applied selectively only to local axon terminals in a three-compartment tissue culture chamber to determine the long- and short-range effects of NGF treatment. NGF-dependent neuronal cell bodies in the central chamber survived when only their terminals were treated with the factor, indicating that target-derived NGF available only to neurites can generate and retrogradely transport the signaling required for cell body survival. Peripheral processes were lost rapidly and selectively in outer chambers where NGF was withdrawn, but were maintained and grew in the outer chambers where NGF was

**FIGURE 19.10** Phenotypic alterations in sensory/motor pathways caused by null mutations in NGF/*trkA* and NT-3/*trkC*. In the dorsal root ganglia (DRG) of normal mice (A), small-diameter (red), medium-diameter (green), and large-diameter (blue) neurons are present. Large-diameter neurons innervate muscle spindles and other proprioceptive end organs and have axon terminations in the lowest laminae of the dorsal horn and in the ventral horn. These neurons are lost when NT-3 or *trkC* is absent (compare A and B). Many of the small-diameter neurons innervate skin, respond to temperature and pain, and have terminations in the dorsal-most laminae of the dorsal horn. These neurons are lost when NGF or *trkA* is absent (compare A and C). DRG neurons indicated in green are neurotrophin-independent mechanoreceptive neurons (peripheral projections not shown). Modified and redrawn from Snider (1994).

**FIGURE 19.11** Models of NGF, the catalytic (full-length) TrkA receptor, and p75NTR and its binding partners (sortilin, Nogo receptor and Lingo 1). Note the ability of one ligand (NGF) to bring together two trk receptor molecules to initiate signaling. P75NTR lacks a cytosolic kinase domain, but associates with partners (including trk receptors, interaction not shown) to assemble signaling platforms. Note that the NGF dimer binds to a p75NTR monomer in an opposite orientation compared to TrkA. C1, C2, cysteine clusters 1, 2; Ig1, Ig2, IgG-like domains 1, 2; LRR, leucine-rich repeat; CRD 1–4, cysteine-rich domains 1–4. Modified from McDonald and Rust (1995) and Barker (2004).

added. This important demonstration illustrates the capacity of target-derived NGF to have both direct long distance effects on the survival of neurons and direct local effects on the growth, maintenance, and sprouting of axonal branches. NGF-responsive neurons possess both a “ligand-specific” receptor, *trkA*, and a “common” receptor, *p75* (Fig. 19.11) that binds all neurotrophins with a similar affinity. Many of the biological activities of NGF have been attributed to the ligand-induced transduction of *trkA*.

### Summary

The modern study of neuronal cell death began with investigations of how synaptic targets of sensory and motor neurons regulate their development. Viktor Hamburger and Rita Levi-Montalcini, beginning in the 1930s, ultimately showed that targets promote the survival and maintenance of innervating neurons. This notion, in turn, provided a conceptual framework for the discovery of the first target-derived NTF, nerve growth factor. From these beginnings, the neurotrophic hypothesis was formulated: neurons compete for limiting amounts of target-derived survival promoting (trophic) agents during development. NGF was established as the prototypical target-derived NTF.

### THE NEUROTROPHIN FAMILY

Only a few subpopulations of peripheral neurons, including sympathetic and some sensory neurons, are exclusively dependent on NGF for survival during development. While cholinergic neurons in the mammalian basal forebrain and noradrenergic neurons in the avian locus coeruleus are NGF responsive, the survival of CNS neurons is largely unchanged following the null mutation of NGF. Other survival factors are now known to regulate neuron survival elsewhere in the nervous system. Extracts made from a number of tissues, as well as media containing proteins secreted by a variety of cultured neuronal and nonneuronal cells, all have been shown to support the survival of many different classes of neurons that are not NGF dependent and that do not express the NGF receptor *trkA*, suggesting that additional NTFs exist. Because NTFs are made in extremely low quantities, the biochemical isolation of NGF-related molecules using conventional protein purification methods proved to be difficult.

A significant breakthrough occurred with the purification of a second NGF-related NTF by Yves Barde and colleagues in 1982. Unlike NGF, which was purified several hundredfold from an extraordinarily rich

biological source unrelated to the nervous system (Table 19.1), endogenous brain-derived neurotrophic factor (BDNF) was purified several millionfold from adult pig brains. Each kilogram of starting material yielded only a microgram of factor which over time was eventually sequenced and cloned to produce recombinant factor. The molecular cloning and expression of BDNF opened the door for an accelerated period of research on NGF-related factors (Table 19.1). When the protein structure of BDNF was compared with NGF, they were both found to encode homodimers of small, very basic secreted peptide ligands with an amino acid homology of approximately 50%. Using polymerase chain reaction primers prepared from homologous domains to search for other related proteins, investigators rapidly identified additional neurotrophin family members in multiple species (Lewin and Barde, 1996). Described as neurotrophins or nerve feeding factors (i.e., NT-3 and NT-4/5, NT-6), these additional proteins were cloned and sequenced without the requirement of exhaustive protein purification.

Each neurotrophin family member is synthesized as an approximately 250 amino acid precursor (pro-neurotrophin) that is processed into a roughly 120 amino acid protomer. Homologous regions of the several different family members are concentrated in six hydrophobic domains containing cysteine residues. The linkage formed by each homodimer ligand utilizes these regions to form a "cysteine knot" that maintains the twin protomers in juxtaposition. The secreted dimer appears as a symmetrical twin with variable regions containing basic amino acid residues exposed on the surface (Fig. 19.11) (McDonald and Rust, 1995). Because all family members share this core structure, they are remarkably similar, with three-dimensional symmetry around two axes. The symmetry of this twin structure allows the neurotrophin ligand to activate trk receptors by binding separate receptor molecules together in the membrane, permitting docking of additional, intracellular signaling molecules and initiation of signal transduction cascades (Figs. 19.11, 19.14). The exposed outer regions that vary between neurotrophin family members are responsible for receptor-binding specificity.

### Summary

The purification, molecular cloning, and expression of BDNF opened a floodgate of research on an NGF-related family of NTFs called neurotrophins or nerve feeding factors. Each neurotrophin family member is released as a homodimer with a conserved region containing a cysteine knot in the core of the molecule. The

secreted factor is a symmetrical twin with duplicate sites used for bivalent receptor binding and formation of signaling platforms.

## NEUROTROPHIN RECEPTORS

NGF binds to a relatively small number of very high-affinity-binding sites and a second set of about 10-fold more abundant, but lower affinity, binding sites at higher concentrations (Roux and Barker, 2002). A 75-kDa protein (p75) was purified and cloned first. It is a transmembrane glycoprotein with extracellular cysteine repeat motifs that share structural homology with the tumor necrosis factor receptor family. The cytoplasmic domain of p75 lacks the kinase domain present in most growth factor receptors for intracellular signal transduction, but it can associate with several other signaling proteins (discussed later) (Fig. 19.11). When expressed in fibroblasts, this receptor has low-affinity NGF-binding properties (ligand binding is rapidly on and off) and therefore also has been called the low-affinity NGF receptor. This name has proven to be a misnomer, as other neurotrophin family members also bind p75 with a similar affinity. It is therefore more appropriately named the "common" neurotrophin receptor (p75NTR).

A major breakthrough in the characterization of the NGF receptors came with the fortuitous discovery and cloning of an oncogene identified in a human colon cancer. The sequence of this 140-kDa transmembrane protein contained a cytoplasmic kinase common to many growth factor receptors. The corresponding proto-oncogene was named *trk* (pronounced "track"—for tropomyosin-related kinase). It rapidly was appreciated as a member of the tyrosine kinase-containing receptor superfamily (Huang and Reichardt, 2001) with *trk* mRNA expression localized to NGF responsive neurons. Low-stringency screening of cDNA libraries with the original *trk* proto-oncogene probes led to the discovery of other related neurotrophin receptors. The NGF binding receptor was called *trkA*, whereas two additional 145-kDa members of this protein family were named *trkB* and *trkC* (Fig. 19.12). Expression of *trkA* in a mouse fibroblast cell line or in frog oocytes conferred specific high-affinity NGF binding and NGF-induced receptor phosphorylation. NGF-signaling properties have been examined most extensively in the NGF responsive pheochromocytoma (PC 12) cell line, derived from adrenal medullary cells. Mutant PC12 cell lines that have lost their capacity to respond to NGF contain many p75NTR receptors but lack *trkA*. Transfection of these mutant cells with *trkA*

**FIGURE 19.12** Ligand binding preferences of neurotrophins for each member of the trk receptor family. Not shown are the truncated (kinase deleted) isoforms of trkB and trkC. Other isoforms containing inserts and deletions also exist, providing a wide variety of receptors. NT-4 is also named NT-4/5. K = tyrosine kinase.

restores their biological responses to NGF treatment. The most convincing evidence for the necessity of trkA comes from the analysis of transgenic mice lacking functional trkA receptors (Huang and Reichardt, 2001). As expected, these mice have a phenotype that is similar to that of transgenic animals that have a null mutation for NGF (Table 19.3).

The trkB receptor is activated specifically by low concentrations of BDNF or NT-4/5 and, to a lesser extent, by higher concentrations of NT-3. NT-3 activates the trkC receptor most effectively. All trk receptors contain three leucine-rich motifs, two cysteine clusters, and two immunoglobulin-like motifs in the extracellular region, a transmembrane domain and a tyrosine kinase domain in the cytosolic region (Fig. 19.11). The unusual combination of extracellular motifs makes up the ligand-binding region and places this family in a novel class of tyrosine kinase receptors. The region of highest sequence homology among family members and other growth factor receptors is in the kinase domain.

\*\*Losses reported by Klein *et al.*, 1993 (*Cell* 75, 113-122) could not be replicated.

Receptor isoforms resulting from splice variants of *trk* mRNA transcripts exist for each family member. A variety of both full-length and kinase-deleted or truncated receptors are widely expressed on neurons throughout the nervous system. Truncated receptors, which also are expressed on glial cells, can bind and internalize their cognate ligand and are capable of limited signaling, but they cannot initiate the phosphorylation events required for mainstream receptor signal transduction (Fig. 19.14). As a result, the distribution and membrane concentration of truncated receptors could potentially modulate neurotrophin activity.

Although *trk* receptors account for many of the biological responses of neurons to neurotrophins, p75NTR can modify *trk* ligand binding and neurotrophin specificity, associates with additional signaling partners, and can initiate pathways for intracellular signaling independent of *trk* receptors (Huang and Reichardt, 2001; Barker, 2004). Sensory neurons from transgenic mice that lack p75NTR require higher NGF concentrations for survival than sensory neurons from normal animals. Antibodies that block NGF binding to p75NTR but not *trkA* reduce high-affinity NGF-binding sites, and p75NTR has been demonstrated to enhance *trkA* receptor phosphorylation. Several mechanisms have been proposed to account for an accessory role of p75NTR. The fast on and fast off kinetics of p75NTR could maintain and increase the local concentration of neurotrophins at the membrane surface and thereby increase the access of *trk* receptors to ligand. Alternatively, p75NTR could form a transient heterodimer with *trk* receptors and thereby “hand off” the factor for *trk* binding (Roux and Barker, 2002). In addition to enhancing NGF binding to and activation of *trkA*, p75NTR initiates NGF responses in cells that lack *trkA*. NGF binding to p75NTR causes activation and nuclear translocation of a transcription factor, nuclear factor kappa B (NF $\kappa$ B), that promotes cell survival. However, p75NTR is related structurally to members of the tumor necrosis factor receptor (TNFR) family, many of which regulate the onset of cell death programs in the immune system and, for that reason, are termed death receptors. The cytoplasmic domain of p75NTR contains a “death domain” sequence similar to active sequences found in the TNFR family, and the p75NTR mechanisms of inducing PCD appear to be shared with other death receptors. In some neuronal cells that express p75NTR but not *trkA*, NGF or proNGF induce cell death via p75NTR binding (Roux and Barker, 2002). Once bound, p75NTR may activate a PCD signaling pathway via the Jun kinase cascade. The Jun kinase cascade activates the transcription factor p53 with gene targets that include the proapoptotic gene BAX. It should be noted that NGF and other trophic

factors can be utilized in different cells or in different epochs of time to induce many diverse biological activities. It is noteworthy that under specific circumstances (such as the absence of *trk* activity), a factor originally identified for the capacity to prevent PCD instead is utilized to execute programs promoting neuronal death.

### Summary

Many neurons have both specific and common binding sites for neurotrophins. Biological responses primarily are associated with high-affinity binding and rapid phosphorylation signaling events. All neurotrophins bind p75NTR, the common neurotrophin receptor. p75NTR lacks a cytoplasmic kinase domain but can independently initiate signaling, can associate with additional signaling partners, and enhances signaling through *trkA*. There are three tyrosine receptor kinase (*trk*) family members: *trkA*, *trkB*, and *trkC*. Each receptor binds one or more members of the neurotrophin family. Splice variants of *trks* result in isoforms that include truncated receptors with reduced signaling capabilities. p75NTR is related to the TNFR family of death receptors and contains a cytosolic “death domain.” Activation of p75NTR, especially by pro-neurotrophins, may serve to kill neurons or other cell types through well-established signaling pathways used to promote PCD.

## SECRETION AND AXONAL TRANSPORT OF NEUROTROPHINS AND PRO-NEUROTROPHINS

### Processing and Secretion of Neurotrophins

Neurotrophins are expressed as larger precursors that are cleaved by furins and prohormone convertases. The extent of cleavage differs between cell types. The precursor forms were believed for a long time to be of little functional significance, and it was thought that the mature neurotrophins were the only important moiety that was secreted. Research by Barbara Hempstead and her colleagues in the early 2000s demonstrated that many cells secrete pro-neurotrophins, and that the release of both pro-neurotrophins and mature neurotrophins contributes to the spectrum of physiological functions. Pro-neurotrophins bind with higher affinity to p75NTR than mature neurotrophins and appear to be the “preferred” ligand for p75NTR. Whether endogenous pro-neurotrophins bind with lower affinity to *trk* receptors is still controversial. To

activate different signaling pathways, the neurotrophin-bound p75NTR can associate with several signaling partners, including Nogo receptor (a GPI-linked protein), sortilin (a member of the VPS10 family), and LINGO-1 (involved in myelin-based growth inhibition, Fig. 19.11). This complex is involved in regulating neurite outgrowth in response to myelin proteins such as Nogo, MAG, and OMgp. Formation of these different platforms may explain the multiple effects of p75NTR in different cell types and contexts. The local balance and concentrations of pro- and mature neurotrophins as well as the availability and activity of binding partners determines physiological functions (Barker, 2004).

### Neurotrophic Factors and Synaptic Plasticity

The classic neurotrophic hypothesis postulates that NTFs, including neurotrophins, are released by postsynaptic target cells and bind to presynaptic receptors for internalization, retrograde axonal transport and activation of signal transduction cascades after arrival at the neuronal soma (Fig. 19.1). Yet NT receptors are present on both post- and presynaptic sites of the synaptic cleft. *In vitro* studies have shown that NTs, and in particular BDNF, have rapid effects on synaptic transmission (Lohof *et al.*, 1993). Numerous studies have confirmed that NTFs have important functions in synaptic plasticity, meaning that these “synaptotrophins” regulate the functional strength of synaptic transmission including long-term potentiation (LTP), an experience-dependent, long-lasting increase in chemical strength of neurotransmission that is a crucial mechanism in learning and memory (see also Table 19.5).

The regulation of secretion of neurotrophins is particularly important for mechanisms of synaptic plasticity (Lessmann *et al.*, 2003). Neurotrophins can be released by constitutive modes (from cell bodies and processes) and by activity-dependent modes of secretion (from dendrites and axons). The pattern of activity, such as high frequency stimulation, is crucial for the release. LTP is relatively synapse-specific—only active and successfully transmitting synapses are strengthened, so the regulated release of neurotrophins and subsequent signaling should be restricted to active synapses. Depolarization and cAMP-dependent pathways are thought to regulate the locally restricted release of neurotrophins such as BDNF. This may contribute to the local “tagging” or marking of the active synapses destined for strengthening. Trafficking of BDNF mRNA through the neuron might also contribute to synapse-specific plasticity, if the mRNA is “captured” for local translation at active synapses.

Interestingly, a naturally occurring polymorphism of the BDNF gene (a Val-Met substitution in the 5'pro-region of BDNF) gives rise to a reduced capacity for activity-dependent (but not constitutive) secretion of BDNF, causing abnormal hippocampal function and some learning and memory deficits in humans (Egan *et al.*, 2003).

Endogenous neurotrophins may be derived from either pre- or postsynaptic sites and they may act on either side of the synaptic cleft in paracrine or autocrine modes to implement functional and structural changes in synaptic plasticity (Poo, 2001). Trophic responses can also be modified by the recruitment of receptors to surface membranes from internal storage sites. Furthermore, after release and binding of newly synthesized neurotrophins, recycling of neurotrophins occurs, and the internalized neurotrophin is not necessarily degraded immediately after the initial binding and internalization steps. Recycled neurotrophins have been shown to play functionally significant roles in LTP.

### The Endosome Signaling Hypothesis of Retrograde Axonal Signaling

The neurotrophic hypothesis postulates retrograde axonal movement of trophic signals. Evidence for retrograde transport of exogenous neurotrophins (NGF) was established in the 1970s (Oppenheim, 1996). Yet the precise mechanisms of axonal transport of trophic signals from the nerve terminal to the neuronal soma remained largely elusive. The prevailing hypothesis is that neurotrophins bind presynaptic surface membrane receptors on nerve terminals, are internalized, and form a ligand-receptor complex with the neurotrophin inside transport vesicles, leaving the trk receptor with its kinase domain on the outside of the vesicle or endosome (Fig. 19.13). The trk receptors may remain “active” (phosphorylated) during axonal transport along microtubules, because the ligand remains bound to the receptor within the vesicle. When the endosome, with the ligand-receptor complex attached, arrives at the neuronal soma, the phosphorylated trk receptor initiates a signal transduction cascade that results in changes of gene expression. Experimental evidence from the Mobley and Ginty labs supports this “signaling endosome” hypothesis (Zweifel *et al.*, 2005). Signaling endosomes can be isolated from axons; trk receptors and other signaling proteins interact at the level of the axon; trks bind to the dynein light chain subunit (part of the dynein motor complex) directly, and thus partake in the axonal transport machinery (Fig. 19.13). Furthermore, endosomes that reach the soma may generate a different signal (activate a differ-

**FIGURE 19.13** The signaling endosome. The internalized neurotrophin (NT)-receptor (Trk) complex is transported retrogradely from the nerve terminal to the cell body. The internalized vesicle serves as a platform for docking of adaptor proteins (light blue) that elicit signal transduction cascades via kinases (red); molecular motors and regulators (green) attach for transport along microtubules (brown). The arrow indicates the direction of transport toward the minus end of microtubules. The main signal transduction cascades are via the phospholipase C- $\gamma$  (PLC $\gamma$ ), Raf-MAPK-ERK, and PI3K signaling pathways (red lightning symbol). For details of signal transduction, see legend to Fig. 19.14. Rap1 and Rab5 are small G-proteins. Other abbreviations: Akt, v-akt murine thymoma viral oncogene homologue (protein kinase B); ARMS, ankyrin-rch membrane spanning protein; B-Raf, v-raf murine sarcoma viral oncogene homologue B1; EEA1, early endosome antigen 1; ERK, extracellular signal-regulated kinase; GAB1, GRB2 (growth factor receptor bound protein 2)-associated binding protein1; HAP, huntingtin-associated protein 1; htt, huntingtin; MEK, MAPK (mitogen-activated protein kinase); NT, neurotrophin; PI3K, phosphatidylinositol 3-kinase; Shc, Src homology 2 domain-containing transforming protein C; Trk, trk tyrosine kinase receptor. For details and references, see Zweifel *et al.* (2005) and Gauthier *et al.* (2004).

ent ERK) than those generated by binding to cell surface receptors on the soma.

However, not all trophic signals from the nerve terminal that arrive at the soma may require the neurotrophin to be physically transported in a ligand-receptor complex. In addition to retrograde axonal transport from nerve terminals to the soma, trophic signals also are transported anterogradely along axons (possibly even a quantitatively more important route) from soma to nerve terminals, mediated by kinesin motors, followed by activity-dependent release of neurotrophins from axon terminals. Indeed, some data

suggest that BDNF and NT-3 may rapidly activate tetrodotoxin-insensitive sodium channels, which would blur the distinction between neurotransmitters, neuromodulators, and NTFs.

### Summary

Expression and secretion of pro-neurotrophins has significant physiological functions in the regulation of cell death. Pro-neurotrophins bind preferentially to the p75NTR. The p75NTR associates with several different signaling partners to form multiple signaling platforms that include sortilin and Nogo receptors. Secretion of neurotrophins requires activity-dependent stimulation patterns that may specifically strengthen active synapses. Neurotrophins are transported retrogradely along axons in signaling endosomes, but they can also be transported anterogradely for release from axon terminals. Trk receptors are expressed both pre- and postsynaptically, forming paracrine as well as autocrine loops of synaptic signaling. Synaptically released BDNF may have rapid effects on sodium channels, acting in a fashion similar to classical peptide neurotransmitters.

