arbors is regulated by extracellular signals, including neurotrophic factors. Neurotrophins (NGF, BDNF, NT-3, and NT-4) exert their effects through the Trk family of tyrosine kinase receptors. Experiments in which the effects of neurotrophins on dendritic growth control have been examined in slice cultures indicate that in general, neurotrophins increase the dendritic complexity of pyramidal neurons by increasing total dendritic length, the number of branchpoints, and/or the number of primary dendrites (Baker *et al.*, 1998; McAllister *et al.*, 1995; Niblock *et al.*, 2000). The response is rapid and an increase in dendritic complexity is readily apparent within 24 hours of neurotrophin exposure. There is a clear specificity in the short-term response of pyramidal neurons of different cortical layers to each of the neurotrophins. For instance, NT-3 strongly increases dendritic complexity in layer 4 neurons, but has no apparent effect on layer 5 neurons. In addition, basal dendrites in specific layers respond most strongly to single neurotrophins whereas apical dendritic growth is increased by a wider array of neurotrophins. Live imaging of layer 2/3 neurons expressing BDNF show a high level of dendrite dynamics. Both dendritic branches and spines are rapidly lost and gained in BDNF transfected neurons (Baker *et al.*, 1998; McAllister *et al.*, 1995; Niblock *et al.*, 2000). BDNF overexpression favors addition of primary dendrites and proximal branches at the expense of more distal segments. Similarly, overexpression of TrkB in layer 6 pyramidal neurons results in a predominance of short proximal basal dendrites (Yacoubian and Lo, 2000).

Recently, Osteogenic Protein-1 (OP-1), which is a member of the transforming growth-factor-beta superfamily, was shown to increase total dendritic growth and branching from dissociated embryonic cortical neurons (Le Roux *et al.*, 1999). Furthermore, insulin-like growth factor-1 (IGF-1) was shown to affect dendrite growth and branching of postnatal layer 2 cortical neurons (Niblock *et al.*, 2000). In contrast to neurotrophins, IGF affects both basal and apical dendritic growth and remodeling, illustrating that the final dendritic complexity of pyramidal neurons is likely to be influenced by the action of multiple neurotrophic factors.

How do neurotrophic factors mediate the morphological changes linked with dendritic remodeling? The observed short-term dynamics indicate a rapid modulation of cytoskeletal elements by neurotrophic factor signaling. Of the major signaling pathways activated by Trk receptors and most other tyrosine kinase receptors, the MAP kinase and PI-3Kinase pathways have been implicated in neurite formation in both neuronal cell lines and primary neurons (Posern *et al.*, 2000; Wu

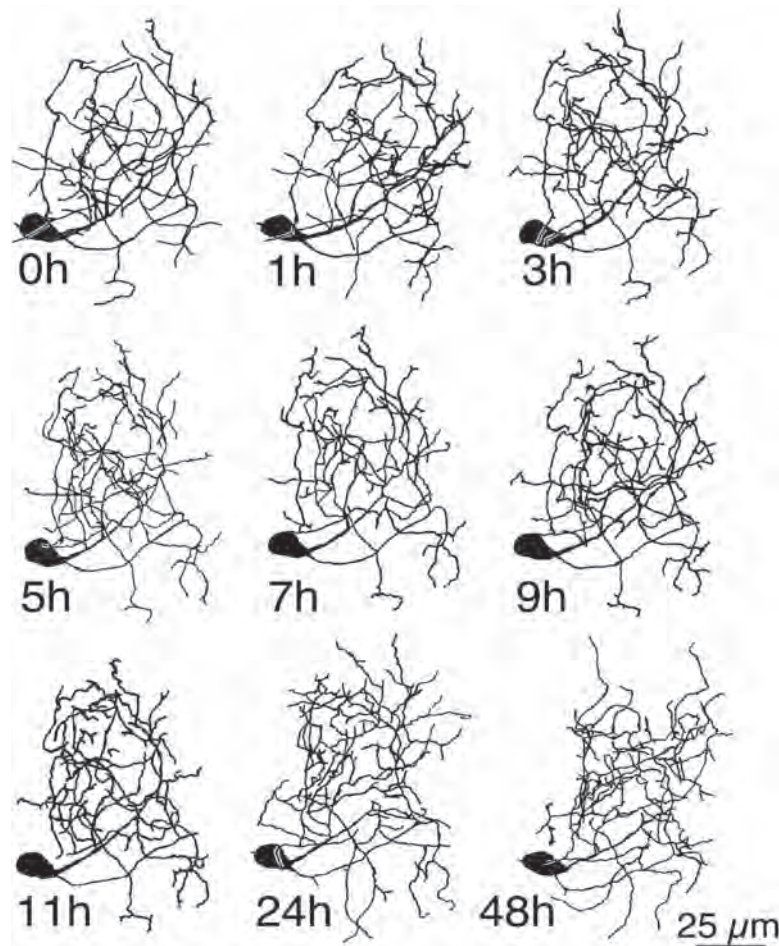

FIGURE 21.5 Reconstructions of the dendritic arbor of a xenopus tectal neuron imaged by time-lapse microscopy. (From Bestman *et al.* 2008).

*et al.*, 2001; Dijkhuizen *et al.*, 2005). It is likely that these signaling pathways influence neuronal morphology by regulating the activity of the Rho family GTPases, which mediate actin cytoskeleton dynamics and are known to induce rapid dendritic remodeling (Box 21.1; Fig. 21.6). Experiments in neuronal cell lines show that NGF can activate the small GTPase Rac1 in a PI-3 Kinase dependent manner, and this activation is necessary for neurite elaboration (Kita *et al.*, 1998; Posern *et al.*, 2000; Yasui *et al.*, 2001).

Part of the neurotrophic factor effect on dendritic morphogenesis may also include their control of expression of structural proteins, since long-term exposure to neurotrophins leads to net dendritic growth. It was reported recently that BDNF can upregulate local protein synthesis in dendrites within hours (Aakalu *et al.*, 2001). In addition, specific mRNAs for several cytoskeletal proteins are present in dendrites (Kuhl and Skehel, 1998). This raises the interesting possibility that local synthesis of structural compo-

nents may be involved in neurotrophic factor control of dendritic growth.

#### *Notch Signaling*

The diversity of signals that can influence dendritic morphology is underscored by a series of studies on the role of mammalian Notch proteins in regulating dendritic growth and branching. Originally identified in *Drosophila*, Notch is a type I cell-surface protein, which functions as a receptor. Proteolytic processing of full-length Notch generates two fragments that associate at the plasma membrane to form a receptor complex. The mechanism of Notch receptor activation involves cleavage and nuclear translocation of the intracellular domain of the receptor (reviewed in Weinmaster, 2000). The intracellular domain of Notch enters the nucleus and binds the transcription factor Suppressor of Hairless (Su(H)) activating gene transcription. Mammalian homologs of Notch (Notch1–4), the Notch ligands Delta (Delta1–3) and Serrate (Jagged1, Jagged2), the

## BOX 21.1

**Rho GTPases CONTROL THE STRUCTURE OF THE DENDRITIC CYTOSKELETON**

Since all the pathways necessarily converge on the regulation of the cytoskeleton, we start by outlining the role of the Rho GTPases in controlling the dendritic cytoskeleton and then examine some of the extracellular cues that regulate GTPases. It is noteworthy that many, if not all, of these pathways also affect gene expression and different aspects of dendritic function, such as synaptic transmission, calcium signaling, and neuronal excitability. Such divergence of signaling from extracellular cues assures that the development of dendritic structure and function are tightly coregulated.

The dendritic cytoskeleton is composed of bundles of microtubules extending within the center of the dendritic shaft, a cortex of actin sandwiched between the microtubular bundles and the plasma membrane, and an actin matrix at the tip of dendritic processes. Fine terminal dendritic branches, or filopodia, have actin filaments as their sole cytoskeletal component (reviewed in Van Aelst and Cline, 2004). Considerable effort has been devoted to understand the interaction between extracellular signaling events and the cytoskeleton, since these interactions are likely to be essential for the highly stereotyped and yet plastic elaboration of the dendritic arbor structure. A general scenario is emerging in which an extracellular signal interacts with a cell surface receptor that activates a cascade controlling the RhoA GTPases that, in turn, affect both the actin and microtubule based cytoskeleton in dendrites (Newey *et al.*, 2005). The significance of these molecules for dendritic morphogenesis is perhaps best illustrated by the fact that the abnormal development of dendritic trees, a hallmark of several different types of mental retardation, is at least in part caused by deficient signaling via Rho GTPases (Govek *et al.*, 2005).

The Rho GTPases regulate the cytoskeleton in all cell types, however the elaborate and plastic structure of neurons poses particularly fascinating regulatory constraints on GTPase signaling (Luo, 2000; da Silva and Dotti, 2002; Van Aelst and Cline, 2004). The Rho GTPases function as bimodal switches, cycling between inactive, GDP-bound and active, GTP-bound conformations. RhoA, Rac1, and cdc42 are arguably the best studied of the small Rho GTPases. These molecules regulate both actin and microtubule dynamics (Gundersen *et al.*, 2004; Zheng, 2004) and the manipulation of their individual activities has shown that each plays a particular role in dendritic structure development (reviewed in Newey

*et al.*, 2005). The interplay of these effects on the cytoskeleton is key in shaping the intricacy of dendritic trees.

As more refined methods are used to probe the molecular and cellular basis of structural plasticity, our understanding of the intricate web of control becomes more complete. A striking example is that of the *in vivo* dendritic arbor development of optic tectal neurons in *Xenopus*. These neurons respond to stimulation of the tadpole visual system with an increased dendritic arbor growth rate, which requires glutamate receptor activity (Sin *et al.*, 2002). Experimental paradigms in which dominant negative or constitutively active forms of RhoA, Rac, and Cdc42 were expressed, demonstrated the participation of the Rho GTPases in the activity-dependent enhanced dendritic arbor growth rate. Expression of dominant negative forms of Rac or Cdc42, or expression of active RhoA blocked dendritic arbor elaboration in response to visual stimulation (Li *et al.*, 2000, 2002; Sin *et al.*, 2002) (Fig. 21.4A). These data suggest that glutamatergic synaptic input regulates the development of dendritic arbor structure by controlling cytoskeletal dynamics, and that the Rho GTPases are an interface between glutamate receptor activity and the cytoskeleton. Furthermore, these data and reports from other systems support a model in which Rac and Cdc42 activity regulate rates of terminal branch dynamics (Ruchhoeft *et al.*, 1999; Li *et al.*, 2000, 2002; Wong *et al.*, 2000; Hayashi *et al.*, 2002; Ng *et al.*, 2002; Sin *et al.*, 2002; Scott *et al.*, 2003) whereas RhoA regulates extension of branches (Ruchhoeft *et al.*, 1999; Lee *et al.*, 2000; Li *et al.*, 2000, 2002; Nakayama *et al.*, 2000; Wong *et al.*, 2000; Sin *et al.*, 2002; Ahnert-Hilger *et al.*, 2004; Pilpel and Segal, 2004) in response to activity.

Branch formation requires the regulation of local cortical actin dynamics to create protrusive forces that allow filopodial sprouting (Luo, 2002; Nimchinsky *et al.*, 2002). Time-lapse imaging indicates that filopodia are extremely dynamic, consistent with the rapid assembly and disassembly of actin filaments. The stabilization of filopodia and their extension as branches likely depends on their invasion by microtubules. Although the invasion of filopodia by microtubules is a key regulatory event in dendritic arbor development, the mechanisms regulating this process are unknown. Microtubules generate the mechanical forces necessary for branch elongation and can serve as tracks for the delivery of new membrane as new branches extend (Horton and Ehlers, 2003, 2004). A close

### BOX 21.1 (cont'd)

interplay between actin and microtubules is then fundamental for the cellular events leading to changes in dendritic architecture. Importantly, in nonneuronal cells, the activity of Rho GTPases not only induces changes in both actin and microtubules but is also itself modified by alterations in the dynamics of the two cytoskeletons, thus serving as the regulator for the interplay between actin and microtubules (Wittmann and Waterman-Storer, 2001; Fukata *et al.*, 2003; Etienne-Manneville, 2004; Zheng, 2004).

It is tempting to hypothesize that in response to activity, the role of RhoA in regulating extension of branches relies on its capacity to control microtubule stabilization (e.g., via mDia; Palazzo *et al.*, 2001) and favor polymerization of cortical actin (Nobes and Hall, 1995; Da Silva *et al.*, 2003), whereas Rac and cdc42 act on branch dynamics by regulating actin (e.g., supporting filopodial formation; Luo, 2002) and by favoring microtubular dynamics (e.g., by regulating catastrophe rates; Daub *et al.*, 2001; Kuntziger *et al.*, 2001). The description of dendritic roles for other Rho GTPases, such as that of Rnd2 in regulating branching via its effector Rapostlin (Negishi and Katoh, 2005), will help in the detailed understanding of how Rho GTPases regulate dendritic arbor development.

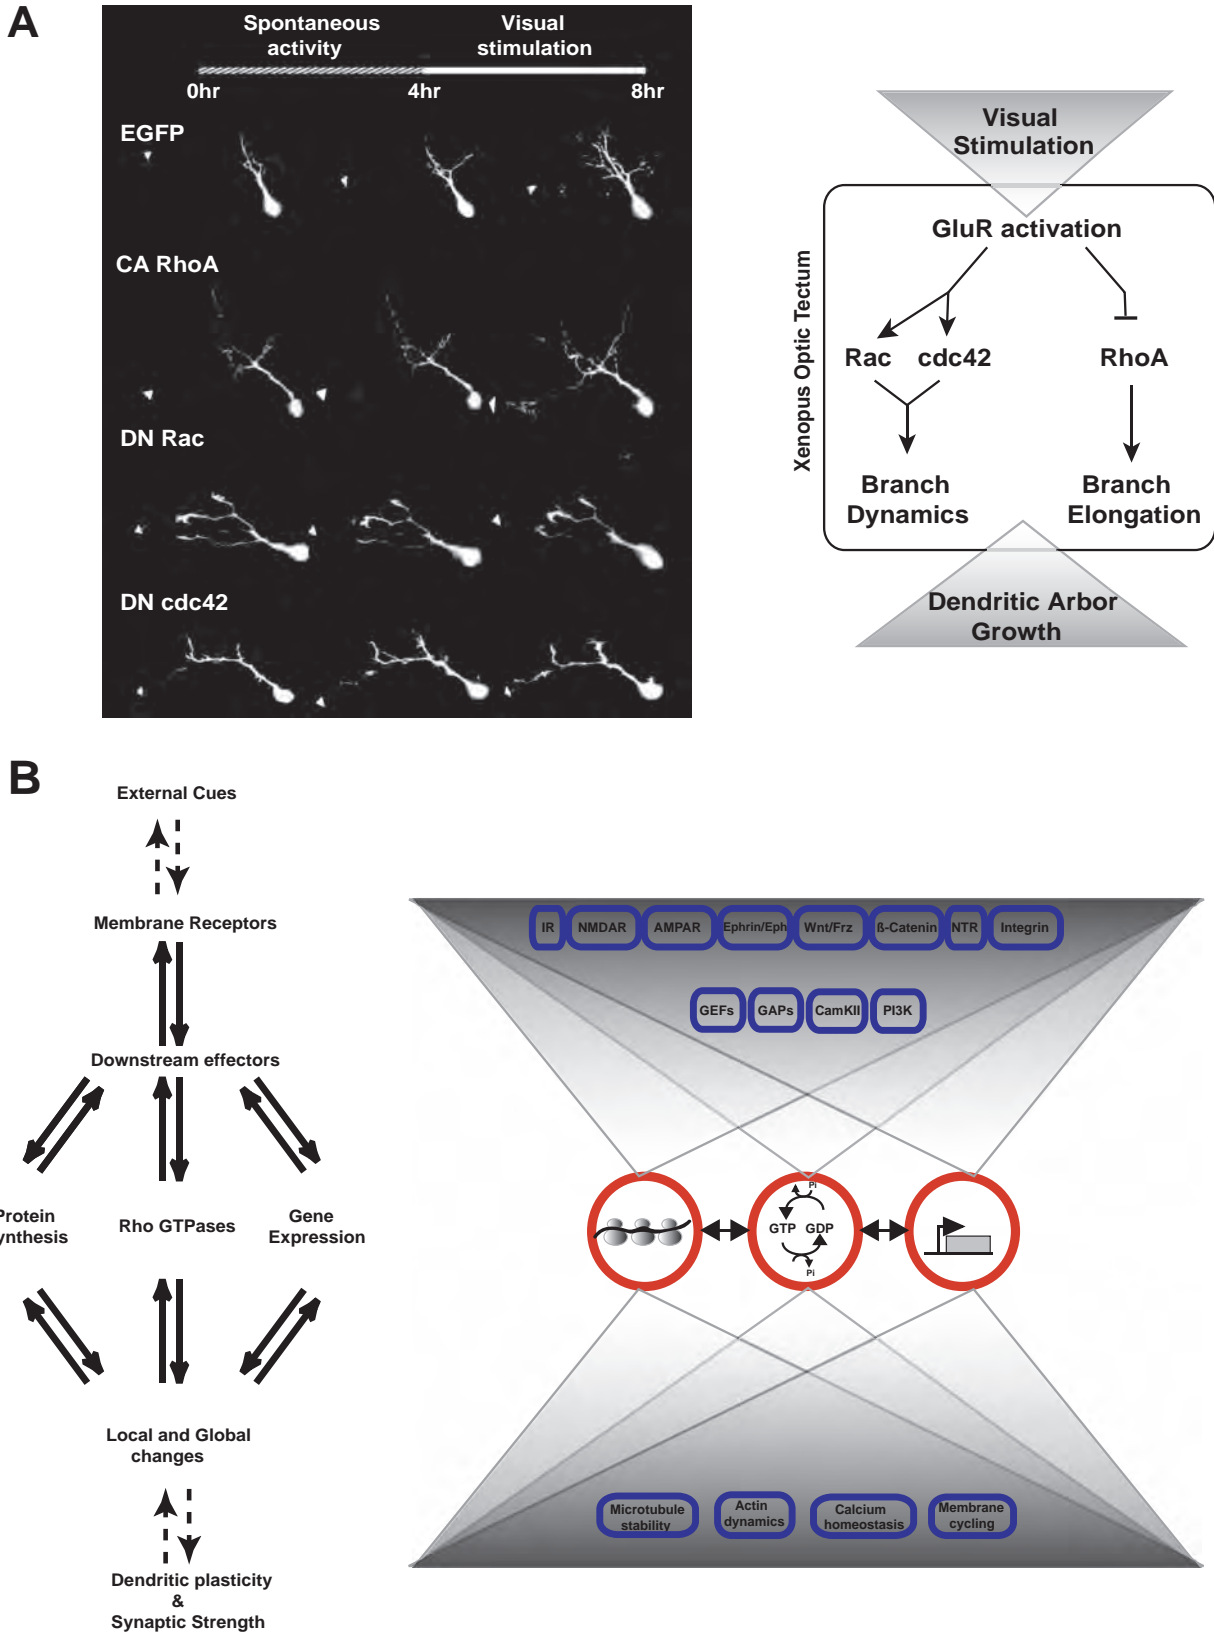

Rho GTPases are distributed ubiquitously throughout the neuronal cytoplasm (Govek *et al.*, 2005) and, consequently, the activity of these proteins must be restrained in dendrites by resident upstream regulators. The link between incoming signals, for instance by activation of neurotransmitter receptors, and GTPase activity is mediated by GTPase regulatory proteins, which are particularly interesting because they are capable of integrating extracellular signaling with other signaling events relevant to neuronal structure. These include the guanine exchange factors (GEFs), which activate GTPases by favoring the substitution of GDP for GTP and GTPase activating proteins (GAPs), which inactivate GTPases by inducing GTP hydrolysis (Schmidt and Hall, 2002; Bernards and Settleman, 2004). A rush of recent papers has examined the potential participation of several GEFs and GAPs in activity-dependent dendritic structural plasticity. GAPs can regulate dendritic development, as is exemplified by

the observation that p190 RhoGAP is necessary for the dendritic remodeling that allows the shift from pyramidal to nonpyramidal morphologies in cortical cultures (Threadgill *et al.*, 1997). Importantly, p190 RhoGAP is likely to exert its effect in an activity-dependent manner as indicated by its importance in fear memory formation in the lateral amygdala (Lamprecht *et al.*, 2002).