## SIGNAL TRANSDUCTION THROUGH TRK RECEPTORS

Neurotrophin binding to trk receptors at the cell surface causes the formation of receptor dimers and coactivation of their tyrosine kinase activity. The homodimeric structure of the factors allows each bivalent ligand to bring two separate receptor molecules into close proximity. Aggregated receptors phosphorylate each other on specific tyrosine substrates within intracellular domains. The generation of phosphotyrosine residues in turn activates the receptor kinase and further catalyzes the formation of large signaling complexes through the recruitment of adaptor proteins. These proteins link the activated receptor kinase with intracellular signaling pathways shared by other growth factors (Ip and Yancopoulos, 1996). Once activated, the receptor initiates intracellular signals both locally in the cytoplasm and by a series of enzymatic cascades that eventually produce changes in gene transcription within the nucleus (Segal and Greenberg, 1996).

Receptor signal transduction involves multiple signaling pathways that can differ between individual neurons or in the same neurons at different periods of time (depending on recent events). Thus, the response of neurons to trophic factor stimuli is dependent on the

intracellular status of the cell in a dynamic fashion. The molecular components of these pathways are so well conserved that many of the signaling proteins are interchangeable among invertebrate and vertebrate species. Three of these pathways have been identified to implement trk signal transduction events that mediate survival as well as many other cellular responses to neurotrophins (Fig. 19.14). They are (1) the *phospholipase C (PLC- $\gamma$ ) pathway*, (2) *Ras-MAP kinase pathway*, and (3) *phosphatidylinositol-3 kinase (PI-3K) pathway*. The latter two pathways begin with adaptor proteins that contain a structural motif, the src homology domain 2 (SH2), which specifically recognizes the phosphotyrosine residue and flanking sequences. PLC- $\gamma$  activity generates two distinct second messenger signals: inositol triphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). IP<sub>3</sub> rapidly releases intracellular Ca<sup>2+</sup> sequestered in local membrane compartments. This signal initiates the activity of local Ca<sup>2+</sup> dependent enzymes (protein kinases and phosphatases). Similarly, DAG regulates the activity of DAG-dependent enzymes. Both Ras and PI-3 kinase pathways are engaged via adaptor and associated linker or extender proteins.

One of the best known Ras-dependent signaling pathways involves the ERK family of MAP kinases. This cascade is composed of serine/threonine kinases that are serially phosphorylated and activated. The initial member of this cascade is Raf, which phosphorylates and activates MEK, which phosphorylates the MAP kinases (ERK1 and ERK2). Once activated, these MAP kinases in turn phosphorylate a number of cytoplasmic and nuclear effectors. Importantly, activation of MAP kinases and their substrate, the protein kinase RSK, results in the phosphorylation of a number of transcription factors, including CREB (cAMP response element-binding protein), which controls expression of immediate-early genes (i.e., *c-fos* and *c-jun*) and delayed response genes. Once activated, transcription factors cause rapid and long-lasting changes in gene expression regulating cell survival, axonal and dendritic growth, neuronal differentiation, synaptic potentiation, and plasticity. The ultimate biological response differs with the duration of Ras activity in response to receptor phosphorylation. TrkA activation of Ras persists much longer compared to only a rapid and transient Ras activation following receptor transduction by epidermal growth factor, suggesting that the duration of Ras activation is a critical determinant of transcriptional activity and biological responses (Huang and Reichardt, 2001). In addition, the requirement on Ras-dependent pathways for biological responses varies among neuron types.

Neurotrophic factor receptor activation of the PI-3 kinase pathway is essential for the normal survival

of many neurons. The phosphatidyl inositides made by PI-3 kinase regulate in part the activity of AKT (protein kinase B). This important protein kinase plays a critical role in controlling the biological activity of several regulatory proteins that govern normal PCD (see Fig. 19.14 and previous sections). BAD is phosphorylated by AKT, but when dephosphorylated by apoptotic stimuli, BAD associates with Bcl-2 proteins, which leads to the release of cytochrome C from mitochondria, resulting in caspase activation and DNA degradation (Fig. 19.14). Trk receptor activation of both the PI-3 kinase and the Ras-ERK pathways suppresses the capacity of activated p75NTR to induce cell death programs via Jun kinase. In some cases, p75NTR may therefore induce neuronal death where appropriate neurotrophin binding to trk receptors is absent. Interactions between the multiple trk receptor signaling pathways in different cell phenotypes and under a variety of dynamic receptor signaling conditions provide a rich assortment of interrelated mechanisms to govern the PCD machinery.

### Summary

Three tyrosine receptor kinases and trk family members—trkA, trkB, and trkC—transduce neurotrophin signals. Signaling pathways used by the trk family members are shared with those activated by many other growth factor receptors. Neurotrophin binding to trk causes receptor dimerization and phosphorylation of cytoplasmic tyrosine residues. Phosphotyrosines recruit cytosolic adaptor proteins that couple the activated receptor with intracellular signaling pathways. The biological response of the cell to a neurotrophic factor is dependent on the dynamic status of the pathway that can vary with recent cell history. Three of the best investigated signaling pathways are PLC- $\gamma$ , Ras-ERK kinase, and PI-3K. Normal PCD is governed in many neurons by PI-3 kinase activation of the protein kinase Akt. Trophic factor deprivation can lead to the release of pro-apoptotic mechanisms that promote cell death.

## CYTOKINES AND GROWTH FACTORS HAVE MULTIPLE ACTIVITIES

### Several Cytokines Mediate Cell Interactions within the Nervous System

We have emphasized neurotrophins as an example of the activities of NTFs in the developing and mature nervous system. Yet there are several other important families of NTFs. Often NTF families utilize receptors

**FIGURE 19.14** Trk and p75NTR signaling pathways. Neurotrophin (NT) dimers bind two trk receptor monomers or one p75NTR to activate survival (1–3) or apoptotic (4) signaling pathways. Ligand binding initiates trk receptor transduction by the phosphorylation (indicated by small red dot) in the cytoplasmic domains. The activated Trk kinase docks adaptor and linker proteins (light blue), which engage signaling cascades often containing multiple kinases (red). The three principal signaling pathways illustrated are the (1) phospholipase C pathway, (2) Ras-MAP kinase pathway; and (3) PI-3 kinase pathway. These pathways lead to nuclear translocation of transcription factors (green), such as CREB and NFκB, and ultimately regulation of gene expression. The binding of neurotrophins or proneurotrophins to p75NTR can activate BAD via the JNK cascade and eventually engages, via release of effectors from mitochondria, caspases involved in apoptosis (see also Fig. 19.9). There are several venues for crosstalk between the survival- and pro-apoptotic signaling cascades as indicated. Abbreviations not explained in Legend 19.13: BAD, bcl-2-antagonist of cell death; Bcl2, B-cell lymphoma 2; Ca, calcium; CREB, cyclic AMP response element binding protein; Cyto C, cytochrome C; DAG, diacylglycerol; JNK, C-Jun N-terminal kinases; NFκB, nuclear factor-kappa B; NRAGE, neurotrophin receptor interacting MAGE (melanoma antigen gene expression) homolog; NRIF, neurotrophin receptor interacting factor; p75NTR, p75 neurotrophin receptor; (pro)NT, pro-neurotrophin; Raf, Ras, and RhoA, small GTPases; RSK, ribosomal S6 kinase. For details, see text, and Huang and Reichardt (2001), Chao (2003), and Barker (2004).

with coreceptor complexes (e.g., neurotrophins—trk, p75NTR; and GDNF family ligands—ret and GFRs). In many tissues, intercellular induction factors are important for governing the proliferation and differentiation of both embryonic and adult stem cells. In addition, these factors also play an important role in the response of tissues to trauma, inflammation, infection, or tumor growth. In 1974, Stanley Cohen proposed that both lymphocyte-derived and nonlymphocyte-derived chemotactic and migration-inhibitory factors be grouped into families of cytokines (“cell movement factors”). More recently, this term has been adopted as a general umbrella for many families of secreted proteins that mediated diverse biological responses, including changes in the immune system (interleukins), tumor cytotoxicity (tumor necrosis factors), and inhibition of viral replication or cell growth (interferons) (Table 19.4).

Many cytokines originally were named according to the particular biological activity that was utilized

for their isolation, only to be later rediscovered or renamed as important mediators of other physiological processes. For example, some factors were isolated on the basis of their ability to enhance the survival of specific populations of neurons isolated *in vitro*. These include ciliary neurotrophic factor (CNTF); glial cell line-derived neurotrophic factor (GDNF); and the other GDNF family members, neurturin, persephin, and artemin. CNTF is a member of a broader family of neurotrophic cytokines, including leukemia inhibitory factor (LIF), oncostatin M, cardiotrophin-like cytokine/cytokine-like factor (CLC/CLF) and cardiotrophin-1 (CT-1), that share a common three-dimensional structure and receptor subunits. CNTF originally was isolated and named because it supports the survival of neurons cultured from the parasympathetic ciliary ganglion. The GDNF family primarily supports enteric neurons, dopaminergic neurons, and some motoneurons (Airaksinen and

TABLE 19.4 Cytokine and Growth Factor Families

Family	Representative members	Original biological activities
Neurotrophins	NGF, BDNF, NT-3, NT-4/5, NT-6	Neuronal survival and differentiation
Neuropoietic cytokines	CNTF, LIF, CT-1, CLC/CLF, oncostatin M	Survival of ciliary neurons and moto neurons, leukemia inhibitory activity, increased cholinergic properties
Tissue growth factors	TGF- $\alpha$ , TGF- $\beta$ , FGFs, IGF-I $\alpha$ , IGF-I $\beta$ , IGF-II, EGF, PDGF	Cell proliferation and differentiation in diverse tissues and organs
GDNF family	GDNF, neurturin, artemin, persephin	Neuronal survival and dopaminergic cell differentiation, and morphogens in kidney and sperm development
Interleukins	IL-1 $\alpha$ , IL-1 $\beta$ , IL-2 through IL-15	Immunoregulation, diverse activities in the immune system
Tumor necrosis factors	TNF- $\alpha$ , TNF- $\beta$	Tumor cytotoxicity
Chemokines	MCAF, MGSA, RANTES, NAP-1, NAP-2, MIP-1	Leukocyte chemotaxis and cell activation
Colony-stimulating factors	G-CSF, M-CSF, GM-CSF	Hematopoietic cell proliferation and differentiation
Interferons	IFN- $\alpha$ , IFN- $\beta$ , IFN- $\gamma$	Inhibition of viral replication, cell growth, or immunoregulation

Saarma, 2002). Other proteins that originally were identified as mitogens or chemotactic factors in non-neuronal tissues also have been shown to affect either the survival or the differentiation of neurons, including the fibroblast growth factors (FGFs), insulin-like growth factors (IGFs), and hepatocyte growth factor (HGF). The first neuronal function identified for LIF was the induction of cholinergic properties in cultured sympathetic neurons, but it also supports the survival of several classes of neurons and induces neural precursors to become astrocytes.

LIF, which has a number of actions in the immune system and other nonneuronal tissues, shares receptor subunits with the CNTF family and therefore can mimic both the survival and the cholinergic differentiation activities of CNTF observed in culture. Many cytokines important for the development or maintenance of other organs and tissues are also widely expressed within the nervous system. Their roles in the nervous system, however, remain to be defined. Likewise, factors first recognized as neuronal survival factors have mitogenic properties for either nonneuronal cells or neuronal precursors. As a result, these pleiotropic factors are grouped into families based on their protein sequences and receptor usage rather than on their biological properties. Table 19.4 summarizes major known ligands, receptors, and biological functions for the CNTF-related family of cytokines, the GDNF/TGF-related superfamily, and FGFs.

### Neurotrophic Factors Have Multiple Activities

Neurotrophic factors that prevent neuronal death during development appear to have many other

important biological activities, including effects on cell proliferation, migration, differentiation, axonal growth and sprouting, alterations in dendritic arbors, and synaptic plasticity of the nervous system (Table 19.5). Frequently, different populations of neurons respond to the same factor in distinct ways, and the same neuron may respond differently to the same factor at different developmental stages. Variations in neuronal responses to the same factor appear to depend not only on modifications of trophic receptors and their binding partners, but also on potential differences in the intracellular context of downstream signaling pathways. The distinctive activities of a NTF on different cells or during different epochs of development reflect the intrinsic properties of differentiating neurons or a dynamic change in a trophic response due to alterations in neural activity or other signaling events.

As described earlier, neurotrophins have been shown repeatedly to play fundamental roles in the survival of many peripheral neuronal populations. Null mutations of neurotrophins or their cognate trk receptors manifest substantial deficits in dependent populations (Table 19.3; Fig. 19.10) (Huang and Reichardt, 2001). However, relatively few changes in the number of neurons have been observed in the CNS of neurotrophin or trk receptor null mutant mice. This observation was surprising because significant cell death occurs in the CNS, and NTFs and their receptors are widely expressed in the CNS during this period. The complexity and number of synaptic relationships established by CNS compared to those established by PNS neurons may partially explain why CNS neurons are not as sensitive to the loss of a single neurotrophin or neurotrophin receptor (Fig. 19.15). The trophic

support to CNS neurons is likely to arise from multiple families of NTFs with possible synergistic and/or compensatory effects.

The traditional view of the neurotrophic hypothesis has been that trophic support is derived from target tissues, but other sources of trophic support are now recognized (Figs. 19.15, 19.16). Interpretation of mRNA localization studies is complicated by the fact that NTFs may not simply be released locally in the region of the cell body, but may also (or instead) be delivered to distant regions of the nervous system by anterograde or retrograde axonal transport. Thus, although the original neurotrophic hypothesis that neurons depend on target-derived trophic factors still holds true for many neurons during critical periods of development (including sympathetic neuron dependence for target-derived NGF), other sources of trophic support appear to play an important functional role in development, as briefly described earlier.

Finally, although beyond the scope of the present chapter, neurotrophins and other NTFs and their

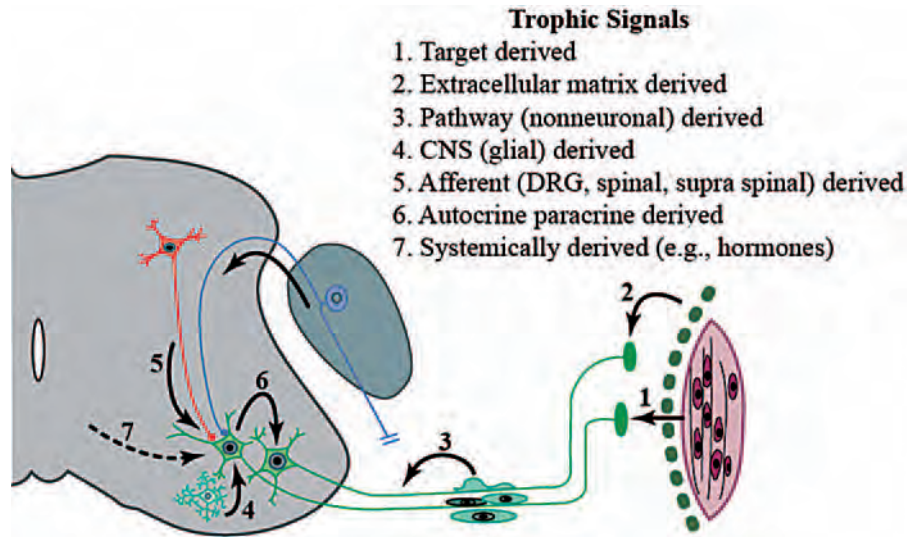

receptors also are distributed throughout the mature brain, and NTFs can alter neural activity by rapid and long-term changes in synaptic transmission. Neurotrophins and other NTFs also play a role in modulating long-term changes in functional and anatomical plasticity in the developing and mature brain by altering long-term potentiation, synaptic connectivity, and responses to stress, inflammation, and trauma (Chao, 2003) (Table 19.5).

### Summary

There are multiple families of NTFs. CNTF and LIF belong to a neuropoietic cytokine family. The expression and biological properties of these cytokines distinguish them from neurotrophins. They possess widespread neurotrophic activity for many different neuronal and nonneuronal populations *in vitro* and facilitate the cholinergic differentiation of sympathetic and motor neurons. The GDNF family (GDNF, neurturin, artemin, and persephin) is related to the TGF- $\beta$  gene family and has effects on enteric, dopaminergic

**FIGURE 19.15** Possible sources of trophic support for peripheral (PNS) and central (CNS) neurons. Many peripheral neurons such as sympathetic and bipolar sensory neurons (left side) have only two sources of support: one in the periphery (Target #1) for retrograde support and one from afferents (AFF #1) or the central target (for bipolar sensory neurons). Glial cells (gray) may also provide trophic factors. In contrast, central neurons (right side) receive synaptic input from many different types of neurons (AFF #1, 2, and 3), which may serve as a source of anterograde trophic support. Central neurons may also project to several different targets (Targets #1, 2, and 3), which each may provide retrograde trophic support. Trophic factors are listed that have been demonstrated to be either anterogradely or retrogradely transported, with question marks when transport is suspected, but not proven. In addition, glial cells in the CNS may also provide trophic factors to CNS neurons. Adapted from Snider (1994) and von Bartheld *et al.* (2001).

**FIGURE 19.16** Schematic illustration of different sources of potential trophic signals acting on motor neurons in the spinal cord. Motor neurons (green cell bodies) can receive trophic support from a number of different sources. Axon terminals of the motor neurons have access to diffusible muscle-derived (1) or extracellular matrix-associated (2) trophic factors. Schwann cells (3) in the peripheral nerve or ventral root are another source of trophic support. Glial cells (4) in the spinal cord (astrocytes and/or oligodendrocytes) may also influence motor neuron survival. Motor neurons receive afferent input from several sources, including descending fibers from the brain, spinal interneurons, and dorsal root axons (5), which could supply trophic support. Finally, motor neurons could influence their own growth and survival via autocrine trophic support (6), as well as respond to trophic support provided by circulating hormones (7).

**TABLE 19.5** Nonsurvival Functions of Neurotrophic Factor\*

Function	Examples of relevant trophic factors and cytokines
Cell fate decisions (stem cell/neuronal precursor derivatives)	BDNF, NGF, EGF, NT-3, CNTF, LIF, oncostatin M, CT-1
Axon guidance	NGF, BDNF, HGF, GDNF, neurturin
Neurite growth, branching	BDNF, NT-3, NT-4, CNTF, CT-1, HGF, GDNF, LIF, IGF-I
Dendrite development	BDNF, NT-3, NGF, GDNF
Synapse development	BDNF, NT-3, GDNF, neurturin, NT-4, CNTF
Synapse stabilization and plasticity	BDNF, NT-3, GDNF, FGFs, HGF, VEGF, CNTF, LIF, NGF, IGF-I
Long-term potentiation, learning, and memory	BDNF, NT-3, NGF, NT-4, IGF-I, interleukins
Pain physiology and pathophysiology	NGF, BDNF, GDNF, artemin, NT-3
Neurotransmitter phenotype	NGF, LIF, FGFs, GDNF, CNTF, BDNF, NT-3, IGF-I
Ion channel regulation/function	BDNF, interleukins
Neurological disease and neurodegeneration	
Seizure, epilepsy	BDNF, NGF, NT-3, VEGF, GDNF, LIF, CT-1, oncostatin M, CNTF
Stress, ischemia	NGF, NT-3, BDNF, IGF-I, VEGF, GDNF, HGF, BMPs
Traumatic injury, axonal regeneration, inflammation, stress	GDNF, IGF-I, LIF, CNTF, oncostatin M, CT-1, NGF
Psychiatric disease: depression	BDNF, NGF, FGFs, IGF-I, GDNF

\*For references, see Snider, 1994; McAllister *et al.*, 1999; Huang and Reichardt, 2001; Poo, 2001; Chao, 2003; Zweifel *et al.*, 2005.

and motor neurons. FGFs may play important roles during development or after injury. NTFs have different functions during different developmental stages: After early effects on proliferation and phenotype determination (stem cells), NTFs influence neuronal migration, survival, differentiation, and

dendritic as well as axonal growth. At later stages, NTFs regulate synaptic competition and plasticity, LTP, responses to injury, regeneration, and adult neurogenesis. The activity of multiple trophic factors from multiple sources is integrated to achieve a functional circuitry.

## PROGRAMMED CELL DEATH IS REGULATED BY INTERACTIONS WITH TARGETS, AFFERENTS, AND NONNEURONAL CELLS

The PCD of vertebrate neurons and their precursors can occur at any stage of neuronal development from neurogenesis and neurulation to the time of establishment of synaptic connections with targets and afferents, and can involve mitotically active cells and migrating neurons, as well as undifferentiated and immature postmitotic cells (Fig. 19.4). However, the most common and historically the best studied type of PCD of neurons involves postmitotic, differentiating cells that die while establishing synaptic connections with other neurons and target cells (Oppenheim, 1991; Pettmann and Henderson, 1998). Because massive neuronal death and its regulation were first clearly recognized in early studies of neuron-target interactions (Table 19.1, Box 19.1), the role of targets in controlling PCD historically has received the most attention. However, as discussed in the previous section, signals derived from afferent inputs, as well as from nonneuronal cells such as central and peripheral glia and endocrine glands (e.g., steroid hormones), have now been shown to be possible sources of trophic regulation of cell death and survival (Fig. 19.16).

Studies of the regulation of vertebrate neuronal PCD have shown that targets are critically involved in regulating how many postmitotic cells in the innervating population survive or die. Complete or partial deletion of targets reduces survival, whereas increasing the size or number of available targets results in increased survival (Oppenheim, 1991; Buss *et al.*, 2006). Although it is thought that the relationship between neuronal survival and the availability of synaptic targets is proportional and linear (this has been called numerical-, quantitative-, size-, or systems-matching), there may also be other ways in which the number of neurons that innervate a target can be regulated. For example, signals from glial cells along axon pathways may modulate neuron numbers prior to target innervation. Spinal motoneurons provide one of the best examples of how systems-matching is regulated by a competition for target-derived signals (NTFs) that promote survival (the Neurotrophic Hypothesis).

In the case of avian spinal motoneurons that innervate limb skeletal muscle, the number of neurons that survive the period of PCD bears a 1:1 relationship with the number of primary myotubes present in individual muscle precursors during the period of cell death, rather than being correlated with the final number of myotubes or myofibers (i.e., muscle size)

present after the cessation of cell death. Accordingly, in this situation, motoneuron numbers are controlled, in part, by signals that are limited by the number of primary myotubes available. Although for many populations of neurons the essential factors provided by targets that mediate neuronal survival are not known, extrapolation from what is known for sensory, sympathetic, and motor neurons suggests that specific target-derived NTFs are involved. Target-dependent motoneuron survival is mediated by muscle-derived proteins. Several candidate motoneuron NTFs have been identified and include BDNF, NT-4/5, IGF, HGF, and CNTF and GDNF family members. The PCD of CNS neurons in the avian isthmo-optic nucleus (ION) and neurons in the mammalian thalamus and substantia nigra are controlled by many of the same mechanisms involved in the PCD of peripheral neurons, including a need for target-derived NTFs such as BDNF. As discussed previously, the survival of myelin-forming glial cells also involves competition, in this case, competition for trophic signals derived from axons. In both neurons and glia, the final outcome of this competitive process (Figs. 19.4 and 19.5) is the survival of optimal numbers of cells for innervation (neurons) or myelination (glia) (Oppenheim *et al.*, 2001).

Motoneurons (and some other neuronal populations as well, including retinal ganglion cells, isthmo-optic neurons (ION) cells, and ciliary ganglion neurons) have another interesting property in that their target dependency appears to be regulated by physiological synaptic interactions with their targets (Oppenheim, 1991). For example, following the formation of initial synaptic contacts between motoneurons and target muscles, the initiation of synaptic transmission activates the muscle and results in overt embryonic movements. Chronic blockade of this activity during the cell death period with specific drugs or toxins that cause paralysis prevents the death of all motoneurons (Fig. 19.17). Although the cellular and molecular mechanisms that mediate this effect are not entirely clear, two major hypotheses have been proposed: the *production hypothesis*, which predicts that the production (expression) of NTFs by the target is regulated inversely by target muscle activity; and the *access hypothesis*, which argues that sufficient NTF initially is produced by targets to maintain all motoneurons, but that activity regulates access to NTFs by modulating axonal branching and synaptogenesis, thus restricting the uptake of the NTFs to axon terminals or synapses. At present, the available evidence favors the access hypothesis (Terrado *et al.*, 2001).

Because PCD is enhanced after the pharmacological blockade of afferent synaptic activity, the functional

**FIGURE 19.17** Daily treatment of the chick embryo with neuromuscular blocking agents during the major period of spinal motoneuron cell death (days 5–10) results in the inhibition of muscle activity and the rescue of motoneurons from PCD (hatching occurs on day 21). Following the cessation of treatment on E10 (transient blockade of activity), the rescued motoneurons undergo delayed PCD as muscle activity gradually recovers, whereas treatment from days 5–20 (chronic blockade of activity) maintains the rescued motoneurons after day 10.

input provided by afferents also appears to be of fundamental importance in this situation (Linden, 1994; Oppenheim *et al.*, 2001). Functional afferent input may act to regulate the survival of both developing and adult-generated postsynaptic neurons by several different mechanisms:

1. Neurotransmitter release results in depolarization by afferents that can alter intracellular calcium levels in postsynaptic cells, which in turn can independently modulate survival.
2. Afferent activity can regulate the expression of NTFs and their receptors in postsynaptic cells.
3. The activity-dependent release of NTFs from terminals of afferent axons or from adjacent glial cells may also provide survival signals to postsynaptic cells.

Because the PCD of many developing neurons may be coordinately regulated by activity-dependent and independent signals derived from targets, afferents, and nonneuronal cells, an important unresolved issue is how these different sources interact to control survival. In the final analysis, the various target- and afferent-derived extrinsic signals influence survival by modulating intracellular signaling pathways that regulate the expression of pro- and anti-apoptotic gene products (Figs. 19.9, 19.14). Although targets and afferents appear to be the major source of signals that regulate the survival of differentiating neurons, they are not likely to be the only source (Fig. 19.16).

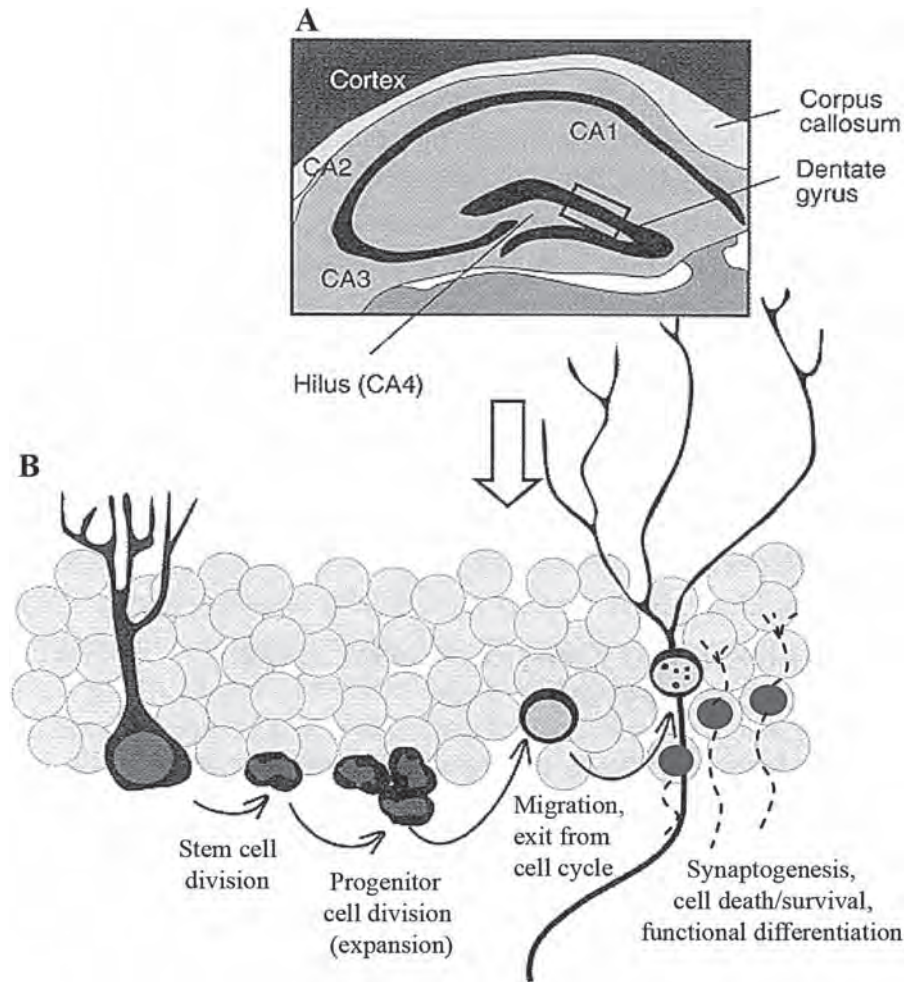

Although the cellular mechanisms are not yet well established, the survival and death of newly generated neurons in the adult hippocampus and olfactory system provide another example of how afferent activity can regulate these events. For example, learning, stress, motor activity, sensory stimuli, and other environmental influences appear to control granule cell numbers in the dentate gyrus of the hippocampus by activity-dependent modulation of neuronal survival (Fig. 19.18). Similar to developing neurons during embryonic and postnatal stages, the default state of developing adult-generated neurons is PCD and (as also occurs during embryonic and postnatal stages) their survival and incorporation into functional circuits requires synaptic input and NTF signaling (Kempermann, 2006).

## Summary

During development, the fate of a cell, including the decision to live or die, can be determined by intrinsic cell-autonomous mechanisms or by extrinsic signals derived from cell–cell interactions. The survival of most developing neurons is likely to be dependent on a variety of signals, including multiple NTFs derived from diverse sources, that serve to maintain survival and regulate differentiation in complex ways that reflect the specific requirements of neurons at each step in their development. Although developing neurons can undergo PCD at any stage of differentiation, the best studied type of PCD occurs as neurons are establishing connections with targets and afferents. Targets and afferents provide critical survival-promoting signals that prevent PCD. One major class of such signals are NTFs. Neurons are thought to compete for limiting amounts of these NTFs. For many populations of neurons, synaptic transmission and physiological activity also plays an important role in regulating survival. Accordingly, both NTFs and electrical activity/synaptic transmission are important for the regulation of PCD and are closely linked functionally.

## THE ROLE OF PROGRAMMED CELL DEATH IN NEUROPATHOLOGY

The widespread occurrence of PCD during normal development indicates that cell loss, together with cell production (proliferation), is a fundamental mechanism for controlling final cell numbers in many tissues. Accordingly, the dysregulation of normal PCD could be maladaptive and pathological. For example, devel-

**FIGURE 19.18** (A) Schematic illustration of the hippocampus including the dentate gyrus a portion of which is shown enlarged in B. (B) The dentate gyrus is comprised of several layers of differentiated granule cells (light gray circles and dark cell with dendrites on the left). Stem cells in the lower subgranule layer of the dentate gyrus undergo cell division and a subset of these migrate into the granule cell layer and differentiate (cell with dendrites on the right), whereas others migrate and begin differentiation but then undergo PCD (small dark cells with dashed axons and dendrites). Modified and redrawn from Kempermann (2006).

opmental, genetic, or congenital neurological defects may be caused by perturbations of PCD. However, there is relatively little solid evidence on this point. Although there are genetic mutations in animals and humans that involve significant alterations in neuron numbers, whether these always reflect the loss of control of normal PCD or reflect other abnormalities (e.g., altered neurogenesis) that could also influence final cell numbers often is not known. Nonetheless, the idea that aberrant cell death in the developing and adult nervous system may reflect a loss of normal control mechanisms for survival is appealing in that the increased understanding of the genetic regulation of PCD provides a potentially powerful and rational approach for the development of therapeutic treatment strategies.

A hopeful sign in this regard comes from reports that neuronal (or glial) death in patients with Alzheimer's, Parkinson's, Huntington's and Motor Neuron Disease, Down syndrome, multiple sclerosis, retinal degeneration, epilepsy, and in some forms of traumatic CNS injury (e.g., head trauma, ischemia, cerebral stroke, spinal cord injury, perinatal asphyxia) exhibit some characteristics of apoptosis, such as the stereotyped fragmentation of DNA and the expression of genes or gene products associated previously with developmental PCD (e.g., the *bcl-2* gene family) (Vila and Przedborski, 2003; Blomgren *et al.*, 2007). In some of these diseases, specific gene mutations have been identified that may directly or indirectly perturb inter- and intracellular mechanisms involved in the maintenance and survival of specific populations of neurons.

Other brain pathologies in which neuron loss by PCD may be involved include fetal alcohol syndrome, schizophrenia, major depression disorders, Shy-Drager syndrome, narcolepsy, and fetal exposure to excitotoxic drugs. Therefore, in addition to the important diverse roles of PCD during normal development and in adult tissue homeostasis, studies leading to a better understanding of the cellular and molecular mechanisms of PCD may ultimately shed new light on the causes and prevention of a variety of neurological disorders and brain pathologies that affect large numbers of the human population. As we learn more about the molecular components of the cell death pathways and their role in neurological disease and pathology, there will be increased opportunities for therapeutic intervention.

Despite this promising perspective for utilizing the increased understanding of the biology of PCD for developing therapeutic strategies to treat pathological neuron death, it is important to consider the validity of the widely held assumption that it is the death of neurons that is the primary cause of the pathophysiology in these diseases. In fact, there is growing evidence that neuronal and synaptic dysfunction that precedes any significant neuronal loss may be a major factor in the behavioral pathology that characterizes many neurodegenerative diseases (Gould and Oppenheim, 2007; Palop *et al.*, 2006).

## Summary

Because PCD is primarily a developmental phenomenon, historically the major focus of investigation has been the normal biology of cell death in the embryo, fetus, and newborn. However, with the growing recognition that pathological neuronal cell death may share certain biochemical and molecular features with PCD, there is growing hope that a better understanding of PCD may reveal potential therapeutic strategies for the treatment of developmental neuropathologies, neurodegenerative disease, and neuronal loss following CNS trauma.

# Synapse Elimination

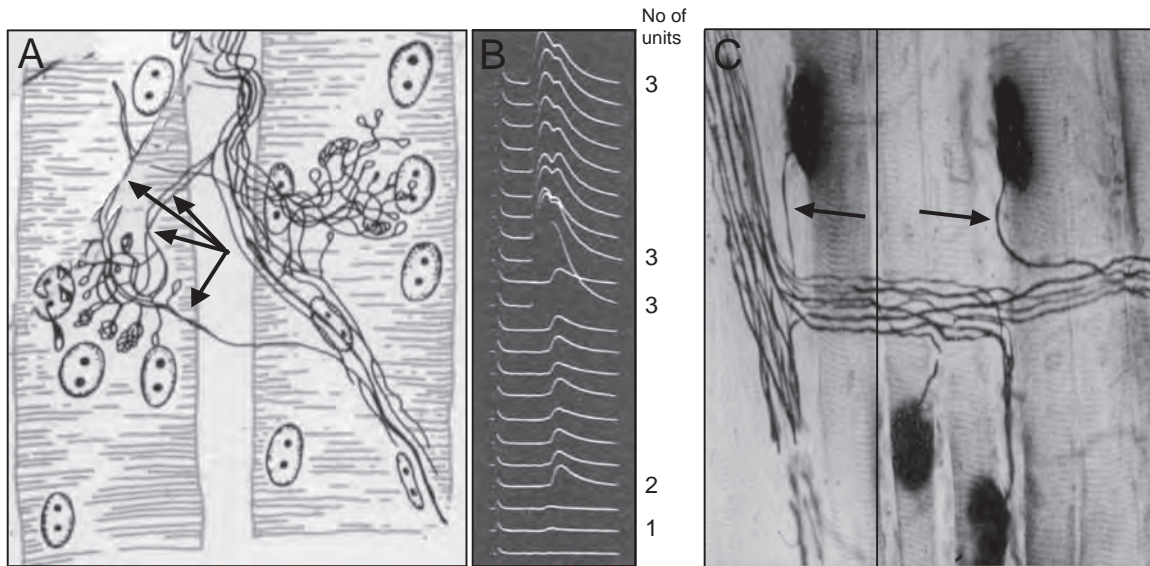

## OVERVIEW

In the development of both central and peripheral nervous systems, synapse formation generates some connections that exist only transiently. Proof that synapses are eliminated comes from the finding that in many parts of the mammalian nervous system, pre-synaptic axons are transiently connected to postsynaptic partners during development. One unambiguous example is the loss of synapses between motor axons and muscle fibers. At birth, each neuromuscular junction receives convergent innervation from multiple motor axons (Fig. 20.1A,B). In adult muscles, however, only a single motor axon innervates each neuromuscular junction (Fig. 20.1C). In another part of the developing peripheral nervous system, autonomic ganglia, axons also transiently supply extra inputs to each ganglion cell (Fig. 20.2). In the developing central nervous system (CNS), several cases of synapse elimination are also well known (Table 20.1). For example, in the cerebellum multiple climbing fibers innervate each Purkinje cell at birth, whereas all but one is removed in early postnatal life. In the auditory system, developing neurons in the magnocellularis nucleus receive innervation from several inputs but in later life only one axonal input per neuron remains. Perhaps the best-known examples of synapse elimination occur in the visual system.

In all these cases, synapse elimination reduces the number of axons that innervate target cells, making the term *input elimination* perhaps a better way of describing the phenomenon. In most of the developing CNS, however, it remains unknown whether synapse elimination is occurring. The difficulty is that *total* number

of synapses may not be decreasing at the stage when axonal inputs are being eliminated. Thus assaying for synapse elimination requires quantifying a change in the number of innervating axons, which in turn requires a means of counting them, or at least having a situation where distinct but overlapping pathways can be separately labeled or stimulated (such as the two eyes). It is therefore possible that there is far more synapse elimination during development than presently documented. For example, stimulation of the optic nerve with progressively larger voltages to count the number of retinal ganglion cells innervating individual lateral geniculate neurons has revealed a dramatic change from more than 20 innervating axons to only 1 or 2 during the first postnatal month (Chen and Regehr, 2000).

Importantly, synapse elimination does not lead to a net weakening of synaptic drive on target cells. In the example just mentioned, the retinogeniculate axons that persist undergo a greater than 50-fold increase in the efficacy, which more than compensates for the loss of other axonal inputs to the same target cells. Analogous increases in synaptic efficacy of inputs that persist have been described for the excitatory drive to neurons of the magnocellularis nucleus (Lu and Trussell, 2007) and for the climbing fiber input to Purkinje cells in the cerebellum (Hashimoto and Kano, 2003). In each case the inputs that remain increase their efficacy by 10-fold or more as other axons are eliminated. The same trend was seen many years ago in the parasympathetic submandibular ganglion, where the remaining single input was always far more powerful than any of the inputs at the earlier stage when five to six multiple axons converged to the same single target cell

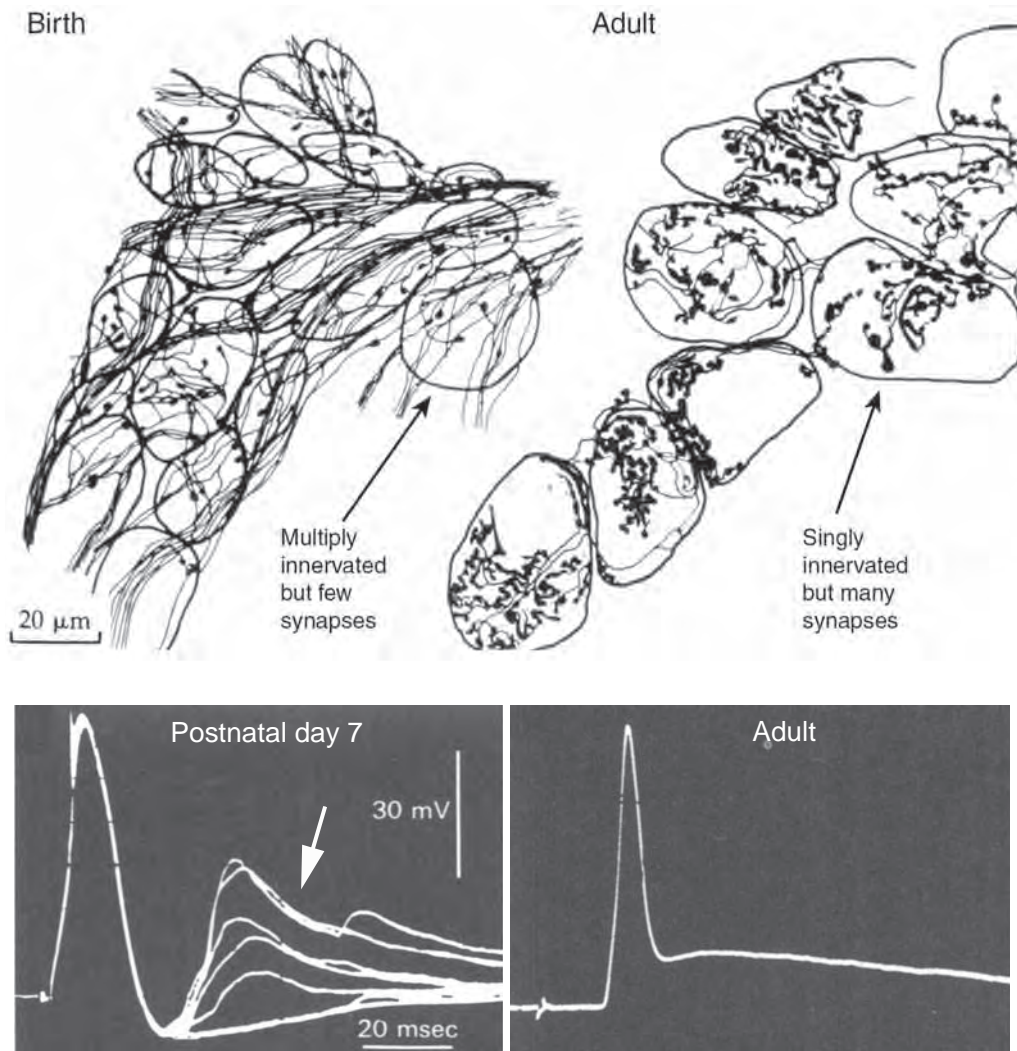

**FIGURE 20.1 Evidence of synapse elimination at the neuromuscular junction.** (A) Drawing of a silver stain made by J. Boeke in 1932 of the motor nerve terminals converging on two adjacent muscle fibers from the tongue muscle of a 4-day-old mouse. Each fiber is innervated by endings from several different axons (see arrows). (B) Intracellular recordings from a muscle fiber in the neonatal rat diaphragm showing multiple innervation of a skeletal muscle fiber. Gradually increasing the strength of motor nerve stimulation elicits three different postsynaptic responses in this fiber. Similar assays in adult animals give only a single postsynaptic response that cannot be fractionated by graded stimulation. The preparation was partially curarized to prevent the endplate potentials from reaching threshold. (C) Photomicrograph of several adult muscle fibers from the rat extensor digitorum longus muscle. Each adult fiber receives innervation from a single axon (arrows). Axons are impregnated with silver and stained for cholinesterase (dark oval smudge on each muscle fiber). Figures adapted from (A) Boeke (1932); (B) Redfern (1970); and Gorio *et al.*, (1983).