GEFs also play important roles in regulating dendrite arbor structure. For instance, Tiam1, a Rac-GEF, is located in dendrites and in particular in spines in cortical and hippocampal neurons. Tiam1 is noteworthy because it associates with the NMDA receptor, is phosphorylated in a calcium- and NMDA receptor-dependent manner and is required for dendritic arbor development (Tolias *et al.*, 2005). This is particularly interesting if one considers that the closely related member of the Dbl family of GEFs (Rossman and Sondek, 2005), Trio, regulates the development of axons in a potentially calcium-dependent manner (Debant *et al.*, 1996), indicating the subcellular localization within different neuronal compartments is key to the specificity of GEF function. Kalirin, another example of a RhoGEF, in this case a dual RhoA- and Rac1-GEF, has been shown to regulate the development and maintenance of dendritic arbors by modulation of RhoA and Rac activities (Penzes *et al.*, 2001). Recruitment of this Rho GTPase regulator in dendrites depends on the ephrin-EphB transsynaptic signaling pathway, another cell surface signaling system linked to the actin cytoskeleton regulatory machinery. EphrinB-EphB receptor signaling may coordinate pre- and postsynaptic structural and functional development (Palmer and Klein, 2003). Its activation results in the translocation of Kalirin to synaptic sites and the activation of a signaling pathway involving Rac1 and the specific downstream effector PAK (Penzes *et al.*, 2003). One intriguing possibility is that the Ephrin-EphB signaling could be coordinated with regulation of NMDA receptor distribution and calcium-permeability in postsynaptic sites (Dalva *et al.*, 2000; Takasu *et al.*, 2002). This kind of crosstalk between proteins involved in cell-cell contact and neurotransmitter receptors provides evidence for coregulation of development of dendritic arbor structure and synaptic communication.

transcription factors Su(H) (CBF1/RBP-Jk) and E(Spl) (Hes1–5) have been isolated (reviewed in Weinmaster, 2000). Several of these genes are expressed in the developing brain and spinal cord and are likely to control various aspects of neural development.

The possibility that Notch might play a role in regulating dendritic patterning was suggested by immunocytochemical localization studies that showed that mammalian Notch1 is expressed by both dividing cells in the ventricular zone (VZ) and postmitotic neurons

**FIGURE 21.6** Effect of Rho, Rac, and Cdc42 on dendritic growth. (A) Visual stimulation over a 4-hour period increases the rate of dendrite growth in optic tectal neurons from *Xenopus*. Expression of constitutively active (CA) RhoA, dominant negative (DN) Rac, or *cdc42* affect specific aspects of dynamic dendritic arbor growth, as shown in the images of GFP-expressing tectal neurons collected *in vivo*. As summarized in the diagram on the right, visual stimulation, acting through glutamate receptors, triggers enhanced dendrite growth by regulating the rho GTPases. (B) External cues acting through membrane receptors and downstream signaling pathways regulate functional and structural dendritic plasticity. Multiple mechanisms operate in parallel to accomplish and control neuronal plasticity. (From Bestman *et al.* 2008)

in the cortical plate (CP) (Redmond *et al.*, 2000; Sestan *et al.*, 1999). Several observations suggest that Notch signaling might mediate contact-dependent inhibition of neurite outgrowth. For example, in postmitotic neurons there is an inverse correlation between Notch1 expression and total neurite length, and overexpression of a constitutively active Notch1 construct leads to a reduction in the total neurite length (Sestan *et al.*, 1999). Cocultures of cortical neurons with Delta- or Jagged-expressing cell lines, or addition of soluble ligands leads to a decrease in total neurite length, suggesting that Delta or Jagged are the relevant Notch1 ligands (Sestan *et al.*, 1999). Also, overexpression of Numb and Numlike, intracellular modulators that inhibit Notch activation via Su(H)/CBF1, leads to an increase in total neurite length (Sestan *et al.*, 1999). Berezovska and coworkers (Berezovska *et al.*, 1999) also have found that expression of constitutively active Notch1 in hippocampal neurons leads to an inhibition of neurite outgrowth. A study examining Notch function in neuroblastoma cells came to a similar conclusion regarding the effects of Notch signaling on neurite length (Franklin *et al.*, 1999). Together these observations indicate that Notch signaling has an inhibitory effect on process outgrowth.

In addition to restricting length, Notch signaling in cortical neurons has a major influence on dendritic branching (Redmond *et al.*, 2000). Inhibition of Notch1 signaling by overexpression of a dominant negative Notch1 construct or with antisense oligonucleotide treatment leads to a decrease in dendritic branching in neurons, and overexpression of a constitutively active Notch1 construct decreases average dendrite length but increases the branching index, resulting in an overall increase in dendritic complexity. Taken together these experiments reveal a positive role for Notch in dendrite branching and a negative role in dendrite and total neurite length.

### **Slit/Robo Signaling**

In a search for other extracellular cues that regulate dendrite development, Whitford *et al.* discovered that Slit proteins simultaneously repel pyramidal neuron axons and stimulate dendrite growth and branching (Whitford *et al.*, 2002). The Slits are a well-studied family of multifunctional guidance cues that have been shown to both repel axons and migrating cells, as well as promote elongation and branching of developing sensory axons (reviewed in Huber *et al.*, 2003). Generally, Slits exert their effects through binding to specific members of the Roundabout, or Robo, family of receptors (Huber *et al.*, 2003). Whitford *et al.* (2002) demonstrated that one of the three vertebrate Slits, Slit1, and two of the three Robo receptors, Robo1 and

Robo2, are expressed in the developing cortex during the time of initial axon and dendrite differentiation. Using the slice overlay assay developed by Polleux *et al.* (1998, 2000), Whitford *et al.* demonstrated that Slit1 is a chemorepellant for cortical axons. Interestingly, in addition to repelling cortical axons, Slit1 also potentially increases dendritic growth and branching of both pyramidal and nonpyramidal cortical neurons, paralleling a similar role for Slit proteins in the regulation of axonal branching. These effects of Slit1 are mediated by the Robo1 and 2 receptors since transfection of neurons with dominant-negative forms of these receptors in dissociated cultures and slices decreases dendritic branching. Thus, in contrast to the guidance role that Sema3A plays in orienting apical dendrites, Slit1 acts as a more general dendrite growth and branching signal for cortical neurons (Whitford *et al.*, 2002).

### **WNT Signaling**

Another illustration of the ability of individual signals to control diverse biological responses including the control of axonal and dendritic development is provided by the WNT family of secreted proteins. The WNTs represent a large family of extracellular cues initially identified as potent morphogens involved in patterning organ development in both invertebrates and vertebrates. WNTs also have been shown to regulate cell proliferation, migration, and survival (Ciani and Salinas, 2004, 2005). Recently, a role for WNT proteins in the regulation of the neuronal cytoskeleton has emerged (reviewed in Ciani and Salinas, 2005). WNT proteins can function as axon-guidance molecules and as target-derived signals that regulate axonal remodeling and synapse formation (Hall *et al.*, 2000; Krylova *et al.*, 2002). WNT proteins signal through at least three different pathways. The binding of WNT proteins to Frizzled receptors results in the activation of the scaffolding protein Dishevelled (Dvl). In the so-called canonical pathway, WNT proteins signal through Dvl to inhibit GSK3- $\beta$  a serine/threonine kinase. Inhibition of GSK3- $\beta$ , in turn, activates  $\beta$ -catenin-T-cell-specific transcription factor mediated transcription. WNT proteins can also signal through Dvl to regulate Rho GTPases during convergent extension movements and tissue polarity during early development. Finally, WNT proteins can activate a Ca<sup>2+</sup>-dependent pathway, again through Dvl. WNT proteins induce axonal remodeling through the activation of Dvl and the subsequent inhibition of GSK3- $\beta$  (Hall *et al.*, 2000). Dvl has been shown to act locally to regulate microtubule stability by inhibiting a pool of GSK3- $\beta$  through a  $\beta$ -catenin- and transcriptional-independent pathway (Ciani *et al.*, 2004).

WNT proteins recently have been implicated in the control of dendritic arborization of hippocampal neurons during development (Rosso *et al.*, 2005). Salinas and colleagues have found that *Wnt7b* is expressed in the mouse hippocampus and induces dendritic arborization of hippocampal neurons during development. This effect is mimicked by the expression of DVL. Importantly, analyses of the *Dvl1* mutant mouse revealed that DVL1 is crucial for dendrite development, as hippocampal neurons developed shorter and less complex dendrites in the mutant than in the wild-type. Neither inhibition of GSK3- $\beta$  nor expression of GSK3- $\beta$  affects dendritogenesis. Moreover, a dominant-negative  $\beta$ -catenin does not block DVL function in dendrites. These results suggest that the WNT canonical pathway is not involved. In this case WNT7B and DVL signal through a noncanonical pathway in which the small GTPase Rac, but not Rho, is involved. First, endogenous DVL associates with Rac but not Rho in hippocampal neurons. Second, WNT7B or expression of DVL activates Rac in hippocampal neurons. Last, expression of a dominant-negative Rac blocks DVL function in dendrites.

Inhibition of the WNT pathway by SFRP1 (a secreted antagonist of WNT proteins) decreases Rac activation by WNT7B and blocks the effect of WNT7B in dendrite development (Rosso *et al.*, 2005). Rosso *et al.* also report that WNT7B and DVL activate JNK, a downstream effector of Rac. Inhibition of JNK blocks DVL function in dendrites, whereas pharmacological activation of JNK enhances dendrite development. It remains to be determined whether JNK acts downstream of Rac, or whether the WNT-DVL pathway regulates Rac and JNK independently. Although Rho GTPases are well-known modulators of dendrite development and maintenance (see following section), the mechanisms by which extracellular factors modulate these molecules during dendrite morphogenesis has remained poorly understood. The findings reported by Rosso *et al.* (2005) demonstrate that DVL functions as a link between WNT factors and Rho GTPases in dendrites, and they reveal a novel role for JNK in dendrite development.

#### *Cadherins and $\beta$ -catenin*

One of the central challenges in the study of dendritic development is to understand how extracellular cues that regulate dendritic branching are integrated with Ca<sup>2+</sup> activity-dependent signals. A potential clue comes from recent results exploring the role of  $\beta$ -catenin and cadherins in dendritic branching (Yu and Malenka, 2003). Yu and Malenka report that overexpression of  $\beta$ -catenin (and other members of the cadherin/catenin complex) enhances dendritic arbori-

zation, whereas sequestering endogenous  $\beta$  catenin causes a decrease in dendritic branching. Importantly, the authors show that blocking  $\beta$  catenin prevents the enhancement of dendritic morphogenesis caused by neuronal depolarization. Yu and Malenka (2003) also show that the release of secreted WNT, which occurs during normal neuronal development, is enhanced by manipulations that mimic increased activity, and that WNTs contributes to the effects of neural activity on dendritic arborization. These results demonstrate that  $\beta$  catenin is an important mediator of dendritic morphogenesis and that WNT  $\beta$  catenin signaling is likely to be important during critical stages of dendritic development (Yu and Malenka, 2003).

These observations are reinforced by the recent demonstration that another class of cadherins (*Celsr1-3*) regulates dendritic branching of cortical pyramidal neurons (Shima *et al.*, 2004). This class of cadherins has been identified in vertebrates as orthologs of *flamingo*, a gene previously implicated in the control of dendritic development in *Drosophila* (Gao *et al.*, 2000). Shima *et al.* (2004) combined loss-of-function techniques including RNAi-mediated gene silencing of single neurons using biolistic-delivery in P8 organotypic slice cultures to demonstrate that knocking-down *Celsr2* expression in both layer 5 pyramidal neurons and Purkinje cerebellar neurons significantly reduces dendritic branching (Shima *et al.*, 2004). Furthermore, using the same technique, Shima *et al.* performed a structure-function analysis demonstrating that these effects of *Celsr2* on dendritic branching require the integrity of a site on the extracellular portion outside the cadherin-domain as well as a portion of the intracellular domain called the EGF-HRM region. These results indicate that cadherins play an important role in the control of dendritic complexity.

### EFFECT OF EXPERIENCE ON DENDRITIC DEVELOPMENT

One of the most striking manifestations of the effects of experience on brain development is the effect sensory input has on dendritic development. Dendrites tend to extend toward sources of afferent input, for instance in the barrel field of somatosensory cortex (Greenough and Chang, 1988), at borders of ocular dominance columns (Katz and Constantine-Paton, 1988; Katz *et al.*, 1989; Kossel *et al.*, 1995), in the olfactory system (Malun and Brunjes, 1996), in the auditory system (Schweitzer, 1991), and in the spinal cord (Inglis *et al.*, 2000). A particularly clear example of this phenomenon comes from study of the retina, where devel-

oping retinal ganglion cells transiently respond to both light on and light off events and their dendritic arbors terminate in both On and Off neuropil laminae. With normal visual experience, the bistratified dendritic arbors are pruned to On and Off laminae. Dark-rearing blocks the normal pruning of dendritic branches in retinal ganglion cells so that retinal ganglion cells remain responsive to On and Off visual stimuli (Tian and Copenhagen, 2003). Bodnarenko and Chalupa have shown that glutamate receptor activity is required for the development of stratification in retinal ganglion cell dendrites (Bodnarenko and Chalupa, 1993).

The advent of *in vivo* time-lapse imaging has allowed the assessment of cellular events underlying the development of dendritic arbors. *In vivo* imaging of dendritic arbor development was pioneered in the 1980s by Purves and colleagues, who discovered that peripheral neurons could be imaged repeatedly in developing mice (Hume and Purves, 1981). These studies revealed considerable heterogeneity in the dynamics of dendritic arbor structure and suggested that dendrite structure was affected significantly by differences in afferent inputs to different neurons. More than a decade passed before the methods were developed to reliably label single central neurons and image them over time without damage (Wu and Cline, 1998). *In vivo* time-lapse imaging of neurons is now routine in a few experimental systems, including some translucent fish and amphibian tadpoles, and *Drosophila*. More recent technical advances, including 2-photon microscopy, have permitted imaging of CNS neurons in rodent brain, which was previously refractory to *in vivo* imaging because of the light-scattering nature of cortical tissue and the difficulty of imaging through the skull (Brecht *et al.*, 2004).

*In vivo* time-lapse imaging studies of newly differentiated neurons in *Xenopus* and Zebrafish optic tectal neurons and peripheral sensory neurons in *Drosophila* demonstrate that the dendritic arbor develops as a result of a gradual process in which fine branches are added and retracted rapidly (Fig. 21.1, Fig. 21.5). Many more branches are added to the arbor than are ultimately maintained, so that the net elaboration of the dendritic arbor occurs as a result of the stabilization of a tiny fraction of the newly added branches. These branches then become the substrate for further branch additions. In this way the complex arbor develops gradually as a result of concurrent and iterative branch addition, stabilization, and extension (Cline, 2001; Hua and Smith, 2004) (Fig. 21.1, Fig. 21.5). A similar pattern of dendritic arbor growth has been observed in hippocampal neurons in slice culture (Dailey and Smith, 1996), suggesting that this is a plan that applies widely. Time-lapse imaging also reveals the changes

in arbor structure over time. In some cases (Figs. 21.1A and 21.1B), the neuron dramatically changes shape by adding or retracting large parts of the arbor (Wu and Cline, 2003). Although this has not been directly tested *in vivo*, it is expected that afferent inputs affect dendritic arbor development through a combination of cell adhesion and diffusible signals, such as neurotransmitters and growth factors. Constant conversation between presynaptic axons and dendrites and back again may result in the mutual stabilization of pre- and postsynaptic structures (Hua and Smith, 2004).

Synaptic inputs and neurotransmitter activity play a significant role in controlling dendritic arbor development. Whole cell recordings from newly differentiated optic tectal neurons in *Xenopus* or cortical neurons in turtle demonstrate that they have glutamatergic and GABA-ergic synaptic inputs as soon as they extend their first dendrites (Blanton and Kriegstein, 1991; Wu *et al.*, 1996). In addition, ambient neurotransmitters, including dopamine, serotonin, glutamate, and GABA may provide low levels of tonic extrasynaptic neurotransmitter receptor activation and signaling in the developing nervous system (Lauder, 1993). These data suggest that neurotransmitters, acting through non-synaptic or synaptic receptors may affect dendritic arbor development. Synaptic communication allows pre- and postsynaptic neurons to assess potential partners, to establish and strengthen optimal connections, and to prune back or eliminate suboptimal contacts. Considerable evidence supports a model in which newly generated glutamatergic synapses are mediated by the NMDA type of glutamate receptor and that AMPA type glutamate receptors are trafficked into developing synapses as they mature. Addition of AMPA receptors to synapses renders them functional at resting potentials and may stabilize the synaptic structure (Cline, 2001) (Fig. 21.7). If this is true, then conditions that affect AMPA receptor trafficking to synaptic sites would be expected to affect synapse stability and the development of the dendritic arbor.

Previous work has established a link between NMDA and AMPA receptor function and dendritic branch stabilization, suggesting that synaptic strengthening and structural stability may be mechanistically linked. LTP-inducing stimuli increase both synaptic strength and spine formation (Engert and Bonhoeffer, 1999; Maletic-Savatic *et al.*, 1999). Similarly, LTD has been shown to lead to the internalization of AMPAR (Snyder *et al.*, 2001) and a reduction in dendritic spine number, which may lead to synapse elimination (Zhou and Poo, 2004). In a recent study LTP and LTD stimuli resulted in bidirectional changes in dendritic spine structure (Zhou *et al.*, 2004). Genetic

**FIGURE 21.7** During dendritic development, newly generated glutamatergic synapses are mediated primarily by NMDA type glutamate receptors (black dots). With the addition of AMPA type glutamate receptors (white dots), synapses can be active at resting membrane conditions and overall synaptic strength is increased leading to dendritic branch stabilization. Dendrites with relatively weak synapses lacking AMPA receptors are retracted (dotted line). The resulting local increases in calcium influx through AMPA/NMDA containing synapses (indicated with “hot” colors) may enhance rates of branch addition and further stabilization. Newly stabilized branches become the substrate for further branch additions. It is the interplay between the dendrites and their synaptic partners that leads to selective stabilization and elaboration of branches toward appropriate target areas (gray and white bars) that is essential for circuit refinement. These processes are not just important during development, but underlie changes in map refinement in the mature nervous system. (From Bestman *et al.*, 2008)

manipulations of NMDA receptor subunits also demonstrate that NMDA receptor function is required for dendritic arbor development (Lee *et al.*, 2005).