(Lichtman, 1977). Similarly, at the neuromuscular junction, the remaining motor axon increases its quantal content as other inputs are eliminated (Colman *et al.*, 1997). It thus appears that although some inputs are being removed, the survivors are potentiated. Such results raise the outstanding question of the degree to which the compensation is explained by changes in the efficacy of the maintained synapses or rather the elaboration of new synapses.

A partial answer comes from studies in the peripheral submandibular ganglion. Here, the simplicity of the neuropil (most synapses are axosomatic) allows for direct counts of synapse number during the period of synapse elimination. In this ganglion, input elimination was accompanied by concurrent synapse addition by the remaining input. In particular, over the first postnatal month, there was approximately a twofold increase in the total number of synapses per ganglion cell, whereas the number of innervating axons was reduced fivefold (Fig. 20.2). This compensation indicates that the remaining axon on each ganglion cell must be increasing the number of synaptic contacts by approximately a factor of 10 as other axons lose all

their connections to the same neuron. Such compensatory synaptogenesis means that assays of the total number of synapses at various developmental stages or following learning paradigms may belie a rather dramatic change in the *source* of the synapses.

It is also clear that in many situations the alterations occurring during this developmental reorganization are better described as a *redistribution of synapses* than as loss per se. The view is based on the fact that counts of the total number of neurons that innervate the target is not changing during the stage when the number of axons innervating each postsynaptic cell is decreasing (see for example, Brown *et al.*, 1976). Moreover, in several regions of the nervous system, it is known that synapse elimination occurs after the period of *naturally occurring cell death* is complete (Chapter 19). Thus, as the elimination process reduces the number of axons converging on postsynaptic cells, it does not entirely remove axons from the postsynaptic target region but rather reduces the number of target cells innervated by each axon—that is, it reduces the axonal divergence as individual axons restrict their synapses to a smaller number of postsynaptic target cells (Fig. 20.3). In

**FIGURE 20.2** In the developing nervous system synapse number is increasing while axonal convergence is falling. The total number of preganglionic synapses on ganglion neurons in the rat submandibular ganglion increases in early postnatal life during the period of synapse elimination. Camera lucida drawings of clusters of ganglion neurons at birth and in adult animals that were treated with zinc iodide osmium. This reagent selectively fills terminal axons and synaptic boutons with a dense black precipitate. The number of synaptic boutons increases (compare the amount of synaptic boutons (arrows) at birth and on adult ganglion cells), and the number of preganglionic axons innervating each ganglion cell, identified by electrophysiological measurements, decreases (see the number of electrophysiological steps (arrow), each representing an input, at early postnatal life and in adult ganglion neurons, see lower panels). Thus, axons that are not removed create new synapses to more than compensate for the loss of synapses from other axons. From Lichtman (1977).

muscle, axonal branch trimming during development has been long appreciated by an electrophysiological assay: the proportion of the total twitch tension an individual axon exerts decreases gradually over early postnatal life (Brown *et al.*, 1976).

Newer techniques of visualizing all the branches of single axons by transgenic expression of GFP have allowed this *branch retraction* to be observed directly (Fig. 20.4). Time-lapse imaging shows that when two axons coinervate the same neuromuscular junction in development one axon atrophies, then disconnects

from the postsynaptic specialization and temporarily appears as a bulb-tipped free axonal ending called a *retraction bulb*. The withdrawing axon sheds small spherical membrane-enclosed axonal fragments filled with synaptic organelles (axosomes) to be engulfed by surrounding Schwann cells (Fig. 20.5).

### Summary

In the developing nervous system both the number of axons that converge on postsynaptic cells, and the

**FIGURE 20.3 Changes in fan-in and fan-out at developing circuits.** In neonatal vertebrates, neurons (A, green and B, red) project their axons to fan-out to many target cells (each labeled ab). These nascent connections are typically weak and mediated only by a small number of synaptic contacts (triangles from the green and red axons). Axons undergo several structural rearrangements before reaching adulthood. First, axons disconnect from many target cells reducing their fan-out or divergence. Second, this rearrangement leads to less fan-in or convergence. Third, at the same time as axons disconnect from some target cells they are strengthening their connection with other target cells by increasing the number of synapses at their remaining targets.

number of postsynaptic cells an axon contacts decreases. The removal of inputs is due to a process of branch trimming. Concurrently, the remaining inputs appear to compensate by adding synaptic strength at least in part by the formation of new synapses. This redistribution refines synaptic circuitry by allowing an axon to strongly focus its innervation on a subset of the cells it initially contacted while each postsynaptic cell is

restricted to responding to a subset of the axons that initially innervated it.

### THE PURPOSE OF SYNAPSE ELIMINATION

Although at first sight it might seem reasonable that synapse elimination is some form of error correction to rid the developing nervous system of connectivity mistakes, this does not seem to be the case. In muscle for example, the lost connections are from exactly the motor neurons as those connections that are maintained because each neuron in the pool is losing some connections. In some situations the outcome of synapse elimination may *sharpen specificity* based on topographic maps (see for example, Laskowski *et al.*, 1998). It is thus possible that the outcome of synapse elimination is biased by the same kind of cues that promote selective synapse formation rather than synapse elimination being the mechanism that achieves the specificity. This view may explain why in some cases there seems to be little evidence of intrinsic positional or other qualitative differences between axons that are maintained and those that are lost from a particular postsynaptic cell.

An alternative hypothesis is that the loss of connections is a consequence of the extreme degree to which mammalian (and other vertebrate) nervous systems are composed of *duplicated neurons* (Lichtman and Colman, 2000). For example, pools of motor neurons that may number in the hundreds innervate individual

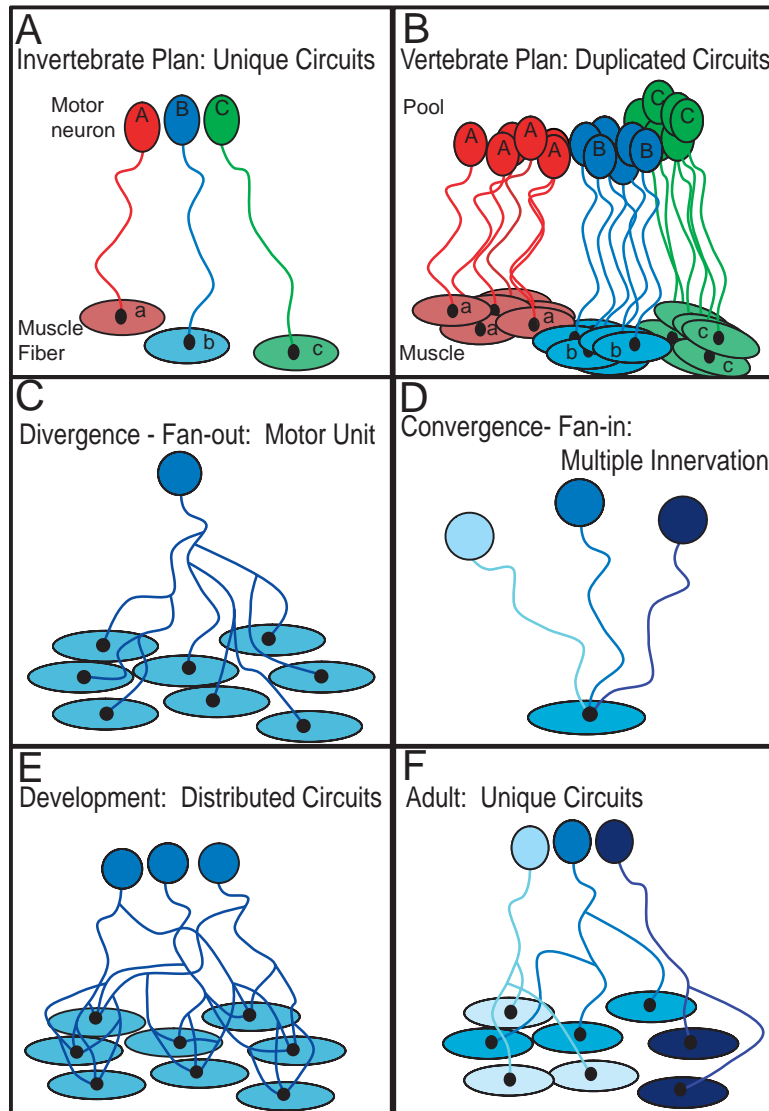

**FIGURE 20.4** Time-lapse imaging shows how axonal branches are lost during synapse elimination at the neuromuscular junction. Two neuromuscular junctions (NMJ1 and NMJ2) were viewed *in vivo* on postnatal days 7, 8, and 9 in a transgenic mouse that expresses YFP in its motor axons (green). The acetylcholine receptors at the muscle fiber membrane are labeled with rhodamine tagged  $\alpha$ -bungarotoxin (red). On day 7, NMJ1 is multiply innervated whereas NMJ2 is singly innervated by a branch of one of the axons that innervates NMJ1. One day later (postnatal day 8), one of the motor axons innervating NMJ1 becomes thinner all the way back to its branch point. When viewed on postnatal day 9, this thin branch is no longer connected to NMJ1 and now ends in a bulb-shaped swelling that is called a retraction bulb. Modified from Keller-Peck *et al.* (2001).

**FIGURE 20.5** Retracting axons shed material as they disappear. The inset shows a surface rendering of a serial electron microscopy reconstruction of a retraction bulb (green, arrowhead) during synapse elimination at a developing neuromuscular junction. The electron micrograph shows that the retracting axon contains clusters of vesicles and mitochondria. In the vicinity of the bulb but not connected are small spherical axonal fragments (axosomes, arrow) that are engulfed by glial cells (i.e., Schwann cells (SC), darker cytoplasm). Scale bars,  $1\mu\text{m}$ . From Bishop *et al.* (2004).

skeletal muscles containing thousands of muscle fibers. This differs from invertebrates that have single identified motor neurons innervating single muscle fibers (Fig 20.6A). Thus nearly identical motor neurons seem to have approximately equivalent roles as does the large population of comparable postsynaptic cells that constitute a muscle (Fig. 20.6B).

There are two potential consequences of such redundancy in pre- and postsynaptic populations. First, many presynaptic neurons could be appropriate matches for each postsynaptic cell causing substantial axonal convergence or fan-in. Second, many postsynaptic neurons are appropriate matches for each presynaptic axon causing substantial axonal divergence or fan-out. For example, in mammalian muscles, because the many nearly identical motor neurons projecting to one muscle may all be equally appropriate presynaptic partners for each muscle fiber, it is not unexpected that multiple axons can converge on the same target cell (Fig. 20.6C). At the same time, the multiple duplicated muscle fibers may all be equally appropriate targets for each motor neuron, causing each motor neuron to diverge to innervate many muscle fibers (Fig. 20.6D). Given the redundancy in both pre- and postsynaptic populations, it would not be surprising that in the mammalian motor system there are overlapping *converging and diverging pathways* (Fig. 20.6E). What is surprising, however, is that this overlap is short-lived. During neuromuscular development, axonal branches are pruned in a highly selective way, causing the projection of each motor

**FIGURE 20.6** A diagram showing differences between the vertebrate and invertebrate synaptic circuits. (A) Invertebrates have small numbers (for example sometimes just one motor neuron) of identifiable neurons innervating small numbers of identifiable target cells (e.g., sometimes just one muscle fiber) whereas in vertebrates, pools of similar neurons innervating targets contain hundreds or thousands of similar postsynaptic cells (B). The redundancy in the vertebrate nervous system allows a neuron to diverge (fan-out) and innervate many equally appropriate target cells (in the neuromuscular system this is called a motor unit), (C). The homogeneity of innervating neurons allows multiple axons to converge (fan-in) on each target cell (D). As a result vertebrate circuits contain a substantial amount of fan-in and fan-out (E), at least initially. Synapse elimination's purpose may be to transform such a set of redundant circuits into multiple unique ones by trimming away the multiple innervation of target cells (F). The result of the widespread loss of synapses is the generation of thousands of nonredundant circuits from an initially much less specific innervation pattern. From Lichtman and Colman (2000).

axon to become completely nonoverlapping, and thus completely distinct from other axons' projections (Fig. 20.6F). From a functional standpoint, once synapse elimination is complete, the recruitment of each motor axon gives rise to activation of a different set of muscle fibers and consequently a substantive increase in tension of the muscle. This stepwise tension increase is a necessary aspect of the *size principle* (Chapter 19).

By parsing highly redundant circuitry into multiple, unique, functionally distinct circuits, synapse elimination may be an essential maturation step for synaptic circuits that begin with considerable redundancy, such as our own nervous systems and those of other terrestrial vertebrates. It is possible that this paring down strategy is less relevant in other kinds of animals.

Indeed a comparison between animals, such as insects, that show little evidence of neuronal redundancy and little evidence of input elimination with animals, such as mammals, with large redundant pools of neurons and extensive elimination during development suggests very different neurodevelopmental strategies. Humans and other mammals seem highly dependent on experience for the acquisition of their behavioral repertoire, whereas invertebrate behavior is, to a greater degree, intrinsic. Compare, for example, the ease with which a newly hatched dragonfly takes wing versus the protracted period necessary for a human child to learn to walk. It is possible that the neuronal redundancy found in higher vertebrates that give rise to overlapping convergent and divergent pathways are used in the acquisition of skills by the experience-mediated *selection* of connections.

This difference between mammals and invertebrates does not mean that synapses cannot be eliminated in invertebrates. Indeed, many studies have made the point that synaptic remodeling through addition and removal occurs in insect nervous systems (see for example, Eaton and Davies, 2003; Ding *et al.*, 2007). The molecular mechanisms involved in invertebrate synaptic remodeling may provide insights into the mechanisms of synaptic loss and maintenance in higher vertebrate nervous systems. In worms for example, the ubiquitin proteasome complex has been shown to regulate the elimination of motoneuron synapses onto vulval muscles (Ding *et al.*, 2007). Similar degradation mechanisms may also be involved in synaptic remodeling of vertebrate neurons. The important point here, however, is that these mechanisms are used in mammals to alter the connectivity of the nervous system (i.e., to alter the number and identity of an axon's postsynaptic targets). In most invertebrate systems and perhaps lower vertebrates such as fish these same mechanisms may play more of a role in modifying the strength of existing connections without altering the circuit's wiring diagram.

### Summary

In contrast to invertebrates, the nervous systems of terrestrial vertebrates contain reduplicated populations of neurons that serve each function. Elimination of synaptic connections during development may be an adaptation that converts highly overlapping connections of redundant neurons into unique circuits. Because this conversion may be based on experiences that affect the development of the nervous system this process may tune the nervous systems of higher animals to the particular environment of each individual animal.

## A STRUCTURAL ANALYSIS OF SYNAPSE ELIMINATION AT THE NEUROMUSCULAR JUNCTION

Thanks in large part to the power of fluorescence microscopy and the accessibility of the neuromuscular junction; it has been possible to describe the physical changes in axons and synapses that take place during synapse elimination. Interestingly this purely descriptive analysis has yielded important clues and some mechanistic insights into the process of synapse elimination. As Yogi Berra said, "You can observe a lot by just watching." Imaging neuromuscular junctions at various ages in early postnatal life makes clear the fact that the process of synapse elimination is not a sudden calamitous event but rather protracted process. At birth, multiple axons converging at a neuromuscular junction are highly intermingled and the extent of the receptor areas occupied by each is similar (Balice-Gordon *et al.*, 1993). These highly intermingled connections eventually become progressively segregated over several days (Fig. 20.7). The partitioning of synaptic areas associated with different axons suggests that there is a spatial component to the mechanism. One scenario for example is that each axon *locally destabilizes* other inputs in their immediate vicinity but cannot as efficiently affect slightly more distant branches of the same axons. If the destabilization of an input was followed in turn by the takeover of its synaptic sites by the remaining axon, then an axon with a larger consolidated area might begin to destabilize more distant inputs. The idea of progressive consolidation was put to the test by the use of transgenic mice expressing different color fluorescent proteins in individual axons. With these animals it is possible to obtain a precise map of the territories occupied by two axons at the same neuromuscular junction. *In vivo* time-lapse imaging of a multiple innervated neuromuscular junction over several days showed both gradual withdrawal of one axon from postsynaptic sites and a corresponding expansion of another axon to takeover those synaptic sites (Fig. 20.8). This result may mean that axons are vying to occupy the same sites. Interestingly, it was not inevitable that the withdrawal of one axon was followed by the takeover of its sites by another input. In some cases an axon that was already somewhat segregated from the other input would vacate its postsynaptic territory but rather than being replaced by the remaining axon, its acetylcholine receptor-rich postsynaptic site would disappear. Synaptic loss without reoccupation by another input suggested that the takeover process per se was not causing withdrawal of the other axon. These

**FIGURE 20.7 Segregation of synaptic territory as axons compete during synapse elimination.** Double transgenic mice expressing YFP and CFP in different motor axons were used to observe axons nerve terminal interactions. At birth is shown two competing nerve terminals, one expressing CFP (blue) and the other YFP (green) at this neuromuscular junction, which are intermingled. By the second postnatal week, however, YFP and CFP axon terminals are generally completely segregated from each other in multiply innervated junctions. Red is fluorescently tagged alpha-bungarotoxin that binds to AChRs. Modified from Gan and Lichtman (1998).

observations suggest that synaptic takeover might be a response to the recent synaptic vacancy.

These time-lapse studies also demonstrated that the shift in favor of one axon was not irreversible. In some junctions for example, it was hard to predict which axon might ultimately be maintained because the input with the majority of the territory shifted back and forth. Such flips in which axon seemed to be dominant suggest that the outcome is not preordained. Instead, axons at multiply innervated neuromuscular junctions appear may be in the midst of a highly dynamic interaction to determine which axon is most likely to stay.

Insights into the regulation of this dynamism come from analyses of each of the branches of individual motor axons. In lines of transgenic mice in which fluorescent proteins are expressed in a very small subset of motor neurons, it has been possible to examine all the branches of one axon during the developmental period when branches are being pruned. These studies show that axonal branch loss is occurring asynchronously among all the branches of one axon (Fig. 20.9). Thus while some branches are recently eliminated (i.e., retraction bulbs), other branches are still connected to neuromuscular junctions that are multiply innervated. This range suggests that the fate of each branch is controlled independently. If axonal branches of one neuron are interacting with different axons at each of its neuromuscular junctions, then perhaps the rate of synapse elimination is regulated by which particular axons that are coinnervating each of these junctions. These interactions might not only determine the rate but also the fates of the terminals; that is, which neuron's branches are maintained and which are eliminated. For example an axon might be eliminated quickly at neuromuscular junctions innervated by some other neurons, but fare better at junctions innervated by other axons.

To explore this possibility, transgenic mice with only two labeled axons (one yellow and one cyan) were generated to examine each of the neuromuscular junctions cooccupied by the same two axons within a developing muscle. The result was dramatic: at each of the shared neuromuscular junctions, the two axons

seemed to be in the same relative state (Fig. 20.10). Thus if the cyan axon was occupying only a small amount of territory at one junction that it shared with the yellow axon, then it occupied a small amount of territory at all the other junctions it shared with the same yellow axon. However, where the cyan axon was interacting with other axons, its fate could be quite

**FIGURE 20.9 Asynchronous synapse elimination among the branches of one axon.** Using transgenic animals that express YFP in a small subset of motor axons it was possible to monitor the behavior of multiple branches of the same axon. This diagram shows the typical result for an axon in the midst of the synapse elimination process. Represented in red are the AChRs on each muscle fiber (represented as gray tubes). This motor axon (black) has won the competition on the bottom muscle fiber and occupies the entire receptor plaque. The same axon has lost the competition for the adjacent muscle fiber, where only a retraction bulb remains. The three other neuromuscular junctions that this axon innervates are still undergoing competition. In one case a small portion of AChRs is being innervated by this axon. It is likely that this synapse will be eliminated. On the other two muscle fibers, each axon terminal occupies ~50% of the AChRs. This indicates that its fate is not yet determined in these junctions. Adapted from Lichtman and Colman (2000).

**FIGURE 20.8 *In vivo* imaging shows takeover of synaptic territory by the remaining axon during the period of synapse elimination.** Neuromuscular junctions in transgenic mice that express YFP (yellow) and CFP (blue) were imaged multiple times during early postnatal life. (A–E) views of one neuromuscular junction between P8 and P15. The CFP axon takes over occupancy of the postsynaptic sites (labeled red) in the upper parts of the junction that were formerly innervated by the YFP axon. The YFP labeled axon withdrew until only a retraction bulb remained (E, asterisk). At P12, a process of the CFP axon had begun to invade the territory of the YFP axon (D, circle and arrow in inset). (F–J) Although the CFP axon (blue and insets) has greater terminal area (~70%) at the first view, it progressively withdraws from the junction (arrows). Its retraction bulb can be seen in (I) and (J) (asterisks). Scale bars = 10  $\mu\text{m}$ . Insets show the blue axons. From Walsh and Lichtman (2003).

**FIGURE 20.10** Axonal fate at individual neuromuscular junctions is related to the identity of the competing axons. Using transgenic animals that express YFP (yellow) and CFP (blue) in a small subset of motor axons was possible to reconstruct two motor units in which several neuromuscular junctions are innervated by the exact same two axons, one expressing YFP and the other CFP. At these coinnervated junctions it appears that the same outcome is occurring at each. In this case, the YFP axon always occupied more territory than the CFP axon. Note also that the axon calibers of the YFP axon branches are thicker than CFP branches to the same junctions. Thus synapse elimination seems to be biased such that when the same two axons compete the fate is the same at each coinnervated neuromuscular junction. Image from Kasthuri and Lichtman (2003).

different. This result argued that the fate of axonal branches and the rate at which they are eliminated is related strictly to the identity of the coinnervating axons. But why might the yellow axon be consistently “better” than the blue at all the coinnervated neuromuscular junctions they share? Counts of the total number of neuromuscular junctions each axon innervated (i.e., its motor unit size) provided a hint; the outcome of synapse elimination seemed to depend on the relative sizes of the two axons’ motor units. In particular, neurons with larger motor units (such as the cyan axon in Fig. 20.10) were at a disadvantage when confronting neurons with smaller arborizations (such as the yellow axon in Fig. 20.10). One interpretation of this result is that axons with few branches in a muscle could dedicate more resources to a multiply innervated neuromuscular junction than neurons with a larger number of branches that are in some sense overextended. If this idea is correct then the consequence for an axon (such as the cyan one in Fig. 20.10) of losing branches is that it can now dedicate more resources to its remaining multiply innervated junctions shared with other axons.

These results raise the obvious question of what resources might be in limited supply in an axon that could affect synapse maintenance. One popular idea is that the synaptic activity of an axon terminal is a key

determinant in its ultimate fate. Is it possible that large motor units have fewer synaptic resources (e.g., synaptic vesicles per synapse) than small motor units? This idea was tested by generating mice in which a subset of axons had diminished choline acetyltransferase (ChAT, the enzyme that synthesizes the acetylcholine; Buffelli *et al.*, 2003). The results showed that when axons containing normal levels of ChAT coinnervated junctions with axons that had subnormal amounts, the subnormal axons typically occupied smaller territories. This result is consistent with the idea that axons that have the greatest number of synaptic branches may be at a disadvantage because they cannot maintain sufficient resources to drive postsynaptic cells as well as axons with fewer branches.

## Summary

Structural studies of synapse elimination at the neuromuscular junction have provided a number of clues as to how and why branches are pruned. One important insight is that synapse elimination at individual neuromuscular junctions may be part of a larger scale circuit optimization. This optimization may be occurring to assure that all the connections that are maintained into adulthood are sufficiently strong that they can consistently drive the postsynaptic cell to threshold. Perhaps such an optimization requires axons to forfeit some of their synaptic connections to assure that the ones that remain have sufficient resources to be consistently efficacious.

## A ROLE FOR INTERAXONAL COMPETITION AND ACTIVITY

A number of lines of evidence suggest that the loss of synapses is the consequence of *competition*. The word “competition,” however, has many different meanings, and which of these definitions is most relevant to synaptic development is an area of some debate (Lichtman and Colman, 2000; Ribchester, 1992; Ribchester and Barry, 1994). In broad terms, competition occurs when more than one individual (in this case, more than one axon) is capable of having the same fate (e.g., sole occupation of a neuromuscular junction), and the probability of having that fate is related inversely to the number of such individuals. The point of defining competition so broadly is to emphasize that competition does not imply what kind of mechanism drives the outcome—even lotteries, where winners are picked by random, are competitions. Synapse elimination occurring on muscle fiber

cells or cerebellar Purkinje cells is thought to be competitive because there is always only one axon remaining at the completion of the process and therefore more than one axon cannot share the same fate.

Importantly, which particular axon is maintained does not seem to be preordained. There is no evidence of an extensive molecular specificity that uniquely matches each motor axon to an exclusive subset of muscle fibers or each climbing fiber to a matching set of Purkinje cells. But if it is a competition, how is this competition being driven? Competitive mechanisms range from situations where the contestants interact with each other directly (e.g., a sumo wrestling match) to mechanisms where the contestants have little or anything to do with each other and a third party (a judge) decides the outcome (e.g., competition for a Pulitzer prize). Evidence in the neuromuscular system suggests that synaptic competition may be more akin to the latter alternative with the muscle fiber playing the role of judge.

### Neuromuscular System

In 1970, Paul Redfern published the first physiological report of synapse elimination. He found that rat diaphragm muscle fibers were innervated by several motor neurons in the first postnatal week but this multiple innervation was short lived; by two weeks of age all muscle fibers were singly innervated (Fig. 20.1). At the time, he suggested that the extra innervation may be explained by the presence of motor neurons that project to a muscle in early life but subsequently undergo *cell death*. A few years later this idea was shown to be incorrect when the tension elicited by activating single motor axons was shown to drop precipitously over the same period of early postnatal life indicating that synapse elimination was accompanied by motor unit branch trimming rather than wholesale motor neuron loss (an event that occurs in the prenatal period) (Brown *et al.*, 1976). Brown *et al.* (1976) also made the important point that because all neuromuscular junctions ended up with exactly one innervating axon, the elimination process was likely explained by interaxonal competition—otherwise all axons should leave a neuromuscular junction or more than one converging axon should persist into adulthood. These two seminal reports stimulated many investigators to seek an understanding of the underlying mechanisms. Much of this effort has focused on the role of activity in synapse elimination. Many lines of evidence show that modifying neuromuscular activity has a large effect on synapse elimination (Thompson, 1985). However, it has remained unclear how activity might mediate interaxonal competition, as conflicting evidence suggested that either active (Ridge and Betz,

1984) or surprisingly, inactive axons (Callaway *et al.*, 1987) are at an advantage. At first glance, it may seem improbable that inactive axons could out-compete active ones (a result that is opposite to one discussed later, on the effects of monocular deprivation in visual system synapse elimination). Callaway *et al.* (1987) argued that the way muscles are used, the axons that are recruited most infrequently were the ones that in adults had the largest motor units. If their large sizes resulted from less branch trimming during development then inactive axons might indeed have the advantage in synaptic competitions. Further complicating matters is the fact that the total number of axons innervating the muscle does not appear to change (Brown *et al.*, 1976). This constancy implies that no individual axon's activity pattern could be considered *the worst*, because all axons maintain some neuromuscular junctions and thus all axons must out-compete other axons at some junctions.

Other experiments have questioned whether activity is even necessary for synapse elimination. For example, after reinnervation of adult muscle, evidence has been obtained showing that electrically silent inputs can displace other electrically silent inputs (Costanzo *et al.*, 2000). Moreover, in some cases the presence of activity does not invariably lead to neuromuscular synapse elimination (Costanzo *et al.*, 1999).

As these conflicting experimental results demonstrate, the role of activity in synapse elimination is not easily summarized. One way to obtain a clearer idea of the role of activity is to view "activity" not as one phenomenon but as several different influences. For example,

- Synaptic competition may be affected by the relative efficacy (i.e., amplitude of the postsynaptic potential) of different axons attempting to drive the postsynaptic cell to threshold, with the most powerful input being favored.
- Alternatively, the firing frequency of an axon (i.e., action potentials per second) may have a negative impact especially if the axon has a large arbor and thus insufficient resources to maintain efficacious synaptic transmission throughout its terminal branches.
- Finally, activity may affect the electrical properties of the postsynaptic cell or cell region either encouraging synapse elimination (excitable encouraging membrane) or preventing it (inexcitable postsynaptic membrane) (Fig. 20.11).

The most accepted hypothesis is that activity differences between axons is critical for synapse elimination to occur. Indeed, because an axon has many synaptic release sites impinging on one postsynaptic cell that

**FIGURE 20.11 Postsynaptic cells that don't fire action potentials don't undergo synapse elimination.** Photomicrographs of multiply and singly innervated snake muscle fibers. The singly innervated neuromuscular junctions are on twitch muscle fibers that have voltage-sensitive sodium channels. The multiply innervated neuromuscular junctions are found on tonic muscle fibers that do not have regenerative potentials. Labeling of different axons with different colors was accomplished by activity-dependent fluorescent labeling of axon terminals. From Lichtman *et al.* (1985).

### BOX 20.1

#### $\alpha$ -BUNGAROTOXIN

A number of different dyes, stains, and markers are useful in revealing synaptic structure and function. Some of the more powerful have been borrowed from nature. Many toxins and poisons bind to specific proteins. One example is the snake toxin  $\alpha$ -bungarotoxin ( $\alpha$ -btx). This toxin is a constituent of the venom of a *Krait* snake of the species *bungarus*. The lethality of  $\alpha$ -btx is the consequence of its ability to bind to the  $\alpha$  subunits of nicotinic AChRs in skeletal muscle cells of vertebrates (with a few notable exceptions: snakes, mongooses, and hedgehogs). Because  $\alpha$ -btx is an irreversible competitive antagonist of the AChR, its binding thus paralyzes and suffocates the prey. Researchers have taken advantage of this snake toxin to study many aspects of the AChR. For example,  $\alpha$ -btx was used to purify AChRs from *Torpedo* membranes. Further-

more, the toxin can be conjugated to radioactive markers or to fluorescent molecules that can be seen in the microscope to stain receptors on muscle cells to determine their distribution, stability, and motility in the membrane. Because the toxin binds essentially irreversibly to the receptor in the muscle fiber membrane, receptors can be labeled once and then their behavior followed over time. This approach has provided substantial evidence about the stability of synaptic regions on muscle fibers, the lifetime of receptors in the membrane at the junctional sites, and how AChRs move within the plane of the membrane. For studies of synapse elimination in particular, the toxin also has been used to selectively inactivate some regions of a synapse by "puffing" it locally over a small region of a junction.

do not seem to compete with themselves, interaxonal activity differences are assumed to be a crucial element of the competition. An experiment in which one part of a neuromuscular junction was desynchronized from the rest by silencing its acetylcholine receptors with alpha bungarotoxin (Box 20.1) examined how activity differences might give rise to synapse elimination. Focal postsynaptic silencing at one site within an otherwise normally active adult neuromuscular junction

induced synapse withdrawal from the silenced site (Fig. 20.12). Postsynaptic silencing of an entire neuromuscular junction, however, did not cause synapse loss. These results suggested that synaptic activity at some synaptic sites can induce synaptic destabilization of other sites if they are not active at the same time. This view of the way activity modifies synaptic connections is related to the well-known theory of plasticity: *Hebb's postulate* (Hebb, 1949; see Chapter 50).

**FIGURE 20.12** An experimental test of the role of postsynaptic activity in synapse elimination. If axons converging on the same postsynaptic cell were competing based on their efficacy in activating the postsynaptic cell, then locally blocking synaptic transmission at one axon's synaptic site should lead to its elimination and the maintenance of the other unblocked inputs. In this test, focal blockade of neuromuscular transmission was accomplished by applying saturating doses of  $\alpha$ -bungarotoxin with a fine glass pipette (upper panels, red) to a neuromuscular junction in a living mouse. The AChR sites (middle panels) and the nerve terminals (lower panels) were viewed at the time of blockade and several times over the next few weeks. Following focal blockade (left panels) progressive loss of the nerve terminal staining and AChRs (arrows) was observed in regions previously saturated with  $\alpha$ -bungarotoxin. However, when the entire neuromuscular junction was blocked (right panels) there was no loss. These results argue that active postsynaptic synaptic sites can cause the disassembly of inactive sites. Adapted from Balice-Gordon and Lichtman (1994).

Although Hebb argued that inputs that are consistently active when the postsynaptic cell is active, are strengthened, this idea is the logical obverse: synapses that consistently fail to excite the postsynaptic cell when the cell is being activated are eliminated (Lichtman and Balice-Gordon, 1990; Stent, 1973). How might active synaptic sites destabilize silent ones? One suggestion is that active synapses generate two kinds of postsynaptic signals: one that protects them from the destabilizing effects of activity and the other that punishes other inputs that are not active at the same time (Fig. 20.13). The physical basis of these protective and punishment signals remains unclear. Since neurotransmitter receptors are sometimes permeable to calcium, and the activity-induced depolarization can also raise

intracellular calcium levels, one idea is that calcium signaling serves one or both of these roles.

This view of the role of activity implies that if all axons were firing synchronously then synapse elimination would not occur, which is exactly the conclusion reached using a regeneration model for synapse elimination (Busetto *et al.*, 2000). Interestingly, during the period of naturally occurring synapse elimination there appears to be a switch from synchronous to asynchronous activity patterns (Personius and Balice-Gordon, 2001; Buffelli *et al.*, 2002). It has been suggested that a gradual loss of electrical coupling among motor neurons may be the reason synapse elimination begins. This hypothesis was recently tested in mice that lack a gap junction protein (connexin 40) in which motor

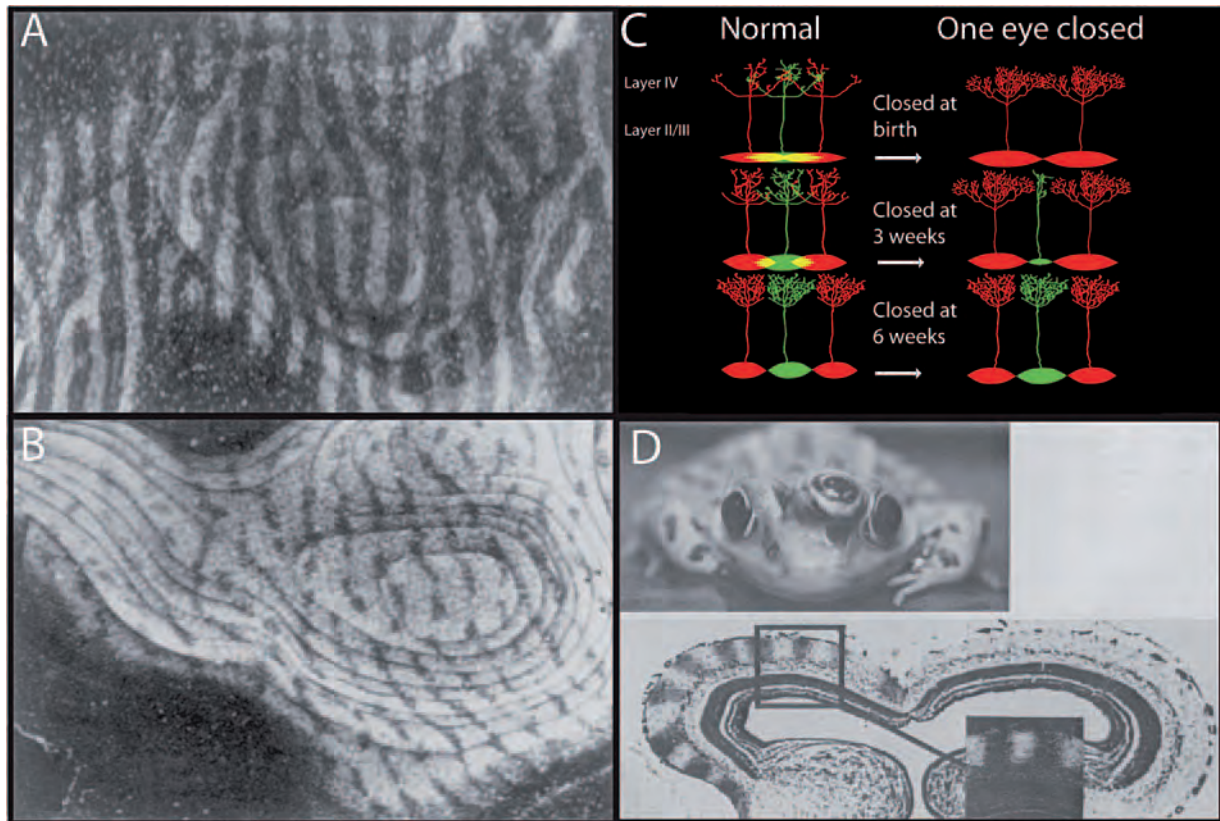

**FIGURE 20.13 Putative mechanism for a postsynaptic role in synapse elimination.** Postsynaptic receptor activation may elicit two opposing signals within a muscle fiber. One consequence of receptor activation is a “punishment” signal (here designated as red arrows) that causes destabilization of synaptic sites. Receptor activation may also generate a “protective” signal (here designated as blue clouds) that locally prohibits the punishment signals from destabilizing synapses in the vicinity of where receptor activation recently occurred. (A) When all the receptors are activated synchronously, as might occur before birth when motor neurons are electrically coupled (Personius *et al.*, 2001), there is no synaptic destabilization (due to protective blue clouds everywhere). (B) However, later in development, when two inputs are activated asynchronously, the active synaptic sites at any time point are protected (i.e., the synaptic sites beneath the active green axon are protected by a local blue cloud) whereas the asynchronously activated synapses (i.e., the synaptic sites under the pink axon) are not protected. (C) This asynchrony allows the more powerful input to destabilize the weaker one. This destabilization can lead to nerve and postsynaptic disappearance and/or nerve withdrawal followed quickly by takeover of its former synaptic sites by the remaining axon, which would restabilize the site. (D) If all synaptic sites are inactive, as might occur with  $\alpha$ -bungarotoxin application that inactivates nicotinic AChRs, then there are no blue clouds to protect synaptic sites, but also no red arrows to destabilize them. Thus synaptically silent and synchronously active synaptic sites (see panel A) do not undergo synapse elimination. Idea adapted from Jennings (1994).

neuronal electrical coupling is reduced. In  $Cx40^{-/-}$  muscles, synapse elimination was significantly accelerated, suggesting that asynchronous firing of neurons enhances synapse elimination (Personius *et al.*, 2007).

Such an activity-based mechanism for synapse elimination would tend to pit the synchronously active synaptic terminals of one axon on a given postsynaptic cell (a *synaptic “cartel”*) against the terminals of other axons contacting the same target cell. In this way an axon’s terminals on one postsynaptic cell cannot compete against themselves but rather serve as a competitive unit vying against the cartels of other axons.