The preceding suggests that the molecular mechanisms involved in dendritic morphogenesis concomitantly control glutamate receptor trafficking to synaptic sites. This suggests a close link between the relative strength of synapses, which depends on the relative contribution of AMPA receptors and the morphology of dendrites (Cline, 2001). Evidence for this idea would strengthen the case for intimate interaction between the development and plasticity of synaptic strength and neuronal structure. Indeed, recently it has been demonstrated that a dendrite-specific immunoglobulin family protein, called dendrite arborization and synapse maturation 1 (Dasm1) promotes AMPA receptor trafficking to excitatory synapses and affects dendrite arborization (Shi *et al.*, 2004a, 2004b).

These data are among a growing number of reports that support a model in which afferent input operating

through AMPA receptors increases dendritic arbor elaboration, potentially through the stabilization of new synapses and new dendritic branches on which they reside. This model is well supported. Glutamate receptors, though favoring arborization at early development stages, actually stimulate branch stabilization at later times, concomitantly with stabilization of local synapses (Rajan and Cline, 1998). This developmental shift reflects the progressive enrichment of synapses with AMPA receptors and an increase in synaptic strength (Wu *et al.*, 1996; Cantallops *et al.*, 2000a; Cline, 2001; Sin *et al.*, 2002). It is noteworthy that this interplay between synapses and the dendrites on which they form is a calcium-dependent event. In the *Xenopus* optic projection, CaMKII is expressed at times when synapses are maturing and dendritic arbors are stabilizing (Wu and Cline, 1998) and its activity was found to slow dendritic growth rates and increase synaptic strength (Wu *et al.*, 1996; Wu, 1998; Zou, 1999). Since these events require modifications in intracellular calcium and this can be achieved by the same molecu-

lar pathways discussed later, namely those targeting the Rho GTPases (Li *et al.*, 2002) (Box 21.1), the interplay between synaptic and structural plasticity in response to signals received by the dendrite seems a logical contraption. Indeed, synaptic strength and dendritic arbor development share the same molecular regulatory pathways (Luo, 2002) and examples of cellular events regulated by synaptic transmission and capable of concurrently governing dendritic arborization are at hand.

In addition to synaptic activity, neurons exhibit a variety of types of electrical and biochemical activity during the period of dendritic arbor growth. For instance, waves of calcium spread across large populations of neurons throughout the brain, including retina, cortex, and hippocampus (Firth *et al.*, 2005). Clusters of electrically coupled cortical neurons show pulses of calcium at early stages of development when cortical circuits are developing (Yuste *et al.*, 1992, 1995). These electrical events may be important for the initial formation of neural circuits that underlie normal brain development and plasticity.

### MECHANISMS THAT MEDIATE ACTIVITY-DEPENDENT DENDRITIC GROWTH

The effects of neuronal activity on dendritic development are mediated by calcium signaling. Calcium levels in neurons are regulated by influx through calcium channels as well as by release of calcium from intracellular stores. Calcium influx is mediated mainly by voltage-sensitive calcium channels (VSCC), and NMDA receptors. Release from internal stores principally involves calcium-induced calcium release (CICR) or activation by ligands that lead to the production of IP<sub>3</sub>, which acts on internal stores. Two major signaling targets of calcium influx are calcium/calmodulin dependent protein kinases (CaMKs) and mitogen-activated kinase (MAPK). Upon calcium entry via VSCC or NMDA receptors, calmodulin binds multiple calcium ions and can activate various intracellular effectors, including CaMKs (reviewed in Ghosh and Greenberg, 1995).

Of the CaMKs, CaMKII has been most extensively studied in relation to a role in dendritic development and function. Two isoforms of CaMKII, CaMKII $\alpha$  and CaMKII $\beta$ , mediate contrasting outcomes on dendrites. CaMKII $\alpha$  has been reported to stabilize or restrict dendritic growth of frog tectal neurons *in vivo* and mammalian cortical neurons *in vitro* (Wu and Cline, 1998; Redmond *et al.*, 2002). CaMKII $\beta$ , however, has a posi-

tive effect on filopodia extension and fine dendrite development mediated by direct interaction with cytoskeletal actin (Fink *et al.*, 2003). CaMKI recently also has been shown to alter cerebellar granule cell dendrite growth and hippocampal neurons process formation (Wayman *et al.*, 2004).

Unlike CaMKI, CaMKII $\alpha$ , and CaMKII $\beta$ , CaMKIV is predominately localized in the nucleus. Mice lacking CaMKIV have a defect in dendritic development (Ribar *et al.*, 2000). Pharmacological blockade of CaMKs inhibits calcium-induced dendritic growth in cortical neurons, and expression of an activated form of CaMKIV mimics the dendritic growth effects induced by calcium influx (Redmond *et al.*, 2002). The nuclear localization of CaMKIV suggests that it mediates its effect on dendrite growth via transcriptional events. The best-characterized target of CaMKIV is the transcription factor CREB, which is phosphorylated by CaMKIV at Ser-133. The effects of calcium influx and constitutively active CaMKIV on cortical dendrites are suppressed by dominant negative mutants of CREB, suggesting that CREB-dependent transcription is required for activity-dependent dendritic growth (Redmond *et al.*, 2002). The small GTP-binding protein Rap1 also appears to be an important effector of calcium-dependent activation of CREB and activity-dependent dendrite development. Rap1 is rapidly activated by calcium influx and inhibition of Rap1 suppresses activity-induced CREB phosphorylation and dendritic growth (Chen *et al.*, 2005) (Fig. 21.8).

Although CREB is required for calcium-dependent dendritic growth, activation of CREB is not sufficient to induce dendritic growth. This suggests that other transcription factors are likely to be involved in mediating activity-dependent dendritic growth. A novel approach for identifying activity-induced transcription factors in cortical neurons led to the discovery of CREST, a calcium-activated transactivator required for dendritic growth (Aizawa *et al.*, 2004). CREST is a CBP-interacting protein that is expressed at high levels in the early postnatal cortex. Dendritic growth is severely compromised in the cortex and hippocampus in CREST knockout mice, indicating that CREST function is required for dendritic development *in vivo*. Importantly, depolarization-induced dendritic growth is abolished in cortical neurons from CREST-mutant animals, supporting a key role for CREST in calcium-dependent dendritic growth. These observations suggest that activity-induced dendritic development in early postnatal life requires activation of a transcriptional program, which is likely to be regulated by CREB, CREST, and CBP.

Mitogen-activated kinases also are activated by calcium influx via NMDA receptors and VSCCs.

**FIGURE 21.8** A summary of signaling pathways by which neuronal activity influences dendritic development. The effects of neuronal activity on dendritic development are mediated by calcium influx via voltage-gated calcium channels (VGCCs) and NMDA receptors, as well as release from internal stores. Local calcium signals act via Rho family proteins to regulate dendritic branch dynamics and stability, whereas global calcium signals recruit transcriptional mechanisms to regulate dendritic growth.

Repeated depolarization can lead to sustained MAPK activation and influences the formation and stability of dendritic filopodia (Wu *et al.*, 2001). In addition MAPK has been implicated in mediating growth of SCG dendrites in response to activity by phosphorylating MAP2 (Vaillant *et al.*, 2002). MAPK signaling also has been implicated in mediating the effects of calcium influx on dendrite growth in cortical neurons (Redmond *et al.*, 2002). Thus CaMKs and MAPKs appear to be key mediators of calcium-dependent dendritic growth.

## CONVERGENCE AND DIVERGENCE

A wide variety of signaling pathways participate in dendritic arbor development by regulating different downstream events such as microtubule stability, actin dynamics,  $Ca^{++}$  homeostasis, and membrane cycling (Fig. 21.9). In addition, many signaling cascades diverge, for example to regulate somatic gene expression, local protein synthesis as well as the Rho GTPases. These diverging pathways ultimately result in modifications of dendritic plasticity. For example, the ephrin-EphB cascade mentioned earlier is one example in which ephrin-EphB receptor interaction results in rapid, local signaling events as well as longer-term

changes in neuronal structure and gene expression. EphB receptors cooperate with NMDA receptors to regulate not only calcium influx but also the subsequent changes in NMDA-receptor dependent gene expression (Takasu *et al.*, 2002). In fact, local changes in  $Ca^{++}$  are responsible for the long-term changes induced by activity-driven gene expression dependent on transcription regulators such as CREB or CREST (West *et al.*, 2001; Aizawa *et al.*, 2004).

Another example of divergence comes from the activation of the Ras superfamily GTPases that regulate membrane cycling downstream of neurotransmitter receptor activity. Synaptic NMDA receptors activate the Rab GTPase Rab5 (Pfeffer and Aivazian, 2004) that in turn regulates the internalization and dephosphorylation of AMPA receptors (Brown *et al.*, 2005), an event associated with changes in dendritic structure (Ikegaya *et al.*, 2001) and synaptic strength. Similarly, decreasing or increasing the activity of the Ras GTPase Rap1 decreases or increases, respectively, dendritic arbor elaboration *in vitro* (Chen *et al.*, 2005). One way Rap1 works is by regulating how calcium influx affects CREB-dependent transcription (Chen *et al.*, 2005). Rap1 also mediates the internalization of AMPA type glutamate receptors from local synaptic sites in response to NMDA receptor signaling (Zhu *et al.*, 2002). Since blocking glutamate receptor activity also decreases

**FIGURE 21.9** Summary of multiple mechanisms that influence dendritic growth and remodeling. Dendritic arbors develop within a complex environment in which they contact and receive signals from afferent axons, glial cells, and other dendrites. Several changes occur at sites of contact between axons and dendrites, marked by 1 and 3 in the image, including local changes in enzyme activity, such as CaM kinase and phosphatases, receptor trafficking, and local protein synthesis. Interactions between glia and neurons, marked by #2, include release of trophic substances that regulate synapse formation and maintenance. Process outgrowth, represented by #4 and #5, is mediated by cytoskeletal rearrangements. Finally activity-induced gene transcription, #6, can change the constellation of protein components in neurons in response to growth factors or synaptic inputs. (From Bestman *et al.*, 2008)

dendritic arbor development (Rajan and Cline, 1998), it is possible that Rap1 may act principally to control cell surface levels of glutamate receptors and this, in turn, affects dendritic arbor elaboration. As with the Rho GTPases, Rap1 and the other GTPases regulating membrane cycling are at nodal points in the cascades controlling cell surface distribution of membrane proteins. For instance, Rap1 is downstream of other receptors, such as the neurotrophin receptors (Huang *et al.*, 2003), plus GTPase-dependent membrane cycling regulates the cell surface distribution of signaling molecules, other than glutamate receptors. As illustrated in Figure 21.9, the pathways regulating dendritic arbor development are nonlinear and neither their regulation nor their targets are independent. Consequently, it is essential to investigate the function of these complex molecules in their normal *in vivo* context in order to dissect their endogenous functions.

## CONCLUSION

Studies such as those summarized here, aided by computational approaches to map biochemical events in space and time will ultimately lead to a complete appreciation of the signaling pathways that regulate dendritic structural and functional plasticity. Elucidation of these pathways will reveal mechanisms by which activity can rapidly affect dendritic structure, and over more-prolonged time frames, exert profound changes in the so-called intrinsic states of the dendritic tree by modifying gene expression (Goldberg, 2004). Knowledge of these events, together with an understanding of the integrative capacity of dendrites, is essential to grasp the function of neuronal circuits and the brain.

## Early Experience and Sensitive Periods

The nervous system has evolved to cope with an environment that is in many ways largely predictable. Therefore, much of the architecture and functional properties of the brain can be specified by genetic determinants that reflect the common experience of previous generations. Most of this circuitry is established prenatally, guided by genetically determined molecular mechanisms and shaped by patterns of spontaneous impulse activity that propagate through the central nervous system (CNS) in unborn animals, as discussed in Chapters 17–20.

Not all aspects of an animal's world are certain, however. Details of an animal's physical characteristics vary, as do habitats and social conditions. To deal with such uncertainties, the CNS maintains the capacity to modify its connections based on the interactions of an animal with its environment. Through adaptive adjustments based on use or quality of performance, the developing nervous system customizes its functional properties to the needs and environment of the individual animal with a precision that does not need to be, and sometimes cannot be, encoded in the genome.

Although the nervous system is capable of making adaptive adjustments throughout the lifetime of an animal, many neural circuits pass through a period during their development when the capacity for adjustment in response to experience is substantially greater than it is after the circuit has matured. This period is referred to as a *sensitive period* (Knudsen, 2004). During a sensitive period, information derived from experience selects particular functional properties from a range of possible properties that a circuit could adopt. If appropriate experience is not gained during a sensitive period, many circuits never attain the ability to process information in a typical fashion and,

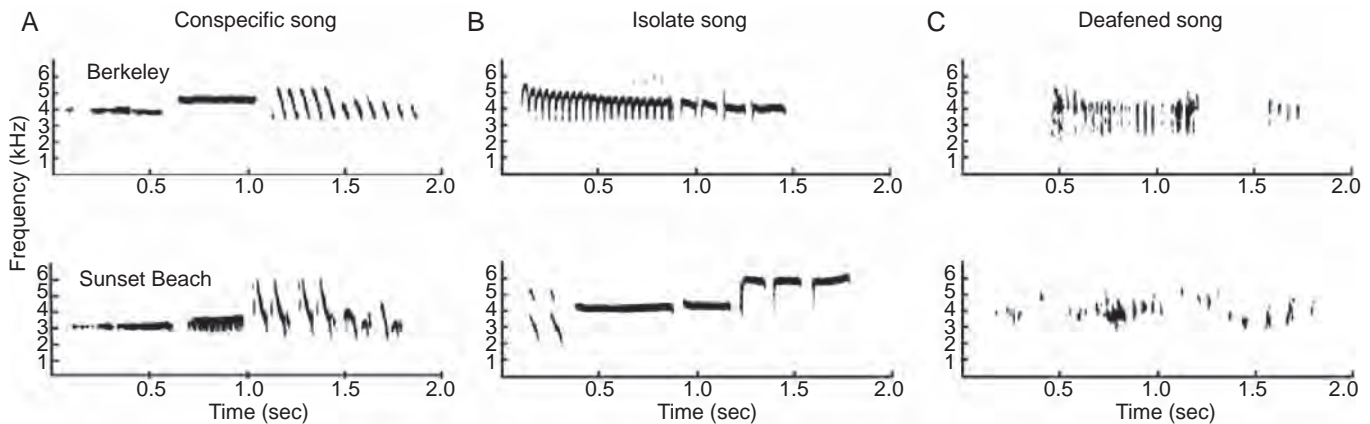

as a result, perception or behavior may be impaired permanently.

This chapter introduces four examples of circuits that have been relatively well studied with respect to their dependence on instruction by early experience for normal development. These examples are the circuits involved in (1) song learning in songbirds, (2) sound localization in owls, (3) binocular representation in the visual cortex, and (4) temperament in rats. Sensitive periods for language learning in humans and filial imprinting in birds are also discussed. These examples are used to illustrate principles that govern sensitive periods. Finally, factors that contribute to the extraordinary capacity of the nervous system for adaptive change during sensitive periods are discussed.

### BIRDSONG: LEARNED BY EXPERIENCE

The song of most songbirds depends on learning that occurs early in life during a sensitive period (Konishi, 1985; Doupe and Kuhl, 1999). Birdsong is a special form of vocal communication used by certain species of birds to identify neighbors, defend territories, and attract mates. Songs are distinguished from other communication sounds by their length, spectral complexity, and periodic structure—properties that give birdsong its melodic quality. The songs sung by birds are characteristic of the species (conspecific song); dialects of the species' song often reflect the geographical area in which the bird was raised (Fig. 22.1A).

Songs are passed on from one generation to the next by a combination of genetic instruction and learning. In a few species of songbirds, the influence of genetic instruction is strong and learning plays a relatively

**FIGURE 22.1** Songs of white-crowned sparrows. These are sonograms (time-frequency sound spectrograms) of songs from birds with different kinds of early experience. Sound energy in each frequency band is indicated by the darkness of the trace. (A) Song dialects. Birds raised in different areas sing slightly different songs. These dialects are stable for many years and are transmitted by learning. (B) Isolate songs. These simpler songs develop in birds raised in acoustic isolation or in birds that fail to copy a tutor song. (C) Songs of deafened birds. These kinds of songs develop in birds that are deafened after the sensitive period for song memorization but before the period of vocal learning. The birds need to hear their own voice to develop normal song. From Konishi (1985).

minor role. In most, however, the role of learning is paramount. Some of these species learn new songs each year (seasonal learners), whereas others learn their songs only once early in life. In the latter case, the birds memorize the song they will sing as adults during a sensitive period.

White-crowned sparrows and zebra finches are species that learn their songs during a sensitive period (Immelmann, 1972; Konishi, 1985). The extent of the sensitive period in each species has been determined by raising birds in acoustic isolation and then exposing them to conspecific song for brief periods in development. The effect of this experience on song learning is assessed by observing the song that the male eventually sings (in these species, only the male sings). Birds raised in acoustic isolation throughout the sensitive period sing an “isolate” song (Fig. 22.1B) that lacks the spectral and temporal complexity typical of normal song. When baby birds are allowed to hear conspecific song even for a few days during the sensitive period, however, they memorize that particular song and reproduce it accurately when they later learn to sing.

Song learning in these species illustrates an important principle that pertains to most sensitive period learning: The nervous system is genetically predisposed to accept only a limited range of potential stimuli as appropriate for learning (Doupe and Kuhl, 1999). For example, baby birds that are allowed to hear only alien songs that differ substantially from their conspecific song develop isolate song, indicating that they reject these distinctly alien songs as models for learning. Even within the range of songs that a bird

will learn, it strongly prefers a conspecific song when given a choice of several similar song types. Moreover, babies learn a conspecific song rapidly, whereas they learn slightly different alien songs only after much longer periods of experience. Thus, the circuits responsible for song memorization contain genetically determined filters that require certain spectral and temporal features before the stimulus is accepted as appropriate, and within the range of stimuli that is deemed acceptable, some song patterns are preferred over others.

Song learning involves two components: song memorization and vocal learning. In white-crowned sparrows, these components are separated by many months (Fig. 22.2A), whereas in zebra finches, which develop much more rapidly, they overlap. During the sensitive period for song memorization, according to a current hypothesis, high-order sensory neurons become tuned to respond selectively to the acoustic patterns of the songs that the bird memorizes. During the period of vocal learning, these high-order neurons act as templates for evaluating the bird’s own song, guiding the development of song so that it eventually matches the previously memorized song pattern.

### A Sensitive Period Exists for Song Memorization

The sensitive period for song memorization begins at about 2 weeks of age and lasts for about 8 weeks in both zebra finches and white-crowned sparrows (Immelmann, 1972; Doupe and Kuhl, 1999). Baby birds that are exposed to a conspecific song before the sensi-

**FIGURE 22.2** The sensitive period for song memorization and the set of nuclei that comprise the song system in songbirds. (A) Time-line for song learning for the white-crowned sparrow. For this species, the sensitive period for song memorization does not overlap with the period when the bird learns to sing. (B) A schematic diagram of a side view of the brain of a songbird. The vocal motor pathway, shown in red, consists of the HVC, the robust nucleus of the archopallium (RA), and the hypoglossal nucleus. The anterior pathway, shown in blue, consists of Area X, the medial portion of the dorsolateral nucleus of the thalamus (DLM), and the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN).

tive period opens do not learn the song, even though they can hear at this early age. This suggests that the neuronal substrate for song memorization is not yet ready to be shaped by experience. Similarly, babies that do not hear a normal song until after 3 to 4 months of age do not learn to sing a normal song. Apparently, by this age the influence of experience on the neuronal substrate for song memorization has become reduced greatly.

The time at which learning occurs during the sensitive period for song memorization is determined by the individual's own experience. Once the sensitive period has opened, exposure of a baby bird to normal song for 1 week is sufficient for the bird to learn the song, although subsequent exposure to other songs can still modify the song that the bird comes to sing. If a baby bird is kept in acoustic isolation (or hears

only songs that are suboptimal as models for learning) for many weeks past the opening of the sensitive period and then hears normal song, it learns the normal song. Thus, during the sensitive period the nervous system waits in a receptive state for appropriate experience-dependent instruction. Once this instruction is received, a particular pattern of connectivity becomes established and the sensitive period closes (Knudsen, 2004).

When a baby bird is deprived continuously of appropriate auditory experience, its capacity to memorize song eventually diminishes with age. Under these conditions, the sensitive period closes gradually because of additional, age-dependent factors (discussed later) that reduce the plasticity of the relevant circuits. As a bird approaches this age, experience with appropriate stimuli must be richer in order to have an effect. For example, white-crowned sparrows raised in acoustic isolation until 50 days of age no longer memorize songs presented from loudspeakers, but do memorize songs presented by live tutors. Thus, enrichment of the sensory experience provided by social interactions with the tutor overcomes the decline in the facility of the pathway for song memorization.

## Vocal Learning

Learning to sing requires a combination of vocal practice and auditory feedback. A young bird that is deafened after song memorization but before the onset of vocal learning, and is thereby prevented from hearing its own voice, will not develop a normal song (Fig. 22.1C). Clearly, auditory feedback is essential for shaping the patterns of connectivity in the vocal motor pathway while the bird is learning to sing. Presumably, auditory feedback is necessary for the bird both to learn how motor system commands correspond with the sounds that it produces and to compare the sounds it produces with its memorized song template.

## A Neural Pathway Exists for Song Learning

The neural mechanisms that underlie song memorization are being explored in many laboratories but, as yet, we know little about this aspect of song learning. In contrast, a great deal is known about the neural mechanisms that underlie song production. The pathway for song production was identified by its sexual dimorphism in species in which only males sing. In these species, a distinct set of nuclei, referred to as the song system, is conspicuously hypertrophied in males (Fig. 22.2B). The song system consists of two distinct groups of nuclei: one group in the posterior

forebrain that is responsible for song production and another in the anterior forebrain that is critical for song learning and maintenance.

The posterior, vocal motor pathway consists of three serially connected nuclei: the HVC and the robust nucleus of the archopallium (RA) in the forebrain and the hypoglossal nucleus in the brain stem (Fig. 22.2B). As a bird prepares to sing, a wave of neural activity spreads from the HVC to the RA, and finally to the hypoglossal nucleus, which contains the motor neurons that control the vocal musculature. Bilateral lesions of the HVC or the RA leave birds permanently incapable of producing song, although they still can make other kinds of unlearned vocalizations.

The anterior pathway (Fig. 22.2B) consists of Area X, a thalamic nucleus (DLM), and the lateral portion of the magnocellular nucleus of the anterior nidopallium (LMAN), and is essential for experience-dependent adjustments of song (Brainard and Doupe, 2000). Lesions made in the LMAN of a young bird that is just learning to sing cause a dramatic cessation of song development, freezing the bird's song in an immature state. This freezing of song resembles song crystallization. In adult birds, LMAN lesions result in birds that sing normal songs, but can no longer adjust the quality of their songs based on experience.

In young birds, the anterior pathway provides information to the vocal motor pathway for the purpose of vocal learning. According to one hypothesis, the anterior pathway compares auditory feedback about the song that a bird produces with a stored template of the memorized song. The result of this comparison is then used to instruct the development and maintenance of connections in the vocal motor pathway. Consistent with this hypothesis, Area X and the LMAN in the anterior pathway contain neurons that respond maximally to the sound of the bird's own song. During development, axons from the LMAN are the first to innervate the RA in the vocal motor pathway. Information transmitted by the LMAN-RA pathway is mediated predominantly by NMDA receptors, a class of glutamate receptors that, when activated, is known in other systems to induce synaptic plasticity. As birds begin learning to sing, a second set of axons enters the RA from the HVC in the vocal motor pathway and begins making glutamatergic synapses. These later connections may be guided by the activity of the pre-existing, LMAN-RA synapses.

### Hormonal Regulation of Learning

The period of vocal learning closes as birds reach sexual maturity and circulating levels of steroid hormones rise. An abrupt increase in androgen hormones

triggers the termination of the period of vocal learning. Exposure of a juvenile bird to high levels of testosterone causes its song to "crystallize" (become stable) prematurely in an abnormal state (Konishi, 1985). Conversely, juvenile birds that are castrated before they learn to sing produce inconsistent song patterns throughout life.

A cellular link between sex hormones and song plasticity has been found in the LMAN. Neurons in the LMAN, as well as in the HVC, RA, and hypoglossal nuclei, bind and accumulate androgens. As the period of vocal learning closes, the density of dendritic spines on LMAN neurons decreases dramatically, suggesting that synaptic selection has taken place. In addition, the total volume of the LMAN regresses precipitously and the influence of LMAN activity on the song motor nuclei declines (Wallhauser-Franke *et al.*, 1995). Thus, the close of the period for vocal learning may be due to synaptic selection and stabilization in the LMAN, triggered by a rise in steroid hormone levels.

Seasonal song learners, such as canaries, appear to recapitulate the process of song memorization and vocal learning each year. This relearning is linked with, and could result from, the waxing and waning of steroid hormone levels. This raises the intriguing possibility that these sensitive periods can be opened and closed by hormonal or environmental factors.

### Summary

Song learning in birds shares many characteristics with language learning in humans (Box 22.1). Song is a learned form of vocal communication used by certain species of birds to attract mates, defend their territories, and identify their neighbors. Songs are learned in two phases. The first is song memorization, which for many species takes place during a sensitive period. The second is vocal learning, during which vocal practice and auditory feedback shape the bird's song to match the memorized song. The neural pathway for song production is sexually dimorphic in many species in which only males sing. A separate pathway, in the anterior forebrain, plays a special role in vocal learning, guiding adjustments in the song production pathway as the bird learns to sing.

### SOUND LOCALIZATION: CALIBRATED BY EARLY EXPERIENCE IN THE OWL

A pathway that is highly modifiable during a sensitive period is the auditory pathway that creates a map of space in the midbrain of the barn owl (Fig. 22.3).

## BOX 22.1

## SENSITIVE PERIODS IN HUMANS

Many human capabilities depend critically on experience gained during early life. These capabilities range from fundamental capacities, such as stereoscopic vision, visual acuity, and binocular coordination, to high-level capacities, such as social behavior, language, and the ability to perceive forms and faces. In each case, normal experience during a restricted period in early life is essential for the normal development of the capacity. The rules that govern these sensitive periods appear to be the same as those that govern sensitive periods in other animals, as described in the text.

The best known and most thoroughly studied sensitive period in humans is for language (Newport *et al.*, 2001). A clear relationship exists between the age of exposure to a language and the level of proficiency achieved in that language. This relationship holds for the learning of both first and second languages. Acquisition of a first language has been assessed in children who have been raised in the absence of any language (feral or abused children) or, more frequently, in congenitally deaf children who have been raised without the aid of sign language. Much more data are available for people who began learning a second language at different ages. For both first and second languages, a thorough command of the language is attained by those who learn the language before 7 years of age. The degree of language proficiency that is eventually achieved decreases progressively with age of exposure and reaches adult levels by the end of adolescence.

Only certain aspects of language are affected by learning during sensitive periods (Newport *et al.*, 2001; Kuhl, 2000). Full proficiency with grammar (the classes of words, their functions, and relations in a sentence), syntax (the way in which words are put together in a sentence), and the production and comprehension of phonetics (the speech sounds of a language) are each dependent on early exposure to language. In contrast, semantics (word meaning) and size of vocabulary are not affected by the age of exposure. Thus, sensitive periods seem to affect the formal and subtle aspects of language, whereas the capacity to learn new words and their meanings continues unabated throughout life.

Physiological measures reveal an age dependence in the way in which language is processed and represented in the brain (Weber-Fox and Neville, 1996; Dehaena *et al.*, 1997). Various techniques have been used to assess brain activity while human subjects make perceptual judgments in language tasks. These techniques include functional magnetic resonance imaging, position emission tomogra-

phy, and event-related potentials. In normal adults, language is processed in specific areas, primarily in the left or "dominant" hemisphere. In people who have learned a second language prior to the age of 7 years, the brain areas that are involved in processing the first and second languages overlap extensively. In contrast, in people who have learned a second language later in life, the areas of the brain that are activated by the second language do not overlap, or they overlap little, with those that are activated by the first language. The brain areas activated by the second language are less lateralized to the left hemisphere and are more variable across subjects. The effect of age at the time of learning on the brain areas activated by language is far more conspicuous for tasks requiring grammatical and phonic judgments than for tasks requiring semantic judgments. Thus, consistent with the behavioral observations of the age dependence for learning grammar and phonetics, the regions of the brain that contribute to the processing of grammar and phonetics are shaped in a unique way during sensitive periods.

Detailed knowledge of the mechanisms that control sensitive periods and of the plasticity that occurs during sensitive periods will provide a basis for formulating optimal therapeutic procedures to help minimize long-term harmful effects of early abnormal experience, associated with neonatal and childhood disabilities, for example, and maximize the acquisition of normal function once normal conditions are restored. Such knowledge may also lead to improved methods of rearing and teaching normal children that take advantage of the full capacity of the central nervous system to learn from experience.

**FIGURE 22.3** The ascending auditory pathway to the optic tectum in the barn owl. Auditory inputs enter the optic tectum from the brain stem (bottom arrows); these inputs already encode frequency-specific information about interaural time difference (ITD). These inputs project into the central nucleus of the inferior colliculus (ICC), where they are organized topographically by frequency. Bands in the ICC represent these frequencies (e.g., 4, 6, 8 kHz). Neurons in the ICC convey information both to the auditory thalamus (the primary pathway) and to the external nucleus of the inferior colliculus (ICX). In the ICX, ITD information is combined across frequency channels to synthesize a map of auditory space. For example, an ITD of  $0\ \mu\text{s}$  is generated by sound stimuli directly in front of the animal, such that sound reaches the two ears at exactly the same time. At the position marked  $0\ \mu\text{s}$  in the ICX are neurons that respond maximally to sounds with an ITD value of  $0\ \mu\text{s}$  and thus respond selectively to sounds originating in front of the animal. Sounds originating, for example, from positions that are further to the left-hand side will reach the ears with progressively greater left ear-leading ITDs and thus stimulate neurons with progressively larger best ITDs. From the ICX, the auditory map of space is conveyed via a topographic projection to the optic tectum. Here the auditory map is aligned and merged with a visual map of space (top arrows, representing inputs from the retina and the forebrain) to produce a multimodal space map.

This pathway transforms a representation of auditory spatial cues that exists in the central nucleus of the inferior colliculus (ICC; Chapter 26) into a topographic representation of space in the external nucleus of the inferior colliculus (ICX). The auditory map of space is

then sent on to the optic tectum, the avian analog of the mammalian superior colliculus, where it aligns with and is integrated with a visual map of space. The function of this pathway is to extract spatial information from sound that can be used to direct orienting movements of the eyes and head toward auditory stimuli (Chapter 33).

The pathway derives the location of a sound source by evaluating spatial cues that are present in the auditory signals at the two ears. The most reliable cues for sound localization are interaural timing differences (ITDs) and interaural level differences (ILDs). ITDs are due to the difference in the path length that sound must travel to reach the near versus the far ear. Because the ears are on the sides of the head, ITD varies systematically with the horizontal (azimuthal) location of a sound source (Fig. 22.4A; contour lines). ILDs result from the fact that each ear is most sensitive to sound coming from certain directions. Consequently, a sound from a particular direction will usually produce a higher sound level in one ear than the other. ILDs vary both with the azimuthal and with the elevational location of a sound source in spatial patterns that depend on sound frequency.

In creating the map of auditory space, the nervous system can only roughly anticipate the relationship between encoded values of ITD and ILD and the locations of sound sources that produce them. The correspondence of ITDs and ILDs with locations in space changes with the size and shape of the head and ears, features that vary across individuals, as well as for a given individual during growth. Moreover, the encoded values of sound timing and level that are transmitted to the CNS depend on the sensitivity and transduction properties of each ear, and these properties can change over time. Therefore, to establish and maintain an accurate map of space in the optic tectum, this midbrain pathway must learn the exact relationship between the encoded cue values and the locations of sound sources that produce them.

The influence of early experience on the owl's auditory space map has been demonstrated using a variety of techniques that change the relationship between cue values and locations in space: For example, the external ears have been altered drastically or the auditory canal of one ear has been plugged chronically (Knudsen, 1999). The midbrain pathway responds adaptively to such manipulations by adjusting the tuning of neurons in the ICX and optic tectum to ITDs and ILDs that restore an accurate map of space. In young animals, this plasticity enables the recovery of a substantially normal auditory map even after severe disruptions of hearing. In adult animals, plasticity is far more limited in extent.

**FIGURE 22.4** Rearing owls with laterally displacing, optical prisms causes an adaptive shift in the tuning of neurons in the optic tectum for ITD. (A) This map represents the space in front of the owl, showing both the elevation and the azimuth of a stimulus in space. Contour lines indicate the correspondence of ITD values (in microseconds) with particular locations in space. The point at which the 0° axes intersect represents the point in space directly in front of the owl's head. The auditory (A) and visual (V) receptive fields of one tectal neuron are shown in the center of the map. This neuron responds optimally when the stimulus is directly in front of the animal. Normally, the auditory and visual receptive fields are aligned. Optical prisms induce a horizontal displacement of the neuron's visual receptive field (VRF), resulting in a misalignment between A and V. (B) Tuning for ITD is shifted by prism experience. These ITD tuning curves were recorded from similar sites in the optic tectum before (blue) and after (purple) 8 weeks of prism experience. Both sites had a VRF at 0° azimuth. After 8 weeks of experience, the neuron is tuned for the ITD produced by an acoustic stimulus at the location of the optically displaced VRF, as shown in A. Arrows indicate the best ITD for each site; the best ITD is defined as the center of the range of ITDs to which the neuron responded with more than 50% of its maximum response. (C) The relationship between best ITD and VRF azimuth is shifted systematically from normal in prism-reared owls. The black line indicates the regression of best ITD on VRF azimuth that is observed in normal owls. Dots represent individual sites in a prism-reared owl. The map of ITD is shifted systematically relative to the visual map of space.

An instructive signal that adjusts the tuning of ICX and tectal neurons is provided by the visual system. The instructive role of vision in guiding the tuning of ICX and tectal neurons has been demonstrated in experiments in which owls wear optical displacing prisms that chronically shift the visual field (Knudsen, 2002). The effect of experience with displacing prisms on auditory spatial tuning is most apparent in the optic tectum, where the visual receptive field of each neuron indicates the location in auditory space to which that neuron should normally be tuned. When prisms that displace the visual field horizontally are placed in front of the eyes, the visual receptive fields of tectal neurons are shifted horizontally and out of alignment with the auditory receptive fields of these neurons (Fig. 22.4A). In juvenile birds, continuous experience with such prisms over a period of 6 to 8 weeks causes the auditory receptive fields of tectal neurons to realign with their visual receptive fields: The tuning of tectal neurons to ITDs and ILDs changes so that they respond to auditory cue values representing the locations of their optically displaced visual receptive fields (Figs. 22.4B, C). As a result, the auditory map of space shifts to match the optically shifted visual map. This adjustment is adaptive because, by making it, the animal

alters its orientation toward sounds so that it sees the source of the sound through the prisms.

### A Sensitive Period for Neuronal Adjustments

This adaptive auditory plasticity is regulated developmentally. The magnitude of the shift in neuronal ITD tuning that is induced under standard conditions of prism experience depends greatly on the age of the animal (Fig. 22.5). Large shifts in ITD tuning, of up to 70 μs, occur only in juvenile owls. In adult owls, equivalent conditions rarely shift ITD tuning by more than 10 μs, even after many months of prism experience. Larger adaptive shifts in ITD and ILD tuning have been induced in adult owls that are required to hunt live prey to survive, but even under these conditions, the adaptive shifts that occur in adults are smaller than those that occur in juvenile owls that do not hunt. The period during which prism experience induces large changes in ITD tuning, the sensitive period, ends as the owls approach sexual maturity, at about 200 to 250 days old.

Although an experience-dependent shift in ITD tuning is observed most easily in the optic tectum (due to the physiological reference provided by the visual

**FIGURE 22.5** The sensitive period for visual calibration of neuronal ITD tuning in the optic tectum. Each dot represents data from a single owl. The large arrow below is a timeline, indicating important developmental stages in an owl's life. Each owl experienced a  $23^\circ$  displacement of the visual field for at least 60 days. ITD tuning was then measured at 15 to 23 sites in the superficial layers of the optic tectum. The difference between the best ITD measured and the best ITD expected normally, based on the location of the site's VRF (see Fig. 22.4C), was taken as the "shift in ITD tuning." The mean shift in ITD tuning for the population of sampled sites as a function of the age of the owl when prisms were first mounted is plotted.

receptive field of the neuron), the site in the pathway where the plasticity actually takes place is in the ICX: The maps of ITD in the ICX and in the optic tectum are shifted by equivalent amounts in prism-reared owls, whereas the representation of ITD in the ICC remains unaltered.

### Mechanisms of Plasticity

A shift of the auditory space map that occurs during the sensitive period is associated with a change in the architecture of the neurons that project from the ICC to the ICX (DeBello *et al.*, 2001). A topographic projection from the ICC to the ICX brings ITD information to the appropriate site in the ICX, where the information is integrated across frequency channels to create spatial receptive fields (Fig. 22.3). A topographic projection is established early in development, before prism experience exerts its effects (Fig. 22.6A). Prism experience causes neurons in the portion of the ICC that represents the shifted values of ITD to project axons to neurons in novel regions of the ICX (Fig. 22.6B; red lines) that then become tuned to those abnormal values of ITD. Thus, experience induces the elaboration of axons at sites in the ICX where they support appropriate responses. In owls that have

**FIGURE 22.6** Schematic model of the change in the pattern of axonal projections from the ICC to the ICX that accompanies the shift in the map of ITD in the ICX. Based on DeBello and Knudsen (2001). (A) The initial state of the projection before prism experience. (B) After prism experience, axonal projections from the ICC to the ICX are shifted systematically as indicated by the red arborizations.

acquired shifted space maps, the learned anatomical circuit coexists with the normal circuit.