### Visual Cortex

Classic studies on the visual system by Hubel and Wiesel were the first to suggest that competition in fact was driving synaptic reorganization in the developing brain (Hubel and Wiesel, 1963; Hubel *et al.*, 1977). In most species of young mammals, input neurons to layer IV in the visual cortex can be activated by inputs driven from both the left and the right eye; that is, they are driven binocularly. Subsequently, however, in many species, cortical input neurons become strongly dominated by either the right or left eye but not both (Fig. 20.14). In agreement with this physiological result, the terminal arbors of the geniculocortical axons from

**FIGURE 20.14 Synapse elimination in the visual system.** (A) Ocular dominance columns of the neonatal monkey primary visual cortex in layer IVC, revealed by injecting  $[^3\text{H}]$ -proline into the vitreous of one eye. Light stripes (columns) represent sites containing the anterograde transported  $^3\text{H}$ -amino acid from the injected eye. Dark regions are occupied by axons driven by the other eye. (B) Monocular deprivation by lid suture of one eye (2 weeks after birth for a period of 18 months) resulted in the shrinkage of the columns representing the deprived eye (dark stripes) and an expansion of the columns of the nondeprived eye (light stripes). (C) A schematic representation of ocular dominance column development represents the way in which a gradual segregation ocular dominance columns could lead to the end of the critical period and progressively more modest effects of monocular deprivation as development ensues. (Top) At birth the afferents from the two eyes (red and green ovals) overlap completely in layer IV and thus each eye is capable of maintaining inputs everywhere. At this young age, monocular deprivation would allow the nondeprived eye to remain in all parts of layer IV so that the entire cortex would be dominated by the red inputs. (Middle) In nondeprived animals, the two sets of afferents become progressively more segregated with age, meaning that by three weeks there would be regions of layer IV that are exclusively driven by the red or, as shown, green afferents. Once an eye's inputs are removed from a territory, it can no longer reoccupy that territory when the other eye is silenced. Hence monocular deprivation (that begins at three weeks) will spare a small strip of the inactive eyes territory (in this case the green regions). (Bottom) Once segregation is complete then monocular deprivation has no effect and the critical period is over. (D) A remarkable example showing how interactions between two eyes can cause segregation was found in frogs in which a third eye is implanted (at the tadpole stage) next to one of the eyes and projects with the native eye to the same optic tectum (ordinarily each frog tectum is monocular). After injection of  $\text{H}^3$ -proline into the normal eye, one optic tectum of a three-eyed frog shows dark and light bands strikingly similar to the ocular dominance columns observed in monkeys (D). A–C adapted from Hubel *et al.* (1977); D from Constantine-Paton and Law (1978).

the two eyes overlap in early postnatal life (Hubel *et al.*, 1977; but see Horton and Hocking, 1996). However with time, their projections appear to resolve into a striking pattern of alternating stripes known as *ocular dominance columns* (Fig. 20.14). This anatomical result was based on anterograde transneuronal transport of radioactive amino acid that was injected into one eye and passed through the thalamus to label the eye specific axons in the optic radiation (Hubel *et al.*,

1977). Despite the remarkable clarity of these stripes, their functional significance is not well understood and in some mammals such as rodents and new world monkeys, ocular dominance columns are absent (Horton and Adams, 2005; Livingstone, 1996).

During development the ocular dominance columns' organization is less obvious because there is overlap in the thalamic inputs driven by the right and left eye to layer IV. Anatomically as development proceeds each

eye's columns become narrower and eventually almost nonoverlapping (especially in primates). Even though the narrowing in the widths of right and left eye ocular dominance columns is likely due to the loss of axonal branches in overlapping regions (Antonini and Stryker, 1993), this retraction of branches should not be taken to mean that the total number of thalamo-cortical synapses in layer IV is decreasing during this period. Similar to the peripheral nervous system, the axons associated with each eye elaborate many new synapses that more than compensate numerically for the lost connections of the withdrawing axons (Crowley and Katz, 2000; Erisir and Dreusicke, 2005). In other words, the process of ocular dominance column formation is one in which individual arbors lose synaptic connections with some targets but gain connections with others. Thus elimination restricts the neuronal population that is directly driven by each eye, but the synaptic addition strengthens the influence of one eye on the regions of cortex it continues to drive.

The most interesting aspect of this segregation is that the gradual removal of overlap in the two eyes' input streams leading to equally sized ocular dominance columns is not inevitable. Hubel and Wiesel showed that during a developmental *critical period* in early postnatal life, the widths of these columns can be dramatically and permanently changed by alterations in the relative amounts of visual experience in the two eyes. In particular, the outcome of the segregation can be radically skewed in favor of one eye if the activity of the other eye is decreased (e.g., by patching one eye). This monocular deprivation results in larger columns for the open eye and smaller columns for the deprived eye (Fig. 20.14). Once the critical period of sensitivity is passed (approximately the seventh postnatal week in kittens, the tenth week in ferrets, and the twentieth week in rhesus monkeys), the widths of the ocular dominance columns are fixed and no longer subject to shifts based on visual experience. Remarkably, even long-term monocular deprivation (of decades or more) apparently has little effect on the width of ocular dominance columns if the visual deprivation is begun after the critical period is over (approximately six years in humans; Keech and Kutschke, 1995). For example, in human patients, in which one eye was removed for surgical reasons in adulthood or late childhood, postmortem analysis of the visual cortex indicated that eye removal has little or no effect on the width of the ocular dominance columns dominated by the removed eye (Horton and Hocking, 1998). What might account for this dramatic change in sensitivity?

One idea is that during the critical period, thalamic afferents driven by the two eyes *compete* for control of

the cortical neurons that they share temporarily. If each eye has the same average amount of activity, each ended up with similar amounts of cortical territory. However, if there were imbalances between the eyes in terms of visual experience, the outcome tipped the segregation in favor of one eye over the other. The skewing that resulted from depriving one eye of vision was due both to additional losses in the connections driven by the inactive eye (shrinking its ocular dominance columns) and to additional maintenance of the connections from the normally active nondeprived eye (maintaining its columns at the wider width it had at an earlier age) (Fig. 20.14). Ordinarily, each eye's afferents would relinquish its connections with approximately half of its postsynaptic target cells in visual cortex. Furthermore, binocular eye closure during the critical period appears to have far less serious effects than monocular occlusion. These results support the idea that synapse elimination is due to an activity-mediated competitive interaction between the connections driven by the two eyes. Because binocular deprivation has less dramatic effects on ocular dominance columns than monocular deprivation, here, as at the neuromuscular junction, active synaptic inputs seem to play a role in destabilizing inactive inputs.

Though these conclusions appear straightforward, the roles of activity in cortical refinements may need reevaluation as new investigations show that the mechanisms may be more complicated than originally imagined. In studies of the rodent visual system, evidence suggests roles for both activity dependent and independent factors in developmental axonal refinements. Although mice lack ocular dominance columns, they do have a binocular cortical region that becomes progressively smaller as development proceeds. This shrinkage can be shifted with monocular deprivation during a critical period (Antonini *et al.*, 1999). This system has been used to show an important role of inhibitory circuits in both the establishment and maintenance of the critical period (Hensch, 2005). For example, deletion of the gene for glutamic acid decarboxylase, the enzyme that is responsible for the synthesis of the inhibitory neurotransmitter, GABA, prevents visual cortical refinements (Fagiolini and Hensch, 2000). Interestingly, these refinements can be reinitiated at any age by injecting GABA receptor agonists such as benzodiazepines into visual cortex. Thus intracortical inhibitory circuitry may be sufficient to trigger the opening or closure of the critical period in mice (Hensch *et al.*, 1998; Hensch, 2004).

In mouse visual cortex it has also been possible to study the sharpening of the retinotopic map in early postnatal life. The small receptive fields seen in adult

visual cortex emerge from shrinkage of receptive field size in development (Issa *et al.*, 1999). Activity plays a complex role in this sharpening; the effects of deprivation of formed vision (by lid suture) are different than the effects of pharmacological blockade or enucleation (Smith and Trachtenburg, 2007). A contralateral eye that is sensing light through a sutured lid impedes the refinement of the open eye's central projection, whereas either an open, or completely silent, contralateral eye does not. This result suggests that when inputs are synchronous (i.e., both eyes open), the activity mediated refinements that shrink receptive fields occur more efficiently than when the same cortical neurons are receiving inputs with different activity patterns (i.e., in an animal with one open and one sutured eye). On the other hand when one eye is entirely silent (i.e., by enucleation or pharmacological blockade), then the refinement of the open eye's inputs can still occur because in this case, there is no competing activity pattern from another eye. Thus some kinds of refinements may be mediated by cooperative interactions between the two eyes rather than competitive ones. One recent trend is that experiments that might have previously been interpreted strictly in terms of activity mediated competition between different axons (à la Hubel and Wiesel) are now recast in terms of *homosynaptic* mechanisms of potentiation and depression or mechanisms of *synaptic homeostasis* (Chapter 50). These newer frameworks for thinking about critical periods suggest that many different regulatory mechanisms working simultaneously may help to assure that the right numbers and kinds of synapses survive the period of developmental refinements.

### Thalamus

Separation of the inputs from the two eyes occurs twice in the visual system. Prior to the emergence of cortical ocular dominance columns, eye input to the lateral geniculate nucleus of the thalamus segregates into layers rather than columns. In embryonic cats, axon terminals of ganglion cells from the two eyes overlap extensively within the lateral geniculate nucleus before gradually segregating to form the characteristic *eye-specific* layers by birth. As in the cortex, this refinement process involves both the retraction of axonal branches from inappropriate regions of the geniculate nucleus and the elaboration of processes within the correct eye layer (Shatz, 1990). Physiological studies support anatomical observations that geniculate neurons initially are driven binocularly but maintain the axonal input from only one eye at maturity (Shatz, 1990). There is also a dramatic change in the convergence of retinal ganglion cell input to thalamic neurons related to a shrinkage in receptive field size

(Tavazoie and Reid, 2000; Chen and Regehr, 2000) (Fig. 20.15).

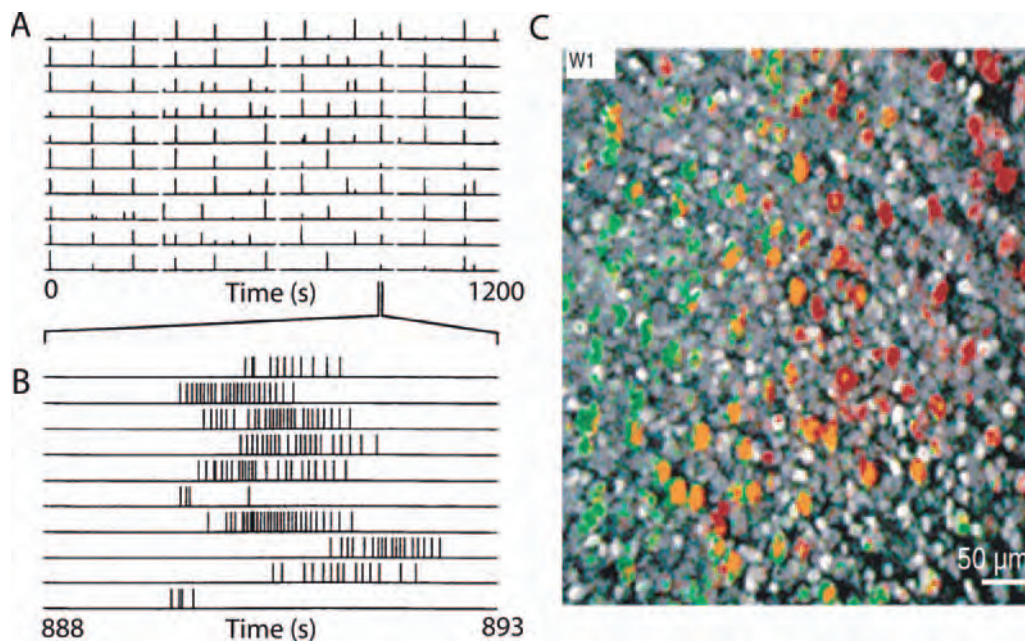

It is likely that *spontaneous activity* as opposed to actual visual experience is important in the segregation of retinogeniculate connections in the thalamus. This view is based on the fact that in cats, ferrets, and monkeys the eye specific layers are established well before the retina is sensitive to light and is dependent on the spontaneous activity of these inputs. What information may be contained in the spontaneous activity patterns of immature retinas that could lead to eye-specific lamination? Electrophysiological recordings and  $\text{Ca}^{++}$  imaging studies demonstrate that each immature retina generates correlated propagating *waves* (Fig. 20.16), which have no preferred direction of propagation and which occur periodically, about once a minute. It is possible that retinal waves contain temporal and spatial cues that guide activity-dependent refinement of retinogeniculate connections. For example, because waves are generated independently in each retina, activities from the two eyes are unlikely to be coincident. Asynchrony between the inputs of the two eyes could account for the segregation of inputs into different eye-specific layers in the thalamus. Since ocular dominance column formation is initiated before birth, the spontaneous patterns of activity from the two eyes could be responsible for the eye specific pathways throughout the visual system. Moreover, because the waves ensure that nearby retinal ganglion cells are better synchronized than more distant cells, geniculate neurons are able to gauge neighbor relationships in the retina by their sequential activation. This feature could be useful for refinements of the retinotopic map in both thalamus and cortex. Pharmacological blockade of retinal waves during the period of eye-specific segregation prevents the emergence of these layers, suggesting that activity from the retinas is involved (Wong, 1999). However, these activity patterns must be only part of the story: the laminar organization of the lateral geniculate is stereotyped from animal to animal suggesting that other developmental mechanisms are also at play.

### Cerebellum

A particularly clear example of synapse elimination in the developing CNS is the *climbing fiber input* onto cerebellar Purkinje cells. Climbing fibers are the terminals of the axons arriving from inferior olive neurons that form strong synaptic connections to Purkinje cells. In adults only one climbing fiber innervates each Purkinje cell. That input might contain 500 synaptic boutons that tightly invest the large ascending proximal dendrite. Immature climbing fibers on the other hand form fewer synapses, mostly on the

**FIGURE 20.15** Synapse elimination in the lateral geniculate nucleus of the thalamus. (A) In the ferret lateral geniculate nucleus, receptive fields of geniculate neurons are larger and much more diffuse at one month of age than those receptive fields observed in adult neurons. Red regions represent the receptive field map of geniculate neurons that correspond to areas excited by bright stimuli. Note that red areas become smaller as development proceeds. The shrinkage in the receptive field is likely to result from the elimination of the convergence of multiple retinal afferents onto each geniculate neuron (B). At P12 in mouse, multiple retinogeniculate axons are recruited as stimulation intensities to the bundle of axons is increased (see also Figure 20.1C). At P17 there are fewer steps and after P28, only one or two inputs innervate each geniculate neuron (i.e., no steps in the evoked-synaptic currents are seen even though optic nerve stimulation is increased). (A) Adapted from Tavazoie and Reid (2000). (B) Adapted from Chen and Regehr (2000).

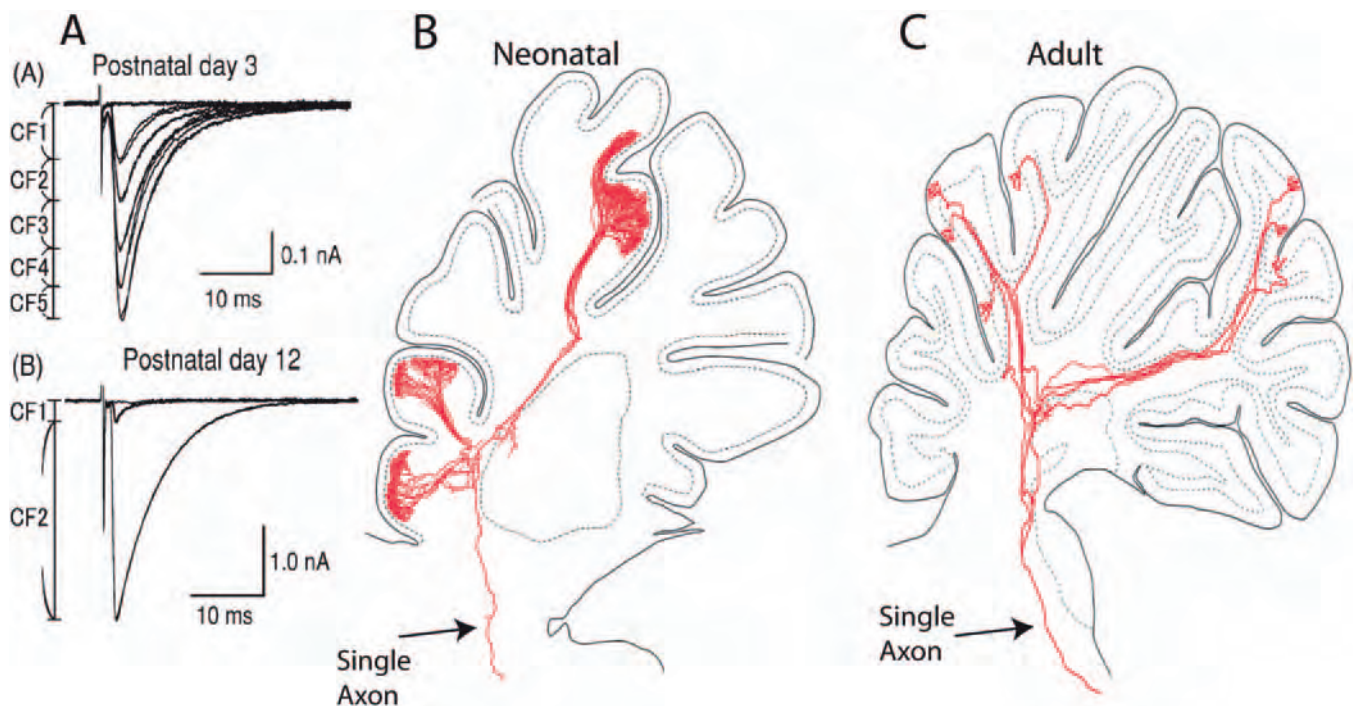

**FIGURE 20.16** Immature retinal ganglion cells show correlated patterns of activity. (A) Using an array of extracellular recordings, rhythmic bursts of action potentials (indicated by vertical lines) are synchronized between neighboring retinal ganglion cells before eye opening in ferret. (B) Action potential bursts expanded in time scale shows that each burst corresponds to ten or more action potentials. (C) Using calcium indicators has been possible to observe waves of neuronal activity in immature retinal ganglion cells (pseudo-colored image). In this example, a wave of neuronal activity propagates through the retina. Pseudo-colored cells indicating the temporal firing pattern of retinal ganglion neurons, cells in green fire before yellow ones, and lastly red cells. (A, B) from Meister *et al.* (1991). (C) from Wong (1999).

Purkinje cell soma, and many climbing fibers project to each Purkinje cell in the first postnatal week (in rodents). The transition from multiple innervation to single innervation of individual Purkinje cells occurs at the same time there is a change in the number of Purkinje cells innervated by each climbing fiber. This “neural unit” shrinkage is remarkably analogous to the reduction in the size of motor units in the peripheral nervous system. Thus, one olivocerebellar axon may give rise to branches that innervate more than 100 Purkinje cells during the first postnatal week but over the next several weeks its projection is trimmed to only ~7 Purkinje cells (Fig. 20.17), albeit these connections are much more powerful.

It has long been appreciated that the loss of climbing fiber inputs depends on the presence of parallel fiber innervation from granule cells of the distal part of the Purkinje cell arbor. Elimination of granule cell inputs to Purkinje cells by X irradiation, viral infection, or in mutants such as *reeler*, *weaver*, and *staggerer* results

in a higher incidence of Purkinje cells that are multiply innervated by climbing fibers in adulthood. Some studies suggest that the activity of the parallel fiber input is the important parameter. Perturbation of activity along the parallel fiber—Purkinje cell pathway in mGluR1 and GluR $\delta$ 2 knockouts mice or application of NMDA receptor antagonists all inhibit the elimination of climbing fibers (Hashimoto and Kano, 2005). In addition disruption of one calcium binding kinase (PKC gamma) appears to selectively prevent climbing fiber elimination (Hashimoto and Kano, 2005). Although the mechanism by which this kinase alters synapse elimination is not known, these animals recently have been shown to have a profound deficit in vestibulo-ocular reflex (VOR) motor learning but not other kinds of cerebellar learning (Kimpo and Raymond, 2007). These results imply that synapse elimination may be important in generating the circuitry for some kinds of adult learning. As we will mention later, however, synapse elimination itself may be a form of learning.

**FIGURE 20.17** Synapse elimination and axonal pruning of climbing fibers in the neonatal period. (A) Recordings from Purkinje cells while olivocerebellar axons are stimulated in the inferior olive show functional evidence of synapse elimination. At birth, each Purkinje cell is innervated by several different climbing fibers, as the strength of stimulation is increased additional inputs are recruited (compare with Fig. 20.1C and Fig. 20.15B). The average number of climbing fibers innervating each cerebellar Purkinje cell, in the rat, decreases gradually as the animal matures until most are singly innervated. (B, C) Reconstructions of the trajectory of single neonatal (B) and adult (C) olivocerebellar climbing fiber axons. Both neonatal and adult axons terminate in several separate lobules in the hemisphere. However, neonatal olivocerebellar axons have much more branches than those in adult axons and presumably innervate many more Purkinje cells than those in adult animals. After pruning is complete, each axon gives rise to ~7 climbing fibers that each singly innervates a different Purkinje cell. (A) Adapted from Hashimoto and Kano (2003). (B, C) Modified from Sugihara (2005).