The newly learned responses that result from prism experience are mediated differentially by a special class of glutamate receptor, the *n*-methyl-D-aspartate (NMDA) receptor. Drugs that specifically block this receptor, such as AP5, eliminate or severely reduce the responses of ICX neurons to newly learned values of ITD while having substantially less effect on their responses to the normal value. Thus, the expression of newly learned responses in this pathway depends heavily on the activation of NMDA receptors. The action of NMDA receptors plays a critical role in many other examples of experience-dependent plasticity as well.

As mentioned earlier, large shifts in ITD tuning in response to visual field displacement occur only in juvenile owls during a sensitive period. In contrast, removal of prisms from adult owls that have been raised from the day of eye opening wearing prisms results in a shift of the map of ITD back to normal. The genetically programmed, normal circuitry persists into adulthood even without validation by experience. In owls that have been raised with prisms, the adult circuit is able to switch back and forth, over a period of weeks, from an abnormal representation of ITD to a normal representation of ITD and vice versa, depending on the visual world the animal experiences. In this case, acquired alterations in circuit architecture resulting from experience during the sensitive period, together with the genetically programmed

circuit architecture, influence the range of connectational states that the circuit can assume later in adult life.

## Summary

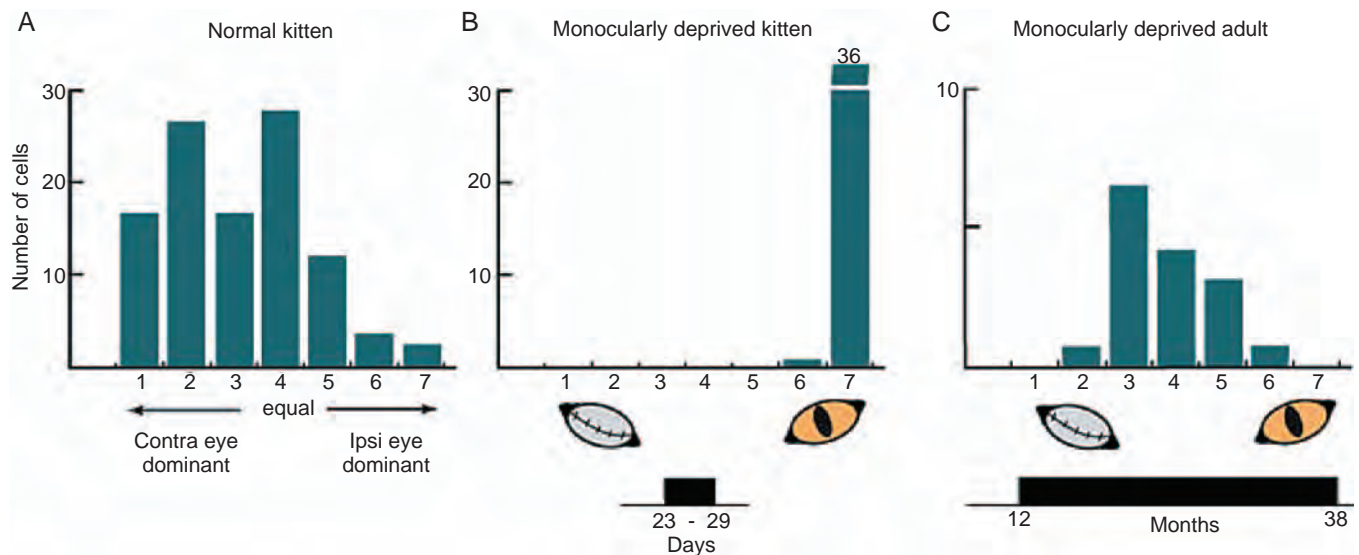

The brain derives the location of a sound source by evaluating spatial cues that are present in the auditory signals at the two ears. Interaural timing differences and interaural level differences are used to determine the position of a sound in space. In owls, this information is used to create a map of auditory space, which is aligned closely with a visual map of space in the optic tectum. Establishing and maintaining the alignment of the auditory space map with the visual space map in the optic tectum is an active process, guided by information provided by experience. The capacity of this pathway to change adaptively in response to experience is particularly great during a sensitive period. Plasticity during the sensitive period involves changes in circuit architecture and depends on the action of the NMDA subtype of glutamate receptor.

## Experience Shapes Functional Organization in the Visual Cortex

In the mammalian nervous system, visual information from the two eyes first comes together at the level of the primary visual cortex. As described in detail in

Chapter 27, visual experience during a limited period early in life has an enormous impact on how much of the visual cortex is devoted to processing input from each eye and the degree to which binocular inputs are combined (Hubel and Wiesel, 1970; Hubel *et al.*, 1977). Early in development (before birth in many species), afferents that provide inputs from the left and right eyes, respectively, begin to cluster in separate, interleaved areas in layer 4 of the primary visual cortex. This early clustering of eye-specific inputs from the lateral geniculate nucleus (LGN) is driven by a combination of molecular mechanisms and patterns of spontaneous neuronal activity (Chapter 20).

Soon after birth, a developmental period opens during which visual experience influences the competition among LGN afferents for territory in layer 4. As long as the eyes are coordinated and used equally, the typical final state, consisting of equally wide ocular dominance columns, is achieved (Fig. 22.7). If, however, vision is impaired in one eye, due to monocular eyelid closure in an experimental animal or to a cataract in a human, for example, the balance between LGN afferents in their competition for layer 4 territory is disrupted: LGN afferents that convey input from the impaired eye lose the ability to drive layer 4 neurons in an abnormally large region of the cortex, whereas LGN afferents that convey input from the normal eye gain the ability to drive layer 4 neurons in an

**FIGURE 22.7** Effect of chronic closure of one eye on the responsiveness of visual cortical neurons to input from each eye. (A) Ocular dominance distribution in the primary visual cortex of two normal kittens, 3 to 4 weeks old. Cells in group 1 were driven only by the contralateral eye; for group 2, the contralateral eye was markedly dominant; for group 3, the contralateral eye was slightly dominant; for group 4, there was no apparent difference in the drive from the two eyes; for group 5, the ipsilateral eye dominated slightly; for group 6, it dominated markedly; and for group 7, cells were driven only by the ipsilateral eye. (B) Ocular dominance distribution was altered dramatically in a kitten exposed to contralateral eye closure for 1 week (from 23 to 29 days of age). (C) Ocular dominance distribution was essentially normal in an adult cat exposed to contralateral eye closure for 26 months. From Hubel and Wiesel (1970).

abnormally large portion of the cortex. As a consequence, activity throughout most of the visual cortex becomes driven by LGN afferents from the normal eye (Fig. 22.7).

The opening of the critical period requires the maturation of inhibitory circuitry in the visual cortex (Hensch, 2005). The processing of visual information depends on a precise balance of excitatory and inhibitory influences. The balance of excitation and inhibition is regulated carefully and dynamically in mature circuits. In the visual cortex, the critical period for ocular representation does not open until inhibitory connections, which develop after excitatory connections, become effective. The critical period opens prematurely in mice in which inhibition has been enhanced pharmacologically, and it is delayed in mice in which GABA levels have been reduced by genetic manipulations. Thus, the critical period in the visual cortex depends on the ability of this circuit to process information.

### Mechanisms of Plasticity

Cellular mechanisms by which binocular experience during this sensitive period shapes the architecture and functional properties of neurons in the visual cortex are described in Chapter 20. In brief, the dramatic change in functional properties in layer 4 is accompanied by an equally dramatic change in the axonal architecture of the LGN neurons that project to layer 4: axonal arbors conveying input from the normal eye expand while those conveying input from the impaired eye shrink. The anatomical remodeling of LGN axons depends on the availability of neurotrophins—BDNF and NT-4—as well as on the expression of their cognate receptor, TrkB (Lein and Shatz, 2001). In addition, the adjustments of synaptic drive by the left and right eyes result from long-term potentiation and long-term depression of synapses in the cortex, and requires the activation of NMDA receptors.

### A Critical Period for Ocular Representation Exists in the Visual Cortex

Because the effects of disruptions of binocular vision on ocular representation in the visual cortex are apparently irreversible when they occur during this limited period in early life, this period has been referred to in the literature as a *critical period*. The critical period for ocular representation in the visual cortex has been studied particularly carefully in cats by measuring the age dependence of the effects of monocular eyelid closure (Fig. 22.8). The onset of the critical period is rapid, beginning at about 3 weeks in cats. By 4 to 6

**FIGURE 22.8** The critical period for ocular representation in the primary visual cortex of the cat. The degree of functional disconnection of cortical neurons from the deprived eye is quantified and plotted as a function of the kitten's age at the time of monocular closure. Chronic monocular closure lasted 10 to 12 days. Each point represents data from a single animal. Functional disconnection was based on the ocular dominance distribution (see Fig. 22.7) and indicated the degree to which the influence of the closed eye was weakened or lost. The index was defined such that the mean value for normal cats was 0, whereas total disconnection resulted in a value of 1. From Olson and Freeman (1980).

weeks of age, the cortex is maximally sensitive to monocular deprivation: A few days of monocular deprivation causes a complete shift in ocular dominance, leaving the cortex almost entirely driven by input from the nondeprived eye (Fig. 22.7B). Beyond 6 weeks of age, the critical period gradually closes: Over the next 10 months, the rate at which ocular dominance can be shifted by monocular deprivation and the degree to which it can be shifted both decrease. Once a cat is about 1 year old, monocular deprivation even for months no longer affects ocular dominance in the cortex (Fig. 22.7C). Similar critical periods, but extending later in life, exist for the visual cortex in monkeys and humans.

### The Critical Period Can Be Prolonged

The close of the critical period in cats can be delayed substantially by raising animals in complete darkness. At the beginning of the critical period, most cortical neurons respond to inputs from either eye, but the responses tend to be weak. In cats that are raised in the dark until well past the end of the critical period (as defined by monocular occlusion), cortical neurons continue to be driven binocularly and their responses remain weak. When these animals are finally allowed visual experience, the responses of these neurons gradually increase in strength and the relative representations of the left and right eyes is shaped by the animal's

experience: In monocularly deprived cats, nondeprived eye inputs become predominant in the cortex, and in cats that experience binocular vision, normal ocular dominance columns develop. This indicates that the critical period has remained open. Thus, without experience-driven input, the mechanisms that control ocular representation in the cortex remain in an uncommitted state, waiting for instruction for a prolonged, if not indefinite, period of time.

The critical period for ocular representation in the cortex is atypical in one respect: There is no predisposition to establish a normal pattern of connectivity based on normal experience. Even after baby cats or monkeys have experienced normal binocular vision for several weeks, monocular deprivation still causes the responses in the cortex to become dominated by the nondeprived eye (Fig. 22.7). Moreover, once the responses in the cortex become dominated by one eye, reinstating normal visual input to the previously deprived eye does not readily restore normal binocular responses in the cortex. Instead, the nondeprived eye continues to dominate the responses of cortical neurons for as long as animals have been studied (up to 5 years after restoration of binocular input). Thus, unlike in the case of song learning in birds, the pattern of neural connectivity that supports normal function in the visual cortex is not stabilized immediately by exposure to normal binocular input. Instead, normal binocular vision must persist throughout the entire critical period to prevent the cortex from becoming dominated by monocular responses. An adaptive advantage of this characteristic of the binocular pathway has yet to be recognized.

### Summary

The representation of the two eyes in layer 4 of the primary visual cortex is shaped by binocular experience during a sensitive period. During prenatal development and before the onset of vision, thalamic inputs representing the left and right eyes segregate from each other to form ocular dominance columns of roughly equal width in the visual cortex. Soon after birth, a period opens during which the visual experience of the animal shapes the representations of the two eyes in the cortex. Normal binocular vision consolidates and refines the established patterns of ocular representation. Impaired vision in one eye, however, causes the LGN axons in layer 4 carrying information from the impaired eye to shrink and their synapses to lose efficacy, whereas axons carrying information from the normal eye expand and their synapses increase in efficacy. In contrast, equivalent, monocular deprivation in adult animals has no apparent effect. The critical period for ocular representation in the

visual cortex can be extended by rearing animals in complete darkness.

### A Sensitive Period for Shaping the Temperament of Rats

The way in which a rat pup is cared for by its mother during a sensitive period has an enormous impact on a rat's temperament as an adult (Weaver *et al.*, 2004). In this example, the primary influence of early experience is to set the expression level of a gene, the gene for the glucocorticoid receptor (GR), in a particular circuit in the hippocampus. The protein product of this gene strongly influences a rat's emotional responses to stressful conditions. The effect of mothering on the expression level of this gene occurs only during the first week of a rat's life, and the behavioral consequences of this experience last throughout adulthood.

Different rats respond differently to threatening situations. For example, when introduced into a new environment, some rats are calm and adventurous, whereas others are anxious and fearful. This fundamental difference in emotional responses to stressors reflects, in part, a rat's interactions with its mother during the first week after birth (Fig. 22.9). Rats raised by a mother who groomed them extensively (high-grooming) and nursed them in a way that facilitated their access to milk (arched-back nursing) are less fearful and less reactive to stressors as adults than are rats raised by a mother who did not treat them in this way.

Cross-fostering experiments demonstrate that the transmission of these traits is dominated by

**FIGURE 22.9** A rat mother grooms her pups during the first week after their birth. This interaction permanently affects the temperament of these rat pups.

experience, and not by genetics. Rats born to low-grooming mothers (nonattentive and no arched-back nursing), but raised by high-grooming mothers, become themselves calm, adventurous, high-grooming mothers. Conversely, rats born to high-grooming mothers, but raised by low-grooming mothers, become anxious, low-grooming mothers. Thus, the transmission of these traits depends on mother-infant interactions during the first week of a rat's life. The experiments demonstrate that, although genetics constrains the ranges of these traits, early experience can modify them dramatically.

The emotional responses of a rat to stressors reflect the reactivity of the hypothalamic-pituitary-adrenal (HPA) system. Activation of the HPA system leads to the release of a special class of stress hormones, glucocorticoid hormones, from the adrenal glands. Animals with high circulating levels of glucocorticoid hormones are anxious and fearful, those with low circulating levels of this hormone are calm.

The hippocampus exerts a powerful negative feedback on the release of glucocorticoid hormones from the adrenal glands. High levels of GRs in the hippocampus result in low basal levels of glucocorticoids and tight regulation of glucocorticoid release when an animal is stressed. Low levels of GRs in the hippocampus have the opposite effects.

### Mechanisms of Plasticity

The expression level of GRs in the hippocampus is adjusted by interactions of a rat pup with its mother. Rats raised by high-grooming mothers express high levels of GRs in the hippocampus, whereas rats raised by low-grooming mothers express low levels of GRs. The same effect is observed in experiments in which mothering behavior is manipulated. For example, removing rat pups from a mother for 15 minutes and then returning them to the mother, causes the mother to increase her grooming of those pups. Rats that experience this increase in grooming express increased levels of GRs in the hippocampus compared with control animals; correspondingly, they are less reactive to stressors, less fearful, and more adventurous. This manipulation has these effects only when applied during the first two weeks after birth.

One mechanism that mediates the effect of mothering on GR levels in the hippocampus, and therefore on an animal's reactivity to stressors, is the methylation of the GR gene. Methylation silences the GR gene by blocking access of transcription factors to a promoter region of the gene. Gene promoter methylation is adjusted during development and is stable thereafter. Experience during the first week after birth with a

high-grooming mother (Fig. 22.9) causes the GR gene promoter to become demethylated, resulting in high levels of GR gene expression and high levels of GRs in the hippocampus. Conversely, experience with low-grooming mothers causes the GR gene promoter to become methylated, leading to low GR levels in the hippocampus. The sensitive period for the effect of mothering on the temperament of rats is accounted for by the narrow window in development when the methylation state of the GR gene is adjusted by experience. The persistence of the effects of this experience is due to the subsequent stability of the gene's methylation state.

A second mechanism that contributes to the effect of mothering on GR levels in the hippocampus is the acetylation of histones. Acetylation of histones in the chromatin of a gene increases the access of transcription factors to promoters. Histones within the nucleosome core that includes the GR gene are more acetylated in rats reared by high-grooming mothers than in rats reared by low-grooming mothers, an effect that increases the transcription of the GR gene and raises GR levels in the hippocampus. The difference in histone acetylation is thought to be driven by the difference in the methylation state of the GR gene, discussed earlier.

The contribution of histone acetylation to controlling GR levels in the hippocampus has been tested by administering an inhibitor of histone deacetylation to adult rats that had been reared by low-grooming mothers. The inhibitor increased acetylation of the histones surrounding the GR gene, increasing access of demethylating enzymes to the gene. The inhibitor thereby caused a decrease in the methylation state of the gene, which increased GRs in the hippocampus and changed the temperament of the adult rats into the calm, adventurous temperament typical of rats raised by high-grooming mothers.

### Summary

Interactions of a rat with its mother during the first week of life shape the way in which a rat responds to stressful situations as an adult. The primary mechanism for this effect is an experience-dependent adjustment of the expression level of the GR gene in the hippocampus. High maternal care during the first postnatal week causes a demethylation of a GR gene promoter, resulting in a stable increase in GR gene expression in the hippocampus and a consequent decrease in basal levels of glucocorticoid hormones and a tighter regulation glucocorticoid hormone release in response to stressors. As a result, the animal is calm, adventurous, and reacts in a measured fashion

to stressors. Maternal behavior has these effects only during a sensitive period in a rat's development when the methylation state of the GR gene can be altered. Thereafter, the methylation state of the GR gene remains stable throughout adulthood.

## PRINCIPLES OF DEVELOPMENTAL LEARNING

During the later stages in the maturation of many neural circuits, patterns of neuronal activity, driven by stimuli or the animal's behavior, shape the circuit's functional properties, architecture, and/or biochemistry. This shaping process selects circuit properties that are appropriate for the individual's experience.

Circuit changes that occur during sensitive periods differ from those that occur in adulthood in terms of their magnitude and persistence and the behavioral conditions under which the changes can occur. As illustrated by the preceding examples in this chapter, sensitive period experience can cause changes in the nervous system that are beyond the range of changes that occur in adults, and the changes that result typically persist for the lifetime of the animal.

Changes in circuit properties are far more readily induced during sensitive periods than in mature circuits. During sensitive periods, circuits may be altered simply by exposing animals to unusual conditions such as monocular deprivation, for example. In mature circuits, equivalent conditions either have no effect or require the attention of the animal to the conditions in order for plasticity to occur.

Sensitive period learning is influenced heavily by genetic predispositions. Only a limited range of stimuli is allowed to operate as an instructive influence for a particular circuit. Within this acceptable range, some stimuli are preferred over others. This property is well illustrated by song learning in birds and by imprinting (Box 22.2). The predisposition of the nervous system to be instructed by "normal" experience probably originates in the selectivity of the response properties, genetically determined as well as shaped by experience, of the neurons that provide input to the sites in the pathway where the learning take place. As learning progresses, the selectivity of the pathway for acceptable input becomes progressively higher.

Whether a particular pathway passes through a sensitive period can vary across species. For example, some songbirds, such as canaries and mockingbirds, learn new songs seasonally throughout life, whereas others, such as white-crowned sparrows and zebra finches, learn their songs only during a sensitive

period. Such species differences may provide a useful tool for uncovering the mechanisms that are responsible for sensitive periods.

The magnitude of changes that may result from experience-driven adjustments varies greatly across circuits and across species. The magnitude of changes depends on the degree of genetic specification of the inputs to the site of change. When the selection of appropriate inputs is from a large potential range of inputs, the effect of experience can have a profound influence on a circuit. Conversely, when the range of potential inputs is highly restricted by genetic specification, the effect of experience is correspondingly small.

The duration of different sensitive periods also varies greatly. At one end of the spectrum are the sensitive periods for imprinting, which may open and close within hours (Box 22.2). At the other end are sensitive periods for acquiring complex cognitive capabilities, such as language (described in Chapter 51), which involve sensitive periods that last for many years.

### **The Opening of Sensitive Periods Depends on Pathway Maturation**

Sensitive periods cannot open until the brain has matured to the point where three conditions are met. First, the information provided to the circuit from lower level circuits must be sufficiently reliable and precise to allow the circuit to carry out its function. Second, the circuit's connectivity must have matured adequately for it to process the information. For example, the critical period in the visual cortex does not open until and unless inhibitory as well as excitatory connections are effective. Third, the mechanisms that enable plasticity must be active.

Because complex behaviors depend on information that is processed through hierarchies of circuits, the first condition implies that sensitive periods for circuits at higher levels in these hierarchies cannot open until the information from circuits at lower levels has become reliable. Sensitive periods for low-level circuits, such as the LGN, occur earlier than sensitive periods for higher level circuits, such as those in the visual cortex. The same principle holds for circuits at different levels in the owl's sound localization pathway. Thus, pathways that support complex behaviors, such as human language (Box 22.1) or object recognition, may rely on circuits that pass through sensitive periods that end at very different stages in an animal's life.

Experience cannot shape a circuit until the mechanisms that enable plasticity are active. Experience-driven changes in functional properties can involve a

## BOX 22.2

## FILIAL IMPRINTING: BABIES LEARN TO RECOGNIZE THEIR PARENTS

For many species of birds and mammals, including ducks, geese, mice, and monkeys, parental care is essential for the survival of the young. The young of these species learn rapidly to distinguish their parents from all other individuals and form a unique and close relationship with their parents from that point on—a process referred to as filial imprinting (Horn, 2004; Hess, 1973). Filial imprinting can involve the learning of visual, auditory, olfactory, and gustatory cues that identify a parent. The learning of these cues takes place during short, well-defined sensitive periods early in postnatal life.

The visual component of the learning process usually is preceded by auditory, olfactory, and/or gustatory components. In many species, the babies learn to recognize the vocalizations of the mother based on experience that begins before or soon after the animal is born. In addition, babies may learn the odor and/or taste of the mother from the odors and tastes experienced immediately after birth. The recognition of the parent based on acoustic and/or chemical cues helps the young select the correct individual for visual imprinting, once the eyes and nervous system are capable of adequate form vision.

Sensitive periods for filial imprinting are relatively discrete and can be as short as a few hours in some species (Ramsay and Hess, 1954). For example, the sensitive period for filial imprinting in ducklings occurs during the first day of life. When a duckling is exposed once, for 10 min, to a model of a male duck on the first day after hatching, the duckling imprints on this particular model. When the duckling is tested 5 to 70 h later, by being offered a choice between the previously presented model and a model of a female duck, the duckling prefers to follow the model of the male duck over that of the female duck, even when the female model is much closer to the duckling and makes louder calls. Measured by the following response, imprinting in ducks is most effective between 10 and 20 h after hatching.

As in other examples of learning during sensitive periods, young animals exhibit an innate preference to imprint on normal stimuli. When given a choice, babies

in the process of imprinting attend preferentially to images that more closely resemble members of their own species. Thus, when baby ducks are given the choice of imprinting on geese or on people, they imprint on the (duck-like) geese. This predisposition is based on genetically programmed preferences for simple, conspicuous features, referred to as sign stimuli by ethologists, that tend to distinguish the species from all others. This implies that the neural circuitry involved in filial imprinting, like that involved in song learning in songbirds, contains genetically determined neuronal filters that help identify stimuli that are appropriate models for learning. As imprinting proceeds, learning causes these filters to become more selective until ultimately the young are capable of discriminating one individual from all others.

Imprinting results in rapid functional and structural changes in a specific part of the forebrain of birds (Horn, 2004). In chicks that have been imprinted on an artificial object, neurons in the intermediate and medial mesopallium (IMM) become responsive to the imprinted stimulus, and some become highly selective for the stimulus. Associated with the acquisition of selective neuronal responses in the IMM are local increases in the number of NMDA receptors, increases in the size of certain synapses, and a temporary surge in inhibitory activity. The increased inhibitory activity, which begins soon after exposure to the imprinting stimulus and lasts for many hours, is thought to contribute critically to the shaping of the specificity of IMM neurons for the imprinted stimulus.

remodeling of axons and dendrites, an elaboration of new synapses, an adjustment of synaptic efficacies, and/or a regulation of gene expression. Anatomical remodeling and the establishment of new synapses may well be guided by the same mechanisms that

control synaptogenesis during circuit development (Chapter 18). Neurotrophins (described in Chapter 19), particularly BDNF for example, are essential for anatomical remodeling during the critical period in the visual cortex (Lein and Shatz, 2001). Mechanisms that

regulate synaptic efficacy during a sensitive period include those that underlie synaptic plasticity in the adult nervous system (Chapter 50). Long-term potentiation (LTP) and long-term depression (LTD), for example, have been shown to operate in many models of developmental learning. Moreover, the ubiquitous presence of NMDA receptors at sites of change in the various models of developmental learning indicates that this class of glutamate receptor plays a key role in adjusting patterns of connectivity during sensitive periods.

### The Closing of Sensitive Periods May Involve Several Mechanisms

Sensitive periods end once an animal has received adequate experience and the relevant circuit is irreversibly committed to a pattern of connectivity. The factors that render the commitment irreversible are not known. Many factors may play a role, and the factors that are most important may differ across different pathways.

One factor that may contribute to the closing of sensitive periods is the age- or experience-dependent alteration of molecular mechanisms that support changes in synaptic efficacy such as LTP and LTD, described in Chapter 49. In addition, in those circuits in which axonal elaboration is a necessary component of experience-dependent changes in connectivity, loss of the mechanisms that support axonal growth would end the sensitive period. In the visual cortex of cats, for example, levels of the growth-associated protein GAP-43, which is thought to be necessary for axonal growth, decrease precipitously during the critical period. A host of other molecular mechanisms could contribute to a decline in plasticity, including the loss of responsiveness of presynaptic axonal arbors to neurotrophins secreted by postsynaptic neurons, the stabilization of synapses by the extracellular matrix or by proteoglycans, the myelination of axons (preventing them from growing or retracting), the appearance of molecules that prevent growth, and the disappearance of molecules that enable growth.

Another major factor that decreases the plasticity of circuits is the experience-driven sharpening of functional tuning. Initially in development, neuronal responses are relatively weak and broadly tuned. Experience causes selective changes in anatomical connections and synaptic efficacy that refine the patterns of both excitatory and inhibitory connections. These changes are self-reinforcing due to the action of self-organizational mechanisms that operate by Hebbian principles (Chapter 49). As a result, once a circuit has been shaped to process information in a certain way,

it becomes far more difficult for altered experience to induce new patterns of connectivity.

### Deprivation Prolongs Sensitive Periods

Sensitive periods typically close once an animal receives adequate experience. Therefore, when an animal is deprived of appropriate experience, the sensitive period is prolonged. For example, raising songbirds in acoustic isolation prolongs the sensitive period for song memorization, and raising cats in complete darkness prolongs the critical period for ocular representation in the visual cortex. This characteristic of sensitive periods indicates that the event that triggers sensitive period adjustments is the powerful and repeated activation of neurons at the site where changes take place. Without the vigorous activation of these neurons, the pathway remains in an uncommitted state and capable of adjusting in response to experience when it becomes available. This characteristic suggests that for young animals (including humans) suffering from a peripheral or central abnormality, a total absence of relevant input is far better than abnormal input. This implies that the optimal therapeutic strategy for such individuals is to deprive them of relevant sensory input until the abnormality is corrected. Otherwise, an abnormal sensory experience may close the sensitive period, resulting in a commitment to an abnormal pattern of connectivity that cannot later be reversed.

### Summary

Early experience shapes the functional properties, architecture, and biochemistry of many circuits so that the properties of these circuits are appropriate for the needs and the environment of the individual animal. The changes in circuit properties that occur during a sensitive period differ quantitatively, if not qualitatively, from those that occur in mature circuits. First, they occur readily only during a restricted period in the lifetime of the animal. Second, they involve the selection of particular circuit properties from a wide range of possible properties. Third, the changes in circuit properties that occur during sensitive periods typically do not require the attention of the animal. Fourth, the changes persist throughout life.

Sensitive periods vary in timing and duration across pathways and across species; some last only a few hours, whereas others last until the individual reaches sexual maturity. Sensitive periods open once the information conveyed to a circuit is sufficiently precise and the circuit is competent to process the information and to undergo plastic change. The signal that induces

change is probably the repeated, vigorous activation of postsynaptic neurons by presynaptic activity representing the occurrence of an appropriate stimulus or the execution of adaptive behavior. The range of stimuli that are effective in driving plastic change is specified by genetic preprogramming, with most pathways biased heavily to prefer normal patterns of stimulation.

After a sensitive period closes, equivalent conditions have much less effect on the architecture, biochemistry, and functional properties of a circuit. The closure of a sensitive period may be triggered by experience itself or as a consequence of circuit maturation. The mechanisms that close a sensitive period probably vary for different circuits. When experience-induced changes require anatomical remodeling, the end of the sensitive period may be controlled by factors that regulate cell growth; when the induced changes require adjustments in synaptic efficacy, the sensitive period will be controlled by factors that influence the capacity of synapses to modify their efficacy; and when the induced changes involve adjustments in the levels of specific receptors, the sensitive period will be controlled mechanisms that regulate the expression of receptors.

SENSORY SYSTEMS

## Fundamentals of Sensory Systems

In bringing information about the world to an individual, sensory systems perform a series of common functions. At its most basic, each system responds with some specificity to a stimulus and each employs specialized cells—the peripheral receptors—to translate the stimulus into a signal that all neurons can use. Because of their physical or chemical specialization, the many types of receptors transduce the energy in light, heat, mechanical, and chemical stimulation into a change in membrane potential. That initial electrical event begins the process by which the central nervous system (CNS) constructs an orderly representation of the body and of things visible, audible, or chemical. To bridge the distance between peripheral transduction and central representation, messages are carried along lines dedicated to telling the CNS what has taken place in the external world and where it has happened. Such precision requires that labor be divided among neurons so that not only different stimulus energies (light vs. mechanical deformation) but also different stimulus qualities (steady indentation vs. high-frequency vibration of the skin) are analyzed by separate groups of neurons.

In addition to their organization along labeled lines, sensory systems perform common types of operations. Foremost among these is the ability of each system to compare events that occur simultaneously at different receptors, a process that serves to bring out the greatest response where the difference in stimulus strength (contrast) is greatest. At late stages in sensory processing, systems make comparisons with past events and with sensations received by other sensory systems. These comparisons are the fundamental bases of perception, recognition, and comprehension.

This chapter gives an overview of the functional attributes and patterns of organization displayed by

the auditory, olfactory, somatosensory, gustatory, and visual systems; and it outlines the physiological and anatomical principles common to all sensory systems. When variations on a common theme exist, they are discussed with the goal of bringing the general pattern into sharper focus.

### SENSATION AND PERCEPTION

#### **The Function of Each Sensory System Is to Provide the CNS with a Representation of the External World**

Because of the changes that occur around an individual, each sensory system has the task of providing a constantly updated representation of the external world. Accomplishing this task is no simple feat because it requires a close interaction between ascending or stimulus-driven mechanisms and descending or goal-directed mechanisms. Together these two mechanisms evoke sensations, give rise to perceptions, and activate stored memories to form the basis of conscious experience. Ascending mechanisms begin with the activity of peripheral receptors, which together form an initial neural representation of the external world. Descending mechanisms work to sort out from the large amount of sensory input those events that require immediate attention. In doing so, the descending mechanisms alter ascending inputs in ways that optimize perception.

Perception of a sensory experience can change even though the input remains the same. A classic example is seen in the image of a vase that can also be perceived as two faces, pointed nose to nose (Fig. 23.1). In this

**FIGURE 23.1** An example of a figure that can elicit different perceptions (faces or vase) even though stimulus and sensation remain constant. The mind can “see” purple figures against a blue background or a blue figure against a purple background.

case the image remains the same—the sensory input remains constant—but the perception of what is being viewed changes as the goal of the viewer changes or as his or her attention wanders. Using this example, it is apparent that detection of a stimulus and recognition that an event has occurred usually are called sensation; interpretation and appreciation of that event constitute perception.

### Psychophysics Is the Quantitative Study of Sensory Performance

A psychophysical experiment determines the quantitative relationship between a stimulus and a sensation in order to establish the limits of sensory performance (Stevens, 1957). Such an experiment relies on reports from a subject who is asked to judge quantitatively the presence or magnitude of a stimulus as careful adjustments in the physical attributes are made. One example of threshold detection is the *two-point limen*, in which two blunt probes, separated by a distance that is progressively enlarged or reduced over a series of trials, are applied to the skin surface. The minimum separation distance at which a subject reports two stimuli half the time and one stimulus the other half is taken as the detection threshold. That distance can be measured accurately and is found to vary markedly across the body surface; the two-point limen is smallest for the fingertips and largest for the

skin of the back. Other studies, such as those exploring the detection of relative magnitudes of stimuli, can include assessments of object heaviness, loudness of sound, or brightness of light. Studies of this sort have been combined with neurophysiological experiments to compare reports from subjects (sensory behavior) with the responses of single cells (neuronal physiology). Through this procedure the neural mechanisms underlying sensory perception can be examined.

Some general principles hold for all sensation measured in psychophysical experiments. As pointed out in the preceding paragraph, one principle is that of threshold for detecting a difference between stimuli. Studies look to determine a difference threshold by asking what a just noticeable difference (JND) between two stimuli (two lights of different brightness) is that an observer can detect. E. Weber was the first to formally recognize that small differences between two minimal stimuli are easier to detect than small differences between two robust stimuli. One example is the ability to detect a difference between two light objects that weigh 0.1 and 0.2 kilograms versus a difference between two heavy objects that weigh 10.1 and 10.2 kilograms. The former is much easier than the latter. Weber’s law states that the difference threshold for a stimulus is a constant fraction of intensity (the Weber fraction). The formula,  $\Delta I/I = k$ , describes that law, where  $I$  is the intensity of a baseline stimulus,  $\Delta I$  is the JND between baseline and a second stimulus, and  $k$  is the Weber fraction. It is important to recognize that  $k$  may be a constant of a particular value for one feature, such as the frequency of sound, but the value changes markedly for another feature of the same sense (sound pressure level). The Weber fraction for sound frequency is exceedingly low (roughly .003) whereas that for sound pressure level is relatively high (0.15). For purposes of comparison, the Weber fraction for luminance is 0.02 and that for concentration of an odorant molecule is 0.10.

G. Fechner proposed that every JND between one stimulus and the next is an equal increment in the magnitude of sensation. That would mean a JND is proportional to a physical variable. His law is formalized in the equation,  $S = k/\log I$ , where  $S$  is the sensory experience in terms of magnitude,  $I$  is the physically measured intensity of a stimulus and  $k$  is a constant. There is strong intuitive value to this equation as it states the magnitude of a sensory experience is related logarithmically to the physical intensity. Lifting 1 kg and 2 kg produces very different sensory experiences, but lifting 10 kg and 11 kg produces almost the same experience, even though the added weight was equal in the two cases. S. Stevens recognized a century later that rather than a logarithmic relation, perceived sen-

sation and physical intensity were related by a power function, described by the equation  $S = kI^p$ . Yet the exponent of  $I$  could be infinite, depending on the relationship of neural response to stimulus intensity. V. Mountcastle and his colleagues proposed that for mechanosensation the relationship between the physical properties of a stimulus and the response of individual neurons is linear. And most recently, K. Johnson and his colleagues have shown that for the complex percept of roughness perception, a linear relationship exists between subjective experience and neural activity. Thus a basic law of psychophysics emerges: how an observer perceives a stimulus is a linear function of the intensity of that stimulus.

## RECEPTORS

### Receptors Are Specific for a Narrow Range of Input

Neurons of the brain and spinal cord do not respond when they are touched or when they are exposed to sound or light or odors. Each form of energy must be transduced by a population of specialized cells, which converts the stimulus into a signal that all neurons understand. In every sensory system, cells that perform this transduction step are called *receptors* (Fig. 23.2). For each of the fundamental types of stimuli (mechanical, chemical, or thermal energy or light) there is a separate population of receptors selective for the particular form of energy. Even within a single sensory system, there are classes of receptors that are particularly sensitive to one stimulus (e.g., heat or cold) and not another (muscle stretch). This specificity in the receptor response is a direct function of differences in receptor structure and chemistry.

### Receptor Types Vary Across Sensory Systems

Systems differ in the number of distinct receptor types they incorporate, and a correlation exists between the number of receptor types displayed by a system and the types of stimuli that system is able to detect. In the somatosensory system, a large number of receptor types exist to detect many types of stimuli. Separate receptors exist to transduce a variety of mechanical stimuli, including steady indentation of hairless skin, deformation of hair, vibration, increased or decreased skin temperature, tissue destruction, and stretch of muscles or tendons (Fig. 23.2). In the auditory system, two classes of receptor—the inner and outer hair cells of the cochlea—transduce mechanical energy of the

**FIGURE 23.2** Receptor morphology and relationship to ganglion cells in the somatosensory, auditory, and visual systems. Receptors are specialized structures that adopt different shapes depending on their function. In the somatosensory system the receptor is a specialized peripheral element that is associated with the peripheral process of a sensory neuron. In the auditory and visual systems, a distinct type of receptor cell is present. In the auditory system, the receptor (hair cell) synapses directly on the ganglion cell, whereas in the visual system, an interneuron receives synapses from the photoreceptor and in turn synapses on the retinal ganglion cell. Adapted from Bodian (1967).

basilar membrane, which is set in motion by sound waves (Dallos, 1996). Here, the motility of outer hair cells provides an additional amplification of the basilar membrane motion to increase sensitivity and allow sharp tuning to sound frequency. The inner hair cells respond to the amplified vibrations and excite the large population of neurons upon which they synapse. Thus the two types of receptors act in concert to transduce a single type of stimulus. In the visual system, transduction is performed by two broad classes of receptor in the retina: rods and cones. The number of cone types varies from one in some species to two in many species to three in a few species; in general cones are tuned to ranges of wavelengths of light. Rods are more sensitive to light and enable vision when light levels are dim. Olfactory receptors also vary in number from a few hundred in primates to more than a thousand in rodents. Here the difference between one olfactory receptor neuron (ORN) and the next is a subtle variation on a common theme, as each ORN differs from its neighbor in the primary sequence of a single

receptor protein. As that protein varies so does the ORN's sensitivity to odorant molecules.