## Summary

In many parts of the central and peripheral nervous system the divergence and convergence of synaptic circuits is decreased. A popular hypothesis, albeit still somewhat perplexing, is that neural activity differences between axons underlies synapse elimination. This hypothesis has driven researchers to try many kinds of experiments to test activity's role. At present, the precise way in which electrical activity exerts an influence on the synapse elimination process remains a central and unresolved question.

## IS SYNAPSE ELIMINATION STRICTLY A DEVELOPMENTAL PHENOMENON?

In this chapter, we presented evidence to demonstrate that synapse elimination is a powerful force that can refine synaptic circuits in young animals, based on interneuronal competition. Is there any reason to think it has more than a strictly developmental phenomenon? The most important form of adult plasticity must certainly be memory. Might synapse elimination have something to do with memory? A number of neurobiologists, including Kandel (1967), Toulouse *et al.* (1986), and Edeleman (1988) have explicitly made arguments for selection (as opposed to instruction) as potentially playing an important role in learning. The idea is that in the brain synaptic circuitry exists *a priori* for many things that may ultimately be learned, so that learning might occur by the selection of synaptic pathways that already exist rather than construction of new circuits. Although such selection could occur by increasing the strength of one set of synaptic interconnections or weakening of others, it could also occur by completely eliminating some circuits. It is important to emphasize the distinction between plasticity that alters the strengths of existing connections and the more extreme kind of plasticity, analogous to the developmental synaptic processes' described here, that causes permanent eradication of an axon's input to particular postsynaptic cells.

Because postsynaptic cells appear to be the intermediary in synaptic competition leading to axonal removal (see earlier), once an axon's synaptic drive to a postsynaptic cell is removed, it can no longer have any influence on the synaptic connections of the other axons that remain connected. Complete loss of influence following synaptic disconnection is thus a plausible explanation for the finite length of critical periods. For example, once all the inputs driven by an eye deprived of vision are eliminated, return of visual

experience in that eye can no longer cause a shift in ocular dominance columns if that shift is mediated via activation of postsynaptic cells. The same argument could also be made for memory. Memories have a kind of indelibility that prevents more recent memories from "overwriting" prior ones. Input elimination is an attractive means of assuring indelibility because by eliminating competing (i.e., asynchronously firing) inputs, a circuit becomes sheltered from disruption by different activity patterns.

A model of memory based on this kind of synapse elimination, however, would require that axonal inputs continue to be eliminated in the adult brain. That critical periods in the visual system are strictly developmental can be used as an argument against the idea that these kinds of changes may underlie adult memory. On the other hand, critical periods in the visual system tend to be prolonged in proportion to their distance from the input. For example, critical periods for higher visual processing areas occur later in development than in those areas that are more proximal in the visual pathway. The loss of overlapping connections is known to occur prenatally within thalamic circuitry well before segregation in layer IV primary visual cortex, and higher anatomical levels in the visual cortex that receive input from layer IV segregate out later than layer IV. A possible explanation for this sequential crystallization of brain regions may be that synapse elimination can occur only when a cohort of synchronous inputs work together to drive the elimination of competing inputs. Such a collection of synchronously active neurons requires that the presynaptic input to these cells has itself sorted out. It also is the case that the length of the critical periods for vision are vastly longer in humans than other mammals, as is the rest of our neotenic development. For example, whereas our closest animal relatives finish the critical period for monocular deprivation by 7 months of age, in humans monocular deprivation can affect visual acuity even in children 6 to 7 years old.

## SUMMARY

We would not like to give the impression that naturally occurring synapse elimination at developing systems is the equivalent of learning and memory. But, as neurobiologists who have studied this phenomenon and mulled these ideas over for many years, we have come to the conclusion that permanent loss of axonal input is an attractive mechanism for information storage. Whether our bias is reasonable based on the data or rather due to structural elimination of competing hypotheses from our brains, we do not know.

# Dendritic Development

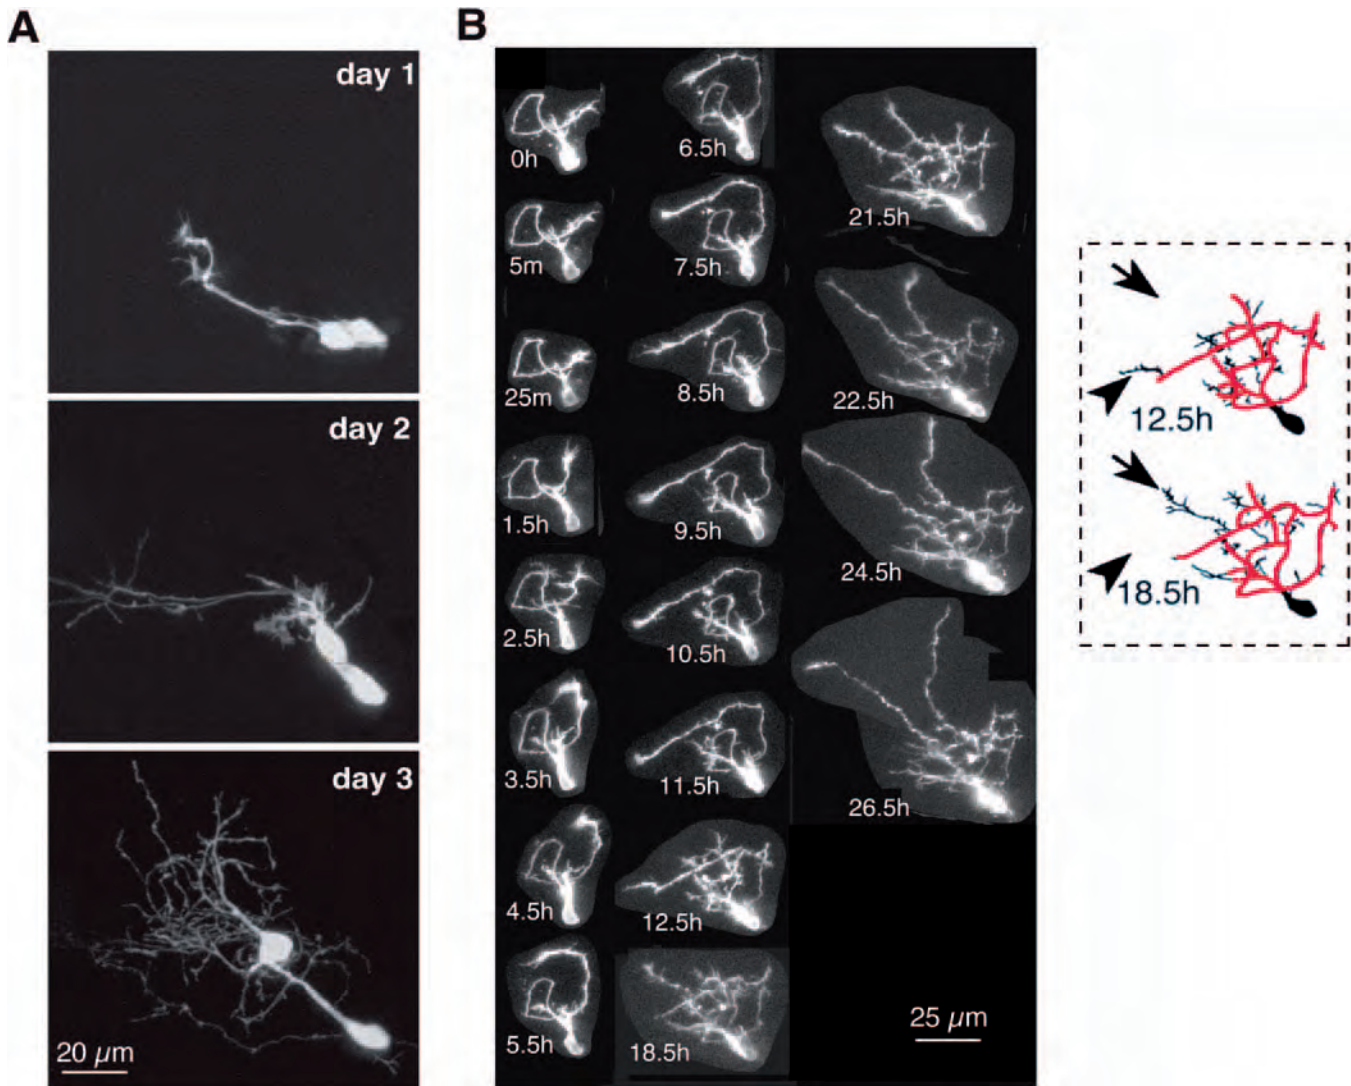

Dendrites play a critical role in information processing in the nervous system as substrates for synapse formation and signal integration. Neurons have highly branched, cell type-specific dendritic trees (or dendritic arbors), that determine the spatial extent and types of afferent input that the neurons receive (Cline, 2001; Wong and Ghosh, 2002). It is now widely recognized that dendrites do not develop in a void, but do so in constant interaction with other neurons and glia. The signals from these other cells affect dendritic arbor development in different spatial domains and time scales. For instance, synaptic inputs may increase calcium influx rapidly and locally to enhance rates of branch addition and stabilization (Lohmann *et al.*, 2005). This dynamic morphological remodeling allows individual neurons to constantly adapt and respond to external stimuli (Cline, 2001; Ruthazer *et al.*, 2003). In contrast, calcium signals with slower temporal dynamics may selectively signal to the nucleus to trigger gene transcription (Dolmetsch *et al.*, 2001; Wu *et al.*, 2001; Kornhauser *et al.*, 2002). Such activity-induced genes can then have profound effects on dendritic arbor structure and function (Nedivi *et al.*, 1998; Nedivi, 1999; Cantalops *et al.*, 2000b; Redmond *et al.*, 2002). Dendrite arbor structure and plasticity are altered under a variety of neurological disorders such as mental retardation (Benavides-Piccione *et al.*, 2004; Govek *et al.*, 2004; Bagni and Greenough, 2005; Newey *et al.*, 2005) and can be affected by exposure to drugs including nicotine (Gonzalez *et al.*, 2005) and cocaine (Kolb *et al.*, 2003; Morrow *et al.*, 2005). The study of dendritic arbor development can therefore provide important insight into the cellular basis of normal brain development, as well as neurological and psychiatric disorders.

This chapter is written with a special emphasis on the regulation of dendritic arbor structure in the context of the developing neuronal circuits. After a brief description of dendritic arbor development, we present representative molecular and cellular mechanisms governing dendrite arbor architecture.

## DYNAMICS OF DENDRITIC ARBOR DEVELOPMENT

Dendritic arbor development requires global, arbor-wide architectural modifications (e.g., generalized arbor growth) as well as localized structural changes (e.g., sprouting and retraction of high order branches). Furthermore, some changes in dendritic arbor morphology may occur rapidly in response to synaptic inputs or growth factors, whereas others may occur with some time-delay, secondary to new gene transcription. Figure 21.1A illustrates the generalized growth of differentiating optic tectal neurons *in vivo* over three days, and Figure 21.1B shows an optic tectal neuron imaged in the intact *Xenopus* tadpole over about one day, but at shorter intervals. Apart from the widespread changes in dendritic architecture, short interval imaging unveils sites of local branch dynamics and growth. Although the initial development of the dendritic tree is under the control of genetic and molecular programs, the growth and refinement of the dendritic tree after synapse formation is strongly influenced by sensory input and calcium signaling. In the dendrites of *Xenopus* tectal neurons, there appears to be a developmental refinement in the spatial spread of  $Ca^{++}$  in response to retinal axon stimulation. At early

**FIGURE 21.1** Time-lapse images of *Xenopus* optic tectal neurons, collected *in vivo*. (A) This example shows two neighboring, newly differentiated neurons, close to the proliferative zone, imaged over a period of 3 days. These cells initially present glial-like morphologies (day 1). By the next day, these cells have migrated elaborated complex dendritic arbors (day 2), which continue to grow to the end of imaging period (day 3). (B) Example showing an optic tectal interneuron imaged at short intervals over about 1 day. Dendritic trees develop as neurons differentiate within the tectum. Although portions of the dendritic arbor are stable over time (red outlined skeleton at 12.5h and 18.5h), other areas are very dynamic as dendritic branches are both added (arrows) and retracted (arrowheads) over time (in this case between 12.5h and 18.5h). From Bestman *et al.* (2008).

stages in neuronal development, when the dendritic arbor is still very simple, retinal axon stimulation results in  $\text{Ca}^{++}$  signals that spread throughout the cell, but  $\text{Ca}^{++}$  signals become more spatially restricted as neurons mature (Tao *et al.*, 2001). These changes in the spatial distribution of  $\text{Ca}^{++}$  signals in response to retinal stimulation could represent changes in dendritic integration as well as synapse-to-nucleus signaling by calcium during development.

### GENETIC CONTROL OF DENDRITE DEVELOPMENT IN DROSOPHILA

Studies using *Drosophila* genetics have been instrumental in the identification of core programs that control dendrite development. The dendritic arborization (da) neurons, a group of *Drosophila* sensory neurons with a stereotyped dendritic branching

pattern, have provided a useful assay system for the genetic dissection of dendrite development (Gao *et al.*, 1999; Grueber *et al.*, 2002).

### Transcription Factors Regulate Cell Type Specific Dendritic Morphology

A striking feature of the nervous system is that there are many different types of neurons, each with a characteristic and recognizable dendritic arborization pattern. How do neurons acquire their type-specific dendritic morphology? Studies with *Drosophila* da neurons indicate that transcription factors are important regulators of the size and complexity of dendritic fields and the logic of their usage is beginning to emerge. Each hemi-segment of the abdomen of the *Drosophila* embryo or larva has 15 da neurons that can be subdivided into four classes based on their dendritic morphology (Grueber *et al.*, 2002). Each da neuron occupies an invariant position and has a highly stereotyped and unique dendritic branching pattern (Fig. 21.2) (Grueber *et al.*, 2002, 2003b). Class I and II have relatively simple dendritic branching patterns and small dendritic fields. In contrast, class III and IV neurons have more complex dendritic branching patterns and large dendritic fields.

In some cases, the “dendritic fate” of a particular neuron can be specified by a single transcription factor. For example, Hamlet functions as a binary switch between the elaborate multiple dendritic morphology of da neuron and the single, unbranched dendritic morphology of external sensory (es) neuron (Moore *et al.*, 2002). *Hamlet* encodes a multiple-domain, evolutionarily conserved, Zn finger containing nuclear protein that is transiently expressed in a subset of neurons at the time of dendrite outgrowth. In a loss-of-function *hamlet* mutant, the es neurons are transformed into neurons with an elaborate dendrite arbor. Conversely, ectopic expression of *hamlet* even in post-mitotic da neurons causes the opposite transformation.

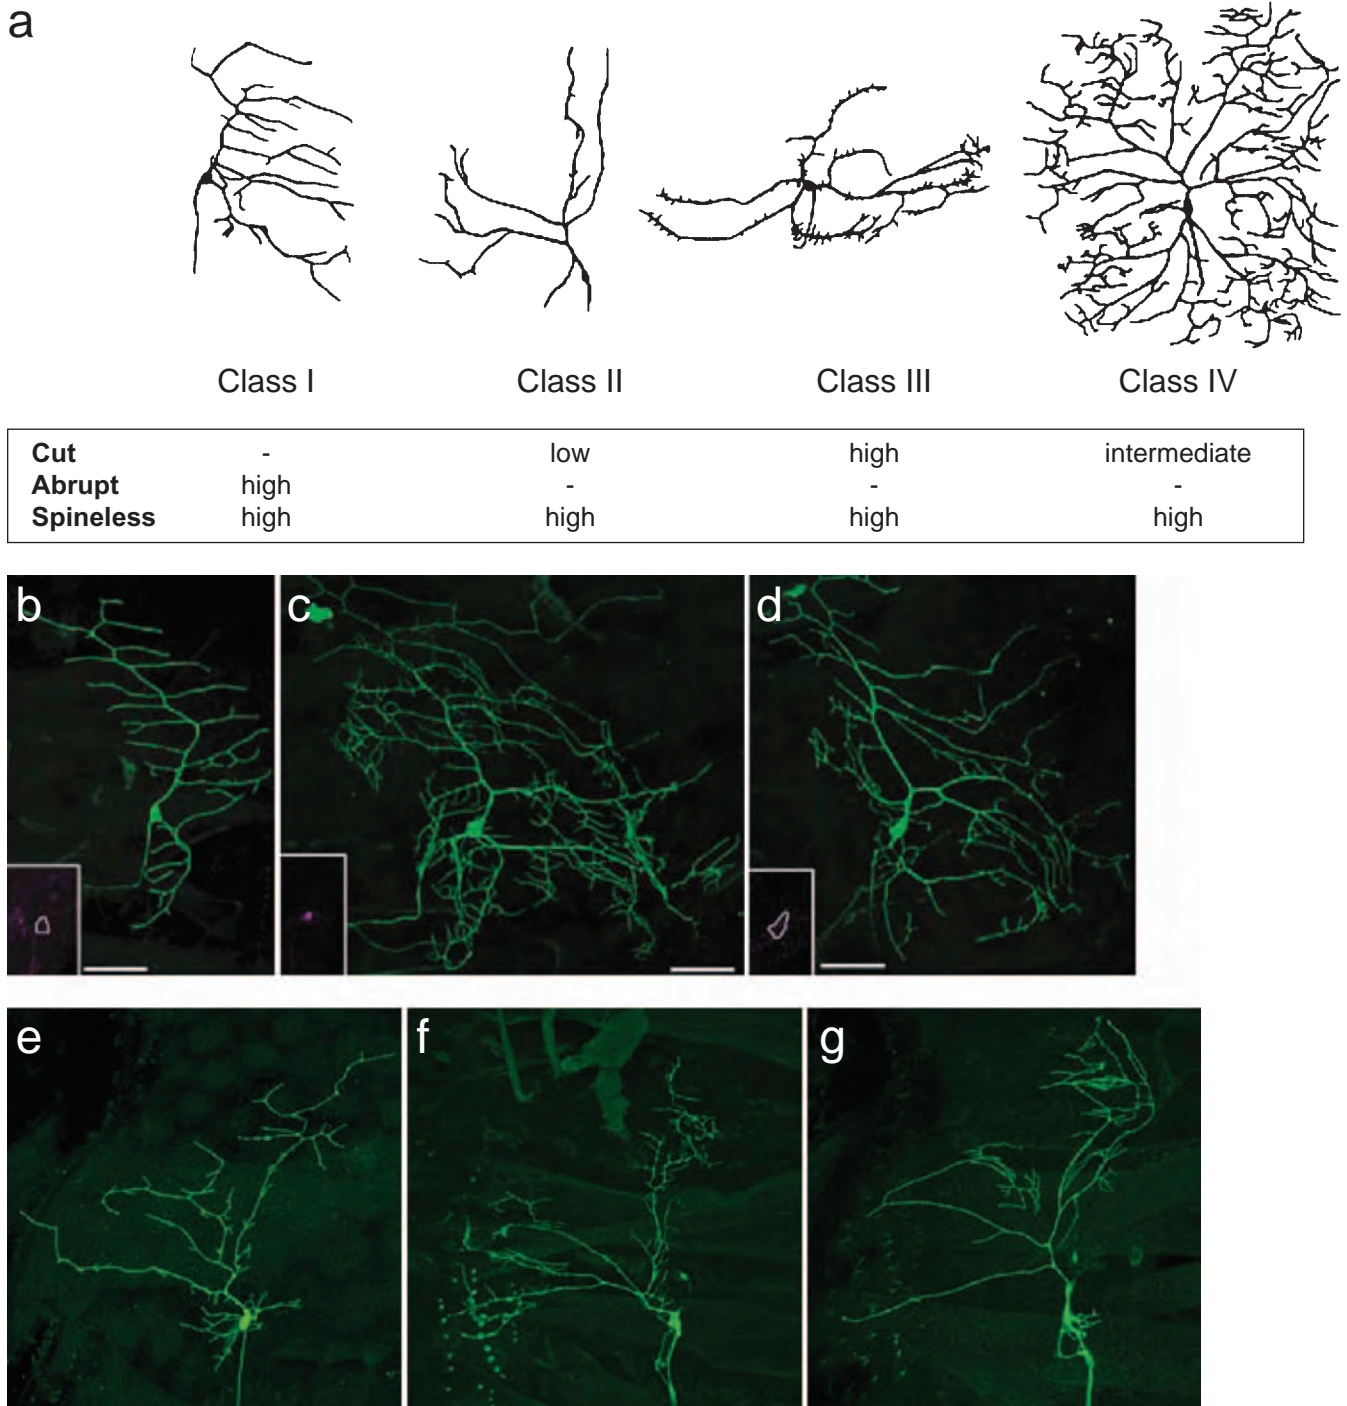

In most cases, however, the dendritic fate is determined by the combined action of multiple transcription factors. Expression of the gene *cut* in the da neurons differs such that neurons with small and simple dendritic arbors either do not express Cut (class I neurons) or express low levels of Cut (class II), whereas neurons with more complex dendritic branching patterns and larger dendritic fields (class III and IV) express higher levels of Cut. Analysis of loss-of-function mutations and class-specific overexpression of Cut demonstrated that the level of Cut expression controls the distinct, class-specific patterns of dendritic branching (Grueber *et al.*, 2003a). Loss of Cut reduced

dendrite growth and class-specific terminal branching and converted class III and IV neurons to class I and II morphologies such that they have relatively simple dendritic branching pattern and small dendritic fields. Conversely, overexpression of Cut in neurons that express lower levels of endogenous cut resulted in transformations toward the branch morphology of high-Cut expressing neurons. Furthermore, a human Cut homologue, CDP, can substitute for *Drosophila* Cut in promoting the dendritic morphology of high-Cut neurons (Fig. 21.2). Thus, Cut may function as an evolutionarily conserved regulator of neuronal-type specific dendrite morphologies.