### Receptors Perform a Common Function in Unique Fashion

All receptors transduce the energy to which they are sensitive into a change in membrane voltage. The task of the receptor is to transmit that voltage change by one route or another to a class of neurons—usually referred to as ganglion cells—that send their axons into the brain or spinal cord (Fig. 23.2). Systems vary in the mechanism whereby receptors and ganglion cells interact. Most receptors in the somatosensory system are part of multicellular organs, the neural components of which are the terminal specializations of dorsal root ganglion cell axons. An appropriate stimulus applied to a somatosensory receptor produces a generator potential—a graded change in membrane voltage (Katz, 1950)—that, when large enough, leads to action potentials that can be carried over a considerable distance into the central nervous system (CNS). The same approach is used by the olfactory system, as ORNs not only transduce the stimulus of an odorant molecule into a change in membrane potential but also conduct those action potentials into the CNS.

Receptors of the auditory, visual, and gustatory systems are separate, specialized cells that transduce a stimulus and then transmit the resulting signal to the nearby process of a neuron. Because the distances between receptor and target neuron are short, auditory hair cells, photoreceptors, and taste receptors do not generate action potentials but signal their response by a passive flow of current. These systems differ, however, in the path between receptor and ganglion cell. In the cochlea, auditory receptors form chemical synapses directly with the processes of ganglion cells so that the response properties of inner hair cells are conveyed directly to the ganglion cells on which they synapse. A similar arrangement is seen for taste receptors (which are epithelial cells and not neurons) and the axons of ganglion cells from cranial nerves VII, IX, and X. Taste receptors synapse directly onto ganglion cell axons. For these systems, the synapse between a receptor and a ganglion cell is little more than the conversion of an analog signal (graded changes in membrane potential) into a digital signal (action potentials). That is not the case in the retina, where photoreceptors relay their response through populations of interneurons interposed between them and retinal ganglion cells (Dowling, 1987) (Fig. 23.2). Because of this additional synapse and the opportunity it affords for summation and comparison of receptor signals, the

retinal ganglion cell response differs appreciably from that of photoreceptors.

The mechanisms whereby receptors transduce and transmit signals are known in greater or lesser detail for each system. Visual transduction is a well-understood, rapid process in which a weak signal (a single photon) can be amplified greatly through a biochemical cascade, leading to the closure of thousands of  $\text{Na}^+$  channels and a hyperpolarizing response (Yau and Baylor, 1989). For auditory hair cells and somatosensory mechanoreceptors, the mechanical deformation of a part of the cell is transduced into a change in membrane voltage (Hudspeth, 1985). The response of mechanoreceptors is similar to that of photoreceptors in being of one sign only, but it is a sign opposite to that of photoreceptors, as an appropriate tactile stimulus leads to the opening of  $\text{Na}^+$  channels and a depolarizing response. This requirement for depolarization may result from the demands placed on the somatosensory ganglion cell to generate action potentials and transmit information over long distances. In contrast, auditory receptors and those of the vestibular system can generate a biphasic response. When protruding villi of a hair cell, called stereocilia, are deflected in one direction, transducer channels open and the cell is depolarized. Yet with deflection of stereocilia in the opposite direction, the same channels close and the cell is hyperpolarized, although to a lesser extent (Hudspeth, 1985). Because sound usually produces a back-and-forth deflection of stereocilia, the result is a back-and-forth movement of the receptor potential—at least for low and moderate frequencies of sound. Thus, the receptor output contains temporal information about the waveform of an acoustic stimulus.

### Receptors Have Characteristic Patterns of Position and Density

Receptors are not scattered randomly across the sensory surface. An orderly arrangement of receptors exists along the skin, basilar membrane, retina, olfactory epithelium, and the lining of the tongue and throat. In the retina, for example, photoreceptors adopt a hexagonal packing array (Wassle and Boycott, 1991) in the region of highest density, called the fovea. Moreover, only cones are found in the fovea and for that of humans and other Old World primates, only red and green cones are found in very center of the fovea. Hair cells of the vestibular system are even more tightly sequestered, as they occupy very small regions in the semicircular canals and the otolith organs. In the skin, the arrangement of receptors is not nearly so orderly but the density of cutaneous receptors varies markedly

across the skin surface. By far the greatest density of receptor terminals is found at the fingertips and the mouth, whereas receptors along the surface of the back are at least an order of magnitude less frequent. In each system, the differences in peripheral innervation density are tightly correlated with spatial acuity. Regions of highest receptor density are also the regions of highest acuity in vision (fovea) and somatic sensation (fingertip).

A perfect test case for innervation density and acuity is seen in the auditory system of microbats. Because these animals use echolocation to navigate and find prey the auditory system greatly overrepresents the frequencies of sound a bat emits as a probing signal and the surrounding frequencies of Doppler-shifted sounds that echo from objects. Throughout most of the cochlea, the physical properties of the basilar membrane change in a steady fashion so that cochlear hair cells display a progressive shift in the frequency that excites them best. But at the frequencies represented in the Doppler-shifted echo, both the amount of basilar membrane and the density of inner hair cells along that region increase markedly. The result is a much greater acuity for those information-rich frequencies than for all other frequencies.

### Receptors Are the Sites of Convergence and Divergence

The relationship between receptor and ganglion cell is seldom exclusive. Most commonly, a single ganglion cell receives input from several receptors and, in many cases, a single receptor sends information to two or more ganglion cells. *Convergence* and *divergence* go hand in hand for the somatosensory system as an individual receptor often is innervated by axons of several ganglion cells while the axon of a single ganglion cell can branch to end as part of several receptor organs. In the somatosensory system, however, the amount of divergence and convergence varies with the class of receptor involved (e.g., thermal receptor vs. mechanoreceptor) and the location of the receptor on the body surface (e.g., shoulder vs. fingertip). Similar features are seen in the visual system, as divergence and convergence dominate different parts of the retina populated by different receptor types. In the cone-rich central retina, each cone provides as many as five ganglion cells with their main visual drive, whereas in the rod-rich periphery, a few dozen rods supply each ganglion cell with its visual input. In its precision and in its implications for sensory processing, nothing approaches the divergence seen in the cochlea, where a single inner hair cell can be the source of all input received by at least 20 ganglion cells (humans) or as

many as 35 ganglion cells (gerbils). Thus, what emerges from a comparison across systems is that convergence and divergence from receptor to ganglion cell vary directly with the demands placed on the system at the specific location. When spatial resolution is a requirement, the convergence of receptor inputs onto individual ganglion cells is low. When detection of weak signals is necessary, convergence is high. When receptor input is used for a complex function or for multiple functions, divergence of input from a single receptor onto many ganglion cells occurs.

### Receptors Vary in Their Embryonic Origin

For auditory, vestibular, somatosensory, and olfactory systems, the various classes of receptors and ganglion cells are part of the peripheral nervous system, generated as progeny of neuroblasts located in neural crests and sensory placodes. That is not the case for photoreceptors and retinal ganglion cells. The retina is generated as a protrusion of the embryonic diencephalon and thus all its neurons and supporting cells are CNS derivatives of neural tube origin. As a result of their origin, receptors and ganglion cells of the auditory, vestibular, and somatosensory systems and the ORNs of the nasal epithelium are supported by classes of nonneuronal cells that include modified epithelial supporting cells and Schwann cells. Photoreceptors and retinal ganglion cells, by contrast, are supported by CNS neuroglial cells. Most dramatic of all the consequences resulting from this difference in origin is the ability of axons in somatosensory peripheral nerves to regenerate and reinnervate targets after they are damaged, as opposed to the complete and permanent loss of visual function when optic nerves are cut or crushed.

For all systems except the olfactory, the receptor neurons you were born with are the ones you will live it. Nothing new is added. ORNs, however, have short lives, as they die off and are replaced every six weeks or so. What is seen for all systems, however, is the progressive decline in the number of receptors and in sensory acuity with normal aging. Somatosensory mechanoreceptors in humans are reduced by more than half from the age of 25 years to 65 years. Degeneration of photoreceptors is common as is a progressive reduction in hair cells of both the cochlea and the vestibular organs. Even the ORNs fail to keep up with the ravages of age, as the rate of generation does not match the rate of degeneration. The result in every case is a marked reduction in acuity that can lessen the hedonic value of foods and flowering plants, render a person deaf or blind, and leave him unsteady while standing or walking.

## PERIPHERAL ORGANIZATION AND PROCESSING

### Sensory Information Is Transmitted Along Labeled Lines

A long-appreciated principle that unites structure and function in a sensory system is the doctrine of specific energy, or the *labeled line* principle. This principle states that when a particular population of neurons is active, the conscious perception is of a specific stimulus (Fig. 23.3). For example, in one particular population of somatosensory neurons (colored orange on Fig. 23.3), activity is always interpreted by the CNS as a painful stimulus, no matter whether the stimulus

is natural (a sharp instrument jabbed into the skin) or artificial (electrical stimulation of the appropriate axons). An entirely separate population of neurons (colored blue on Fig. 23.3) would signal light pressure. Why this is so can be seen from the fact that receptors are selective not only in what drives them, but also in the postsynaptic targets with which they communicate. Each ganglion cell transmits its activity into a well-defined region of the CNS, after which a strictly organized series of synaptic connections relays information in a sequence that eventually leads to the thalamus and then to the cerebral cortex (Darian-Smith *et al.*, 1996). It is this orderly relay from receptor to ganglion cell to central neurons at each of several stations that makes up a labeled line. All sensory informa-

**FIGURE 23.3** Example of labeled lines in the somatosensory system. Two dorsal root ganglion (DRG) cells (blue) send peripheral axons to be part of a touch receptor, whereas a third cell (red) is a pain receptor. By activating the neurons of touch receptors, direct touching of the skin or electrical stimulation of an appropriate axon produces the sensation of light touch at a defined location. The small receptive fields of touch receptors in body areas such as the fingertips permit distinguishing the point at which the body is touched (e.g., position 1 vs. position 2). In addition, convergence of two DRG axons onto a single touch receptor on the skin permits touch stimulus 2 to be localized precisely. Electrical stimulation of both axons produces the same sensation, although localized to somewhat different places in the skin. Sharp stimuli (A, B) applied to nearby skin regions selectively activate the third ganglion cell, eliciting the sensation of pain. Electrical stimulation of that ganglion cell or of any cell along that pathway also produces a sensation of pain along that region of skin. Stimulus A and B, however, cannot be localized separately with the pain receptor circuit that is drawn. As the labeled lines project centrally, they cross the midline (decussate) and project to separate centers in the thalamus.

tion arising from a single class of receptors is referred to as a *modality* (e.g., the sensations of pain and light pressure involve distinct modalities). Thus, the existence of labeled lines means that neurons in sensory systems carry specific modalities.

### Topographic Projections Dominate the Anatomy and Physiology of Sensory Systems

Receptors in the retina and body surface are organized as two-dimensional sheets, and those of the cochlea form a one-dimensional line along the basilar membrane. Receptors in these organs communicate with ganglion cells and those ganglion cells with central neurons in a strictly ordered fashion, such that relationships with neighbors are maintained throughout. This type of pattern, in which neurons positioned side by side in one region communicate with neurons so positioned in the next region, is called a *topographic pattern*. As an example, the two touch-sensitive neurons in Figure 23.3 innervate somewhat different positions in the skin. Thus, light touch at position 3 will activate the right-most ganglion cell in the dorsal root ganglion, whereas touch at position 1 will activate the neighboring ganglion cell. The central projections of these cells are kept separate and activate different targets in the thalamus and above. The end result is a map of the sensory surface of the skin. A different topography is seen in the olfactory system. ORNs divide the nasal epithelium into zones in which sensitivity to a particular range of odorants is maximally represented. A large-scale map has the ORNs in neighboring zones of the epithelium communicate with neighboring regions in the olfactory bulb. Yet the small-scale map from epithelium to bulb displays a fundamental rearrangement in which all ORNs expressing a particular receptor protein send convergent inputs to a single synaptic region (a glomerulus) in the bulb. In general topographies are a place code for sensory information in which the location of a particular neuron tells you what that neuron responds to, both in place along the sensory surface and in modality.

### Neural Signaling Is by a Combination of Rate and Temporal Codes

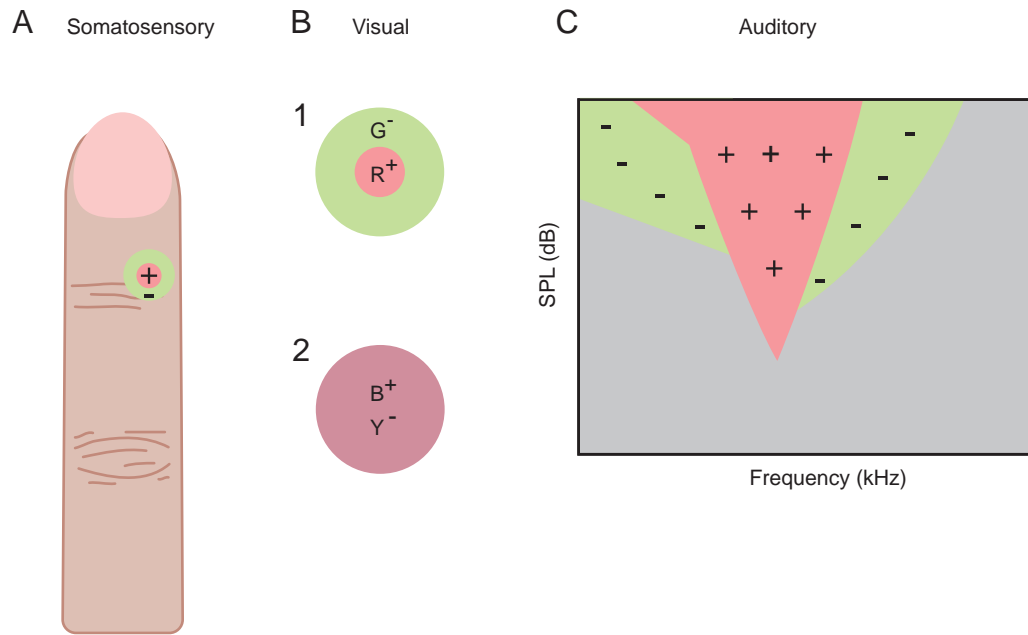

A great deal of research has been aimed at determining the codes by which neurons signal the presence and the intensity of a stimulus. In addition to place codes, neurons can signal information in the rate at which they respond and in the temporal pattern of their response. For a given receptor, the firing rate or frequency of action potentials signals the strength of

the sensory input. The perceived intensity arises from an interaction between this firing rate and the number of neurons activated by a stimulus. Together the number of neurons active with any sensory stimulus and the level of their activity gives rise to an intensity code. This is the kind of code used by retinal ganglion cells to signal the intensity (luminance) of light and by spiral ganglion cells to signal the intensity (sound pressure level) of sound. Temporal codes are also used in some systems. For instance, the phase-locking ability of auditory neurons extends to sound frequencies up to several thousand cycles per second (kHz), and this code is used (largely by accident) for the perception of the pitch of sounds. In addition, all sensory systems must deal with the fact that stimuli can move, as with vibratory stimuli on the skin. This temporal information in a stimulus is carried by the time-varying pattern of activity in small groups of receptors and central neurons.

### Lateral Mechanisms Enhance Sensitivity to Contrast

A hallmark of all sensory systems is the ability of neurons at even the earliest stages of central processing to integrate the activity of more than one receptor. The most common and easily understood of these mechanisms is *lateral* (or surround) *inhibition* (Fig. 23.4). By this mechanism, a sensory neuron displays a receptive field with an excitatory center and an inhibitory surround (Kuffler, 1953). Such a mechanism serves to enhance contrast: each neuron responds optimally to a stimulus that occupies most of its center but little of its surround. In some cases the comparisons involve receptors of different types so that the center and surround differ not only in sign (excitation vs. inhibition, ON vs. OFF), but also in the stimulus quality to which they respond. One such example occurs in visual neurons that possess centers and surrounds responsive to stimulation of different types of cones. These cells display a combination of spatial contrast (the difference in the location of cones that produce center and surround) and chromatic contrast (the difference in the visible wavelengths to which these cones respond best).

Similar types of responses are evident in the somatosensory system, where the difference between center and surround is the location on the skin from which each is activated. In this case, skin mechanics produce receptive fields with a central hot spot of activity and a surrounding inactive zone. In the auditory system, lateral suppressive areas (Fig. 23.4) also are produced by mechanics, in this case the mechanics of the basilar membrane of the cochlea. These two-tone suppression

**FIGURE 23.4** Center/surround organization of receptive fields is common in sensory systems. In this organization, a stimulus in the center of the receptive field produces one effect, usually excitation, whereas a stimulus in the surround area has the opposite effect, usually inhibition. (A) In the somatosensory system, receptive fields display antagonistic centers and surrounds because of skin mechanics. (B) In the retina and visual thalamus, a common type of receptive field is antagonistic for location and for wavelength. Receptive field 1 is excited by turning on red light (R) at its center and is inhibited by turning on green light (G) in its surround. Receptive field 2 is less common and is antagonistic for wavelength (blue vs. yellow) without being antagonistic for the location of the stimuli. Both are generated by neural processing in the retina. (C) In the auditory system, primary neurons are excited by single tones. The outline of this excitatory area is known as the tuning curve. When the neuron is excited by a tone in this area, the introduction of a second tone in flanking areas usually diminishes the response. This “two-tone suppression” is also generated mechanically, as is seen in motion of the basilar membrane of the cochlea. All these center/surround organizations serve to sharpen responses over that which would be achieved by excitation alone.