In contrast to Cut, Spineless (*ss*), the *Drosophila* homologue of the mammalian dioxin receptor, is expressed at similar levels in all da neurons. In *ss* mutants, different classes of da neurons elaborate dendrites with similar branch numbers and complexities (Fig. 21.2), suggesting that da neurons might reside in a common “ground state” in the absence of *ss* function. Studies of the epistatic relationship between Cut and Spineless indicate that these transcription factors likely are acting in independent pathways to regulate morphogenesis of da neuron dendrites (Kim *et al.*, 2006). A comprehensive analysis of transcription factors with RNAi screens has revealed more than 70 transcription factors regulate dendritic arbor development of class I neurons in *Drosophila*. These findings suggest that complicated networks of transcriptional regulators likely regulate neuron-specific dendritic arborization patterns (Parrish *et al.*, 2007).

### Dendro-Dendritic Interactions Regulate the Shape and Organization of Dendritic Fields

Dendro-dendritic interaction can have a profound influence on determining the size and shape of the dendritic field as well as the spatial relationship between different dendritic fields. In many areas of the nervous system, dendrites of different types of neurons are intermingled and packed into a tight space. This arrangement is not random but well organized. At least three mechanisms contribute to the orderly organization of dendritic fields: self-avoidance, tiling, and coexistence. Dendrites of a neuron rarely bundle together or crossover one another (self-avoidance). Presumably, self-avoidance contributes to maximal dispersion of a neuron’s dendritic arbor for efficient and unambiguous signal processing. Certain types of neuron also exhibit a phenomenon known as tiling, which refers to the avoidance between the dendrites of adjacent neurons of the same type. This proper tie allows neurons to cover large areas of the nervous system like tiles covering a floor, completely and without redundancy. Tiling was first discovered in

**FIGURE 21.2** Transcription factors regulate the diversity and complexity of dendrites. (a) Dendrite morphologies of representative class I, II, III, and IV dendritic arborization (da) sensory neurons in the *Drosophila* PNS and a summary of the relative levels of expression of the transcription factors Cut, Abrupt, and Spineless in these neurons. (b–d). Ectopic expression of *cut* increases the dendritic complexity of class I da neurons. (b) Wild-type dendritic morphology of the ventral class I neuron vpda. Cut is normally not expressed in vpda (*inset*). (c) Ectopic expression of Cut in vpda leads to extensive dendritic outgrowth and branching. (d) Ectopic expression of CCAAT-displacement protein (CDP), a human homolog of *Drosophila cut*, also induces overbranching. (e–g) Loss of *spineless* function leads to a dramatic reduction in the dendritic diversity of different classes of da neurons. In loss-of-function *spineless* mutants, class I (e), class II (f), and class III (g) da neurons begin to resemble one another. From Parrish *et al.* (2007b).

mammalian retina (Wassle *et al.*, 1981). The dendrites of the same type of neurons may repel one another based on self-avoidance or tiling, however it is essential that dendritic fields of different types of neurons don't repel each other so different types of neurons can process different aspects of inputs. Thus, a neuron's dendritic branches needs to be able to recognize other branches of the same neuron, and in the case of tiling, branches of other neurons of its own kind. In addition, branches of different types of neurons need to be able to ignore each other to coexist. How do neurons manage such a plethora of dendritic interactions? What are the underlying molecular mechanisms?

These general organizational principles of dendritic fields can be studied in *Drosophila* da neurons. Their dendrites show self-avoidance and tend to spread out. Of the four classes of da neurons, class III and class IV neurons show tiling (Grueber *et al.*, 2003b; Sugimura *et al.*, 2003). Further, different classes of da neurons don't repel each other and they can coexist with their dendritic fields superimposed on each other. Recent studies of the organization of da dendritic fields have begun to reveal the molecular mechanisms including the roles of Dscam (Down syndrome cell adhesion molecule) (Hughes *et al.*, 2007; Matthews *et al.*, 2007; Soba *et al.*, 2007), Tricornered, and Furry (Emoto *et al.*, 2004).

Dscam, a member of the immunoglobulin superfamily, originally was identified as an axon guidance receptor. Alternative splicing can potentially generate over 38 thousand isoforms (Schmucker *et al.*, 2000). A neuron typically expresses only a small subset (a couple dozen) of those isoforms (Neves *et al.*, 2004). Dscam appears to be involved in self-recognition of certain *Drosophila* neurites (Hummel *et al.*, 2003; Wang *et al.*, 2002; Zhu *et al.*, 2006). Biochemical studies showed that Dscam exhibits isoform-specific homophilic binding. Strong homophilic interactions are observed only between the same isoforms, and differences of even a few amino acids greatly reduced the strength of the interactions (Wojtowicz *et al.*, 2004). These results suggest that only when neurite express the same set of Dscam isoforms, there is high level of signaling resulting in repulsion. If they express different isoforms, neurites don't repel each other (Wojtowicz *et al.*, 2004).

Dscam is necessary for da neuron dendrite self-avoidance. Mutant neurons devoid of Dscam exhibit dendrite bundling and a crossing-over phenotype. This self-avoidance phenotype can be rescued largely by expressing a randomly selected single isoform in the neuron, suggesting that it is necessary to have Dscam in the da neuron for their dendritic self-avoidance but the particular isoform is not important

(Hughes *et al.*, 2007; Matthews *et al.*, 2007; Soba *et al.*, 2007).

In contrast, tiling does not seem to be affected in Dscam mutants. Thus, tiling requires some cell surface recognition molecules other than Dscam to mediate the homotypic repulsion between neurons of the same type. Although the signal(s) that mediate tiling behavior remain to be identified, the evolutionarily conserved protein kinase Tricornered (Trc) and the putative adaptor protein Furry (Fry), have been identified as important components of the intracellular signaling cascade involved in tiling (Emoto *et al.*, 2004; Gallegos and Bargmann, 2004). In *trc* or *fry* mutants, dendrites no longer show their characteristic turning or retracting response when they encounter dendrites of the same type of neuron. In the mutants, unlike in the wild-type, there is extensive overlap of dendrites between adjacent neurons of the same kind. As a result, the mutant neurons have enlarged dendritic fields (Emoto *et al.*, 2004).

Given that a neuron's dendrites can self-avoid as long as it has at least one Dscam isoform and it doesn't matter what particular isoform is expressed, what might be the reason for having such large number of potential isoforms? One idea is that a given neuron would express a small number of Dscam isoforms (a dozen or so) more or less stochastically (Neves *et al.*, 2004). Since there are a large number of isoforms (over 38,000), the chance of two adjacent neurons expressing the same set of isoforms and therefore repelling others is very small. This notion predicts that overexpression of the same Dscam isoform in two different kinds of neurons that normally have overlapping dendritic fields would cause the dendrites to repel each other. Indeed, overexpression of the same Dscam isoform in different classes of da neurons whose dendritic fields normally overlap extensively leads to their mutual repulsion (Hughes *et al.*, 2007; Matthews *et al.*, 2007; Soba *et al.*, 2007). The idea that the diversity of Dscam is essential for overlapping dendritic fields is further supported by another experiment in which the Dscam diversity was reduced so that a single isoform is expressed in all da neurons and different classes of da neurons repel each other (Soba *et al.*, 2007). Although single Dscam isoform is sufficient for dendrite self-avoidance, different neurons need to express different isoforms so they can share the same space. Thus Dscam functions as a tag for neuron to recognize itself and the diversity is needed for coexistence.

## The Maintenance of Dendritic Fields

Dendrite development is a dynamic process involving both growth and retraction. Thus, selective

stabilization or destabilization of branches might be one important mechanism to shape dendritic arbors. Studies of *Drosophila* class IV da neurons revealed that dendritic fields are actively maintained and there is a genetic program used to maintain dendritic fields. The tumor suppressor Warts (Wts), as well as the Polycomb group of genes are required for the maintenance of the class IV da dendrites.

*Drosophila* has two NDR (nuclear Dbf2-related) families of kinase: Trc and Wts. Wts and its positive regulator Salvador originally were identified as tumor suppressor genes that function to coordinate cell proliferation and cell death. Loss-of-function mutants of either gene causes a progressive defect in the maintenance of the dendritic arbors, resulting in large gaps in the receptive fields (Fig. 21.3). Time-lapse studies suggest that the primary defect is in the maintenance of terminal dendrites, so Wts may normally function to stabilize these dendrites.

How are the establishment and maintenance of dendritic fields coordinated? In *Drosophila* class IV neurons, the Ste-20-related tumor suppressor kinase Hippo (Hpo) can directly phosphorylate and regulate both Trc, which functions in the establishment of dendritic tiling, and Wts, which functions in the maintenance of dendritic tiling (Emoto *et al.*, 2006). Furthermore, *hpo* mutants have defects in both establishment and maintenance of dendritic fields. How Hpo regulates the transition from establishment to maintenance of dendritic fields remains to be determined.

What might be the downstream genes regulated by Wts? In the *Drosophila* retina, Wts regulates cell prolif-

eration and apoptosis by phosphorylating the transcriptional coactivator Yorkie (Huang *et al.*, 2005). However, Yorkie does not appear to function in dendrite maintenance. Instead, the Polycomb genes are good candidates as targets for Wts/Sav for dendritic maintenance. The Polycomb genes are known to regulate gene expression by establishing and maintaining repression of developmentally regulated genes. PcG genes can be separated into two multiprotein complexes: Polycomb repressor complex 1 (PRC 1) and PRC2. PRC2 is thought to mark the genes to be silenced by methylating histone H3, and PRC1 then comes in and blocks transcription. Mutants of several members of PRC1 and PRC2 have dendrite maintenance phenotype very similar to that of Wts. Further, genetic and biochemical experiments suggest a functional link between Hpo/Wts signaling and the PcG and that PcG genes regulate the dendritic field in part through Ultrabithorax (Ubx), one of the Hox genes in *Drosophila* (Parrish *et al.*, 2007).

## EXTRACELLULAR REGULATION OF DENDRITIC DEVELOPMENT IN THE MAMMALIAN BRAIN

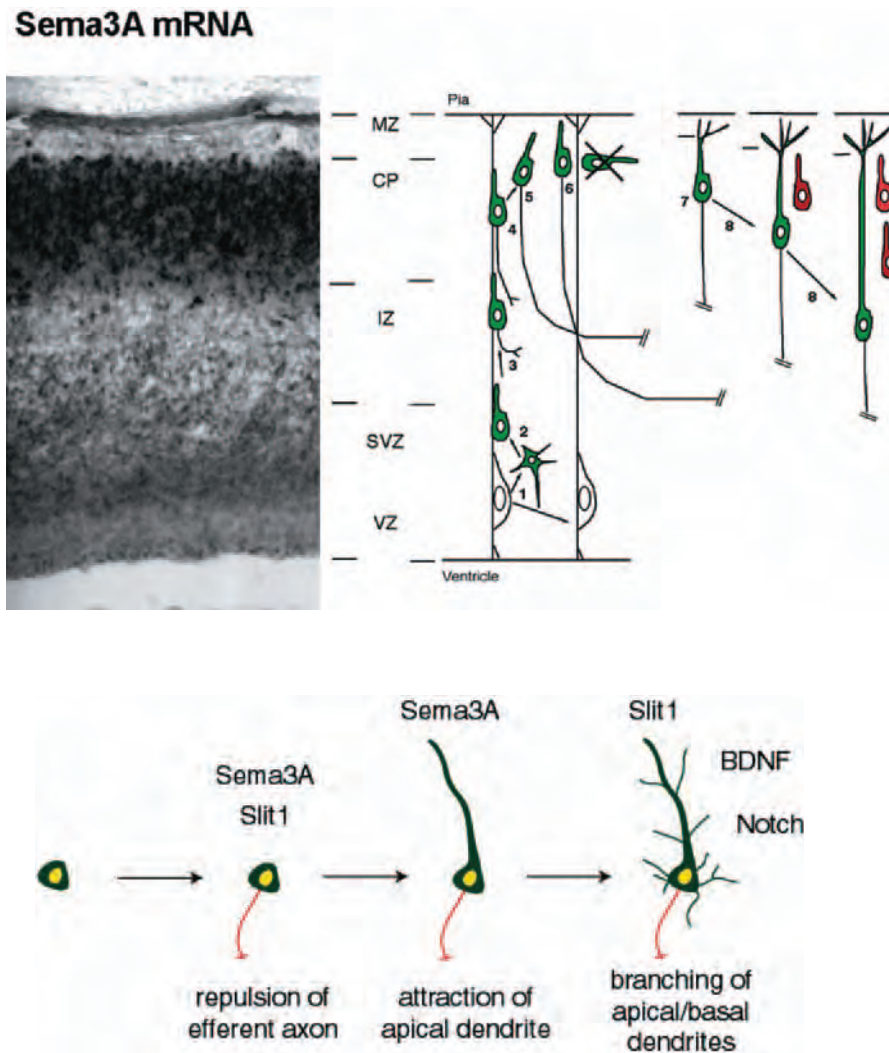

### Regulation of Dendrite Orientation

Much of our understanding of the molecular mechanisms of dendritic growth control in vertebrates comes from investigations in the developing cerebral cortex. Most cortical neurons are generated from precursors proliferating in the germinal zones lining the ventricle (Fig. 21.4). Once the cells become postmitotic, they migrate from the ventricular zone to the cortical plate.

Dendritic differentiation, as determined by expression of dendrite-specific genes such as MAP-2, does not begin until the cells have completed their migration. Following migration, pyramidal neurons extend an axon toward the ventricle and an apical dendrite toward the pial surface. To test the role of the local cortical environment in directing the growth of nascent axons and dendrites, Polleux and Ghosh developed an *in vitro* assay in which dissociated neurons from a donor cortex were plated onto cortical slices in organotypic cultures. Strikingly, neurons plated on cortical slices behave just like the endogenous pyramidal neurons and extend an axon toward the ventricular zone and an apical dendrite toward the pial surface. Both the oriented growth of the axon and the apical dendrite are regulated by the chemotropic signal Sema 3A, which is present at high levels near the pial surface, and acts as a chemorepellant for axons and a chemoattractant for dendrites (Polleux *et al.*, 1998, 2000).

**FIGURE 21.3** Dendritic fields are largely unchanged once established during development. Late-onset dendritic loss in *Drosophila warts* mutants (*wts*<sup>-/-</sup>) in late larval stages. Live images of wild-type (WT) and *wts* mutant (*wts*<sup>-/-</sup>) dendrites of class IV da neurons at different times after egg laying (AEL). In *wts* mutants, dendrites initially tile the body wall normally but progressively lose branches at later larval stages. Adapted from Emoto *et al.* (2006).

**FIGURE 21.4** Upper Panel: Development of the dendritic morphology of cortical pyramidal neurons. Pyramidal neurons are generated from radial glial precursors in the dorsal telencephalon during embryonic development. Upon cell cycle exit from the ventricular zone (VZ), young post-mitotic neurons migrate along the radial glial scaffold and display a polarized morphology with a leading process directed toward the pial surface and sometimes a trailing process directed toward the ventricle. The leading process later becomes the apical dendrite. The trailing process of some neurons (but not all) develop into an axon that grows toward the intermediate zone (IZ; the future white matter) once cells reach the cortical plate (CP). Upon reaching the top of the cortical plate, postmitotic neurons detach from the radial glial processes and have to maintain their apical dendrite orientation toward the pial surface and axon outgrowth orientation toward the ventricle, which appears to be regulated by Sema3A, which acts as a chemoattractant for the apical dendrite and a chemorepellant for the axon. Adapted from Polleux and Ghosh (2008). Lower Panel: A model of how sequential action of extracellular factors might specify cortical neuron morphology. A newly post-mitotic neuron arrives at the cortical plate, where it encounters a gradient of Sema3A (Polleux *et al.* 1998), which directs the growth of the axon towards the white matter. The same gradient of Sema3A attracts the apical dendrite of the neuron toward the pial surface (Polleux *et al.*, 2000). Other factors, such as BDNF and Notch, control the subsequent growth and branching of dendrites. Adapted from Polleux and Ghosh (2008).

The differential response of axons and dendrites to Sema3A led Polleux *et al.* to explore the mechanisms that might lead to the generation of opposite responses in two compartments of the same neuron. They discovered that the enzyme that regulates cGMP production, soluble guanylate cyclase (sGC), was localized asymmetrically in immature cortical neurons and was preferentially targeted to the emerging apical dendrite (Polleux *et al.*, 2000). Pharmacological inhibition of sGC activity

or one of its downstream targets, cGMP-dependent protein kinase (PKG), abolishes the ability of Sema3A to attract apical dendrites, but does not affect the axons. Thus the basis of the differential response of axons and dendrites to Sema3A appears to be asymmetric targeting of sGC to the emerging dendrite.

The nonreceptor tyrosine kinases Fyn and Cdk5 also play important roles in mediating the effects of Sema3A on cortical dendrite orientation (Sasaki *et al.*, 2002). Fyn

is a member of the Src family of nonreceptor tyrosine kinases. Cyclin-dependent kinase 5 (Cdk5), a member of the serine/threonine kinase Cdk family, has enzymatic activity only in postmitotic neurons due to a neuron-specific expression of the regulatory subunit p35 (Lew and Wang, 1995). Cdk5 and p35 play critical roles in the laminar organization of the cerebral cortex by regulating the migration of neurons (Chae *et al.*, 1997; Ohshima *et al.*, 1996). Sasaki *et al.* provided genetic evidence that Fyn acts downstream of *Sema3A* by showing that the apical dendrite orientation of layer 5 and layer 2/3 pyramidal neurons is not different from wild-type controls in *Sema3A*(+/-) and Fyn (+/-) single heterozygous mice but is significantly impaired in *Sema3A*(+/-)/Fyn(+/-) double heterozygous mice.

The generality of the concept of dendritic guidance is supported by studies in *Drosophila* on the role of Netrin-Frazzled signaling in axonal and dendritic development (Huber *et al.*, 2003; Yu and Bargmann, 2001). Netrin-A and Netrin-B, two netrin-family proteins in *Drosophila*, are diffusible glycoproteins produced by specialized midline cells. The activation of Frazzled, a cell-surface receptor for netrins (known in vertebrates as deleted in colorectal cancer (DCC)), causes chemoattraction and midline-crossing of axons from neurons located near the midline (Huber *et al.*, 2003; Yu and Bargmann, 2001). In single-cell analysis of bilaterally paired neurons, axons and dendrites show cell-autonomous use of Frazzled at the midline (Furrer *et al.*, 2003). For example, the RP3 motoneuron in wild-type *Drosophila* extends axons across the midline and extends dendrites on both sides the midline. However, in both frazzled-null and netrinA/netrinB double-null mutants, the RP3 neuron fails to direct its axon or dendrite toward the midline in three-quarters of the cases examined, suggesting that the midline-directed outgrowth of the RP3 axons and dendrite requires the Netrin-Frazzled signaling (Furrer *et al.*, 2003). In robo mutants RP3 dendrites converge at the midline, indicating that Robo signaling also regulates dendritic guidance.

### Regulation of Dendritic Growth and Branching

The growth and branching of dendrites can be influenced by a large number of extracellular signals (Fig. 21.5). In this section we discuss how specific extracellular factors regulate the development of the dendritic tree.

#### Neurotrophins

Studies from the last few years provide compelling evidence that the growth and branching of dendritic