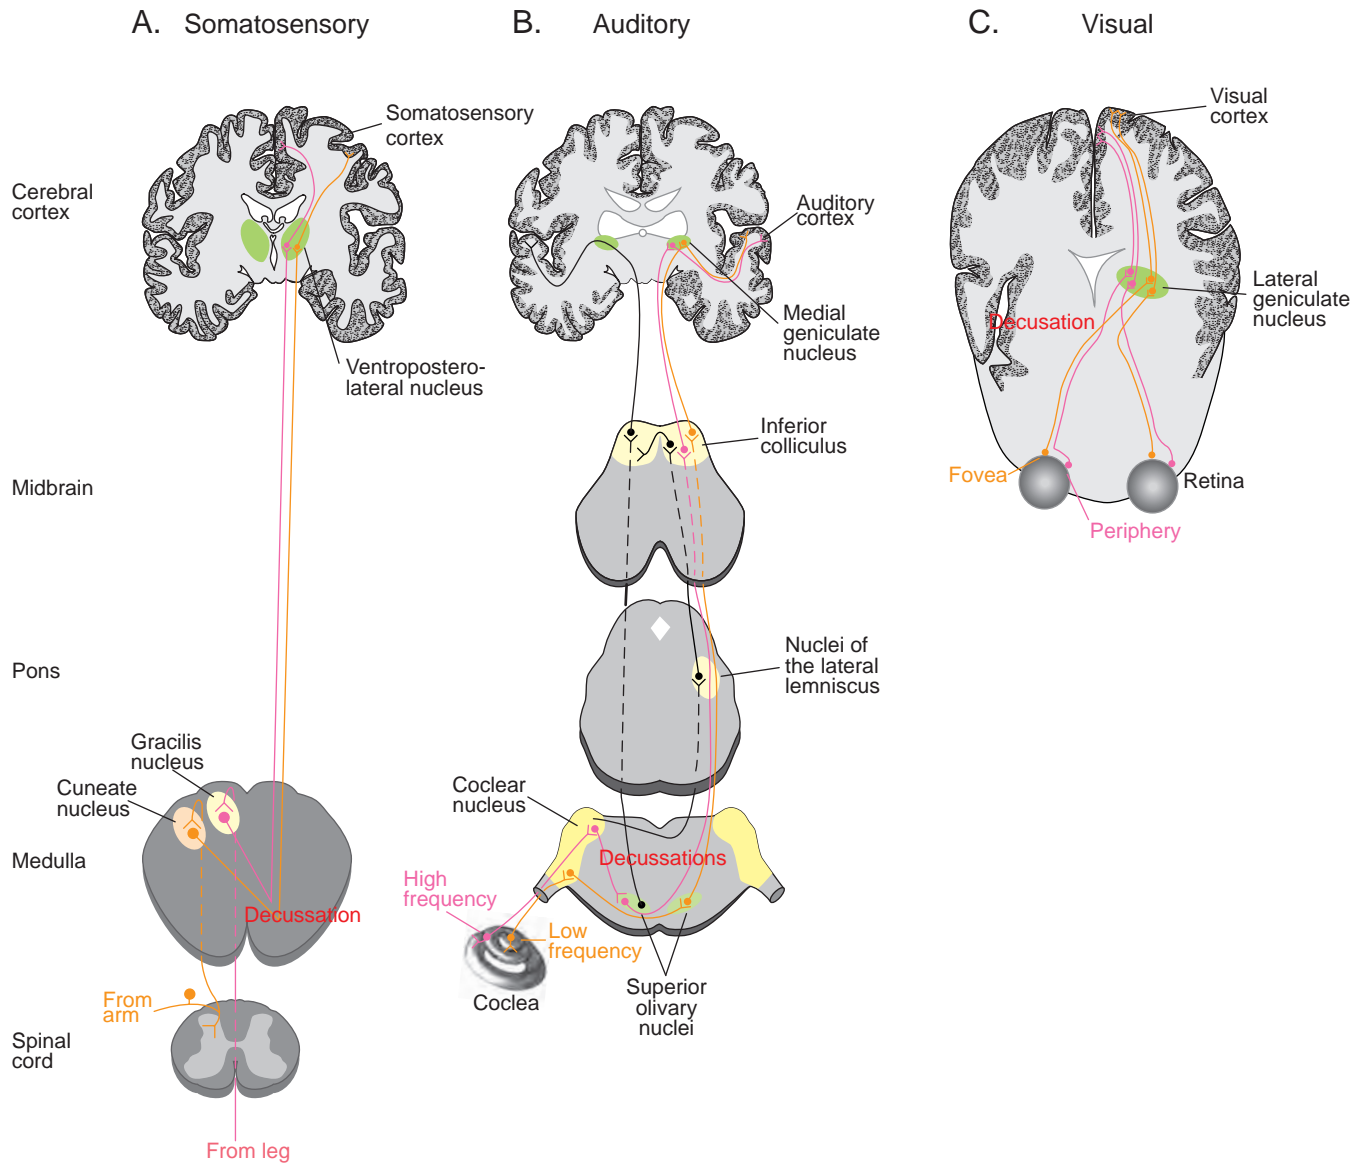

areas are demonstrated by exciting the auditory nerve fiber with a tone in the central excitatory area and observing the response decrease caused by a second tone in flanking areas (Sachs and Kiang, 1968). In all these sensory systems, center/surround organization serves to sharpen the selectivity of a neuron either for the position of the stimulus or for its exact quality by subtracting responses to stimuli of a general or diffuse nature.

## CENTRAL PATHWAYS AND PROCESSING

### Axons in Each System Cross the Midline on Their Way to the Thalamus

Axons of ganglion cells entering the CNS form the initial stage in a pathway through the thalamus to the cerebral cortex (Fig. 23.5). Axons in visual, somatosensory, and auditory systems cross the midline—they *decussate*—prior to reaching the thalamus, but those

of the olfactory and gustatory systems do not. A single, incomplete decussation occurs in the visual system of primates and carnivores, where slightly more than half the axons of the optic nerve cross the midline at the optic chiasm. Near complete decussations at the optic chiasm are seen in animals with laterally placed eyes. Decussation in the somatosensory system is nearly total, as all but a small group of axons cross the midline in the spinal cord or brain stem. These decussations serve two broad functions. They bring together into one hemisphere all axons carrying information from half the visual world or they bring somatosensory information into alignment with visual input and motor output. In contrast, multiple decussations occur in the auditory system prior to the thalamus, as comparison of input from the two ears is the dominant requirement of sound source localization. Nevertheless, at high levels in the auditory system, one side of the brain is concerned mainly with processing information about sound sources located toward the opposite side of the body, as demonstrated by lesion/behavioral studies of sound localization.

**FIGURE 23.5** Comparison of central pathways of sensory systems. In every case, soon after peripheral input arrives in the brain, decussations result in one hemifield being represented primarily by the brain on the opposite side. Each pathway has a unique nucleus in the thalamus and several unique fields in the cerebral cortex. Within each of these areas, the organized mapping that is established by receptors in the periphery is preserved.

### Specific Thalamic Nuclei Exist for Each Sensory System

Information from all sensory systems except the olfactory are relayed through the thalamus on its way to the cerebral cortex (Fig. 23.5). Olfactory information reaches primary olfactory cortex without a relay in thalamus. Yet even in this sense, perception of odors and discrimination of one odorant from another occurs only after a thalamic relay. This relay of sensory input through the thalamus involves either a single large nucleus or, in the case of the somatosensory

systems, two nuclei: one for the body and one for the face. In each nucleus, synaptic circuits are said to be secure because activity in presynaptic axons usually leads to a postsynaptic response. Within the thalamic nuclei, neurons performing one function (e.g., relay of discriminative touch) are segregated from those performing another (e.g., relay of pain and temperature). Even within one function, mappings of neurons are preserved so that there is separation of neurons providing for touch information from the arm vs. from the leg and of neurons responding to low vs. high sound frequencies (Fig. 23.5). Usually, for each

thalamic nucleus, there is a population of large neurons and one or two populations of small neurons (Jones, 1981). In each case the larger neurons carry the most rapidly transmitted signals from the periphery to the cortex.

### Multiple Maps and Parallel Pathways

Nuclei in the central pathways often contain multiple maps. For instance, in the auditory system, axons of spiral ganglion cells divide into branches as they enter the CNS and terminate in three subdivisions of the cochlear nucleus. Each division contains its own map of sound frequency (tonotopic map) that was originally established by the cochlea. The greatest number of maps generated from ganglion cell input is found in the visual system of primates, in which as many as six separate retinotopic maps are stacked on top of one another in the lateral geniculate nucleus (LGN, in the thalamus), which receives direct input from the retina (Kaas *et al.*, 1972). Such a large number of distinct maps in the LGN is indicative of inputs from ganglion cells that vary in location, structure, and function. For vision, one idea is that surface features such as color and form are carried along a path separate from the one that handles three-dimensional features of motion and stereopsis. The functional significance of multiple maps in general, however,

remains to be clarified. Perhaps the need for multiple parallel paths exists because of the relatively slow speed and the limited capacity of single neurons. So rather than have the same group of neurons perform different functions in serial order, each of several parallel groups performs a separate function. This leads eventually to the problem of binding together all features of a stimulus into a coherent percept, the neural basis for which may be the synchronized activity of neurons across several areas of the cerebral cortex (Singer, 1995).

## SENSORY CORTEX

### Sensory Cortex Includes Primary and Association Areas

Axons of sensory relay nuclei of the thalamus project to a single area or a collection of neighboring areas of the cerebral cortex, thereby providing them with a precise topographic map of the sensory periphery. These parts of cortex are frequently referred to as *primary sensory areas* (Fig. 23.6). Neighboring areas with which the primary areas communicate directly or by a single intervening relay area are *sensory association areas*.

**FIGURE 23.6** The location of primary sensory and association areas of the human cerebral cortex. The primary auditory cortex is mostly hidden from view within the Sylvian fissure. From Guyton (1987).

## Response Mappings and Plasticity

Each area of sensory cortex shares with its subcortical components a map of at least part of the sensory periphery. Thus, retinotopic, somatotopic, and tonotopic maps are evident in the relevant areas of cortex. The retina and skin are two-dimensional sheets so the map of the sensory periphery on the surface of the cortex is a simple transformation of the peripheral representation onto the cortex. In the auditory periphery, there is a one-dimensional mapping of frequency. This tonotopic mapping is represented faithfully along one dimension of cortical distance, and the orthogonal direction may map a second, as yet undiscovered, property.

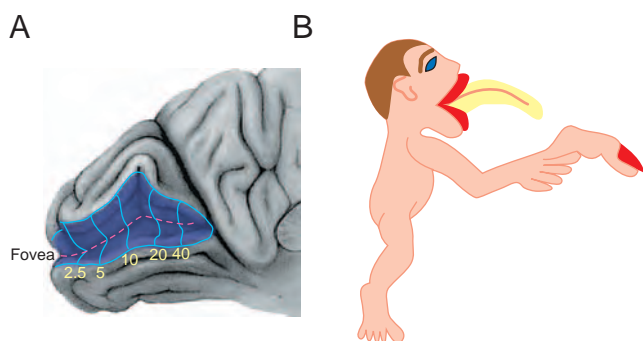

As previously indicated, the distribution of receptors is uneven for most systems. Thus, the fovea of the primate retina and the fingertips of the primate hand are regions that possess a high density of receptors with small receptive fields. Such an uneven distribution of neurons devoted to a structure is further amplified in the CNS. A much greater percentage of neural machinery subserves the representation of the retinal fovea or the fingertips than deals with the representation of other regions of the retina or body surface (Fig. 23.7). This expansion of a representation in the CNS, referred to as a *magnification factor*, appears particularly impressive in humans, in whom a very large part of primary visual cortex is devoted to the couple of millimeters of retina in and around the fovea. In the auditory cortex, such magnification of frequency representation is again seen in echolating bats, as the region devoted to the Doppler-shifted signaling fre-

quency is much enlarged over that for any other set of frequencies.

It is now clear that mappings of sensory cortex are not fixed and immutable but rather plastic. In the somatosensory system, if input from a restricted area of the body surface is removed by severing a nerve or by amputation of a digit, that portion of the cortex that was previously responsive to that region of the body surface becomes responsive to neighboring regions (Merzenich *et al.*, 1984). In the auditory system, following high-frequency hearing loss, the portion of cortex previously responsive to high frequencies becomes responsive to middle frequencies. Frequency tuning of neurons or auditory cortex can also be shifted with classical conditioning methods (Weinberger, 2007). Such plasticity of cortical maps requires some time to be established and could result from strengthening of already established lateral connections or from growth of new connections. It is likely but not firmly established that the same types of mechanisms cause cortical changes during the processes of learning and memory.

## A Common Structure Exists for Sensory Cortex

Neurons in areas of the sensory cortex (and most other areas of the cerebral cortex) are organized into six layers. The middle layers (III and IV) are the main site of termination of axons from the thalamus (Fig. 23.8). In the primary sensory cortices, these middle layers are enlarged and contain many small neurons. Because the small cells resemble grains of sand in standard histological preparations, the sensory areas are themselves referred to as granular areas of cortex.

**FIGURE 23.7** Examples of sensory magnification in the visual and somatosensory systems. (A) Determination of a visual field map in the human primary visual cortex shows that more than half this area is devoted to the central 10° of the visual field. Very little is devoted to the visual periphery beyond 40°. From Horton and Hoyt (1991). (B) Figure of how the human body would appear if the body surface were a perfect reflection of the map in the first somatosensory cortex. The mouth and tongue and the tip of the index finger enjoy a greatly enlarged representation in the thalamus and cortex.

## Columnar Organization

Properties other than place in the periphery are mapped in primary sensory areas of the cortex. The third spatial dimension of the cortex, that of depth, arranges neurons in adjacent 0.5- to 1-mm-wide regions, referred to as *columns* (Mountcastle, 1997). In these columns, neurons stacked above and below one another are fundamentally similar but differ significantly from neurons on either side of them. One example of columns with a clear anatomical correlate is the division of the primary visual cortex of most primates and some carnivores into a series of alternating regions dominated by the right and left retinas. Each ocular dominance column contains cells driven exclusively or predominantly by one eye; adjacent columns are dominated by the other eye. Other properties, such as selectivity for the orientation of a visual

## Cortical layer

**FIGURE 23.8** Cellular organization of the sensory cortex into six layers (I–VI). Inputs from the thalamus terminate mainly in layers III and IV. The main output neurons of the cortex are pyramidal cells, which are distributed in different layers according to their projections. Descending projections are to the thalamus (neurons in layer VI) or to the spinal cord, pons and medulla, tectum, or striatum (neurons at various levels in layer V). Ascending projections to other “higher” cortical centers are often from neurons located above layer IV; some of these projections are to the same hemisphere (layer II) or to the opposite hemisphere (layer III). Adapted from Jones (1985).

stimulus and the contrast between it and the surround, are also arranged in columns of primary visual cortex (Hubel, 1988). Similar types of columns are evident in the somatosensory system, as regions of modality and place specificity. They are most clearly seen in the representation of mystacial vibrissae in rodent somato-

sensory cortex, where a one-to-one matching of vibrissa with cortical territory gives rise to structures called barrels.

In the auditory system, neurons within a column generally share the same best frequency and the same type of binaural interaction characteristic: either one

ear excites the neurons and the other inhibits or suppresses the response to the first ear (suppression column) or one ear excites and the other ear also excites or facilitates the response to the first ear (summation column). Moreover, in areas of nonprimary cortex, the feature displayed most commonly by neurons of a particular area is one that often comes to occupy columns. A good example is found in the middle temporal area (MT) of visual association cortex, where neurons are tuned for the direction of a moving visual stimulus. Neurons selective for one particular direction of visual stimulus movement are organized into columns through the depth of MT; these are flanked by columns of neurons tuned for other directions of movement (Albright *et al.*, 1984). So consistent are these findings among sensory, motor, and association areas that columnar organization is viewed as a principal organizing feature for all of the cerebral cortex (Mountcastle, 1997).

### Stereotyped Connections Exist for Areas of Sensory Cortex

Neurons of the cerebral cortex send axons to subcortical regions throughout the neuraxis and to other areas of the cortex (Fig. 23.8). Subcortical projections are to those nuclei in the thalamus and brain stem that provide ascending sensory information. By far the most prominent of these is to the thalamus: the neurons of a primary sensory cortex project back to the same thalamic nucleus that provides input to the cortex. This system of descending connections is truly impressive, as the number of descending corticothalamic axons greatly exceeds the number of ascending thalamocortical axons. These connections permit a particular sensory cortex to control the activity of the very neurons that relay information to it. One role for descending control of thalamic and brain stem centers is likely to be the focusing of activity so that relay neurons most activated by a sensory stimulus are more strongly driven and those in surrounding less well activated regions are further suppressed.

The overwhelming majority of cortical neurons project to other areas of cortex (Fig. 23.8). Cortico-cortical projections link primary and association areas of the sensory cortex and establish parallel paths so that different aspects of vision, audition, and somatic sensation come to be handled by different areas of cortex. These connections establish a hierarchy within a system, such that "ascending" or "forward" connections begin with neurons from superficial cortical layers (I–III) and end with axonal terminations mainly in layers III and IV of higher cortical regions. Similarly, the ascending projection from the thalamus terminates

mainly in these layers in primary sensory cortices. Corresponding descending projections from higher to lower cortical regions begin in the deep or superficial cortical layers and project to layers outside of III and IV. In addition to projections to the ipsilateral hemisphere of cortex, there are also projections to the contralateral hemisphere via the corpus callosum and other commissures. In visual and somatosensory systems, these commissural connections are restricted in origin and termination; they exist to unite the representation of midline structures into a coherent percept (Hubel, 1988).

### Response Complexity of Cortical Neurons

Responses of cortical neurons in primary sensory cortices are more complex than those seen for neurons in the periphery. One example is seen in the primary visual area of the cerebral cortex, where neurons are responsive to stimuli that are not concentric circles (center and surround) but elongated lines possessing a specific orientation. Comparable synthesis of simpler inputs to reconstruct more complex features of stimulus is apparent at higher levels in the visual system (Logothetis and Sheinberg, 1996) and in the somatosensory and auditory areas of the cerebral cortex.

Physiologically, processing, and selectivity for stimulus features become progressively more complex within the hierarchically organized pathways that connect primary with association areas of the cortex (Gallant and Van Essen, 1994). In the visual system, separate "streams" involved in visuosensory and eventually visuomotor functions have been described; one is responsible for using visual cues to drive appropriate eye movements and the other for dealing with the tasks of visual perception (Gallant and Van Essen, 1994). In the somatosensory system, separate motor and limbic paths exist to perform much the same functions for the entire body, supplying sensory input to coordinate and adjust motor output and using complex input from many receptor types to match the shape of a tactual stimulus with one already stored in memory (Johnson and Hsiao, 1992). In the association pathways of the human auditory system, a specialized area of cortex, Wernicke's area, plays a fundamental role in processing speech and language information and in communicating with Broca's area to form a speech motor response. These streams are not separate, as traditionally viewed "motor" areas such as Broca's are now known to become activated in comprehension tasks. Apparent from this pattern in association areas of the cortex is the continued pressure for a division of labor within each sensory system; not one that produces separate paths for analyzing elemental features

of a stimulus but one that combines those features either to elicit appropriate movements or to match a stimulus with an internal representation of the world.

## SUMMARY

The functional organization of sensory systems shares common themes of transduction, relay, organized mappings, parallel processing, and central modification. It is no surprise that a case has been made for a common phylogenetic origin of sensory systems. Differences among the systems, however, demonstrate that each has existed and operated independently for as long as there have been vertebrates. What remains in overview is a well-ordered basic plan from periphery to perception that has been modified in its details as variations in niche have led to specializations in function.

## Chemical Senses: Taste and Olfaction

Some of the most remarkable feats in the animal kingdom are accomplished using chemical detection. For example, the male silkworm can follow the scent of a female for several miles to reach its mate. A great white shark can detect one part blood in 1 million parts water, or one drop of blood in an Olympic-size swimming pool, and swims toward its injured prey from a quarter mile away. Strychnine, a plant alkaloid from the *Strychnos nux vomica* plant in Southern Asia and Australia, tastes bitter to humans in minute quantities ( $10^{-6}$ M), allowing us to detect and avoid consumption of toxic quantities that produce a convulsive violent death approximately 20 minutes after swallowing.

The number of chemical compounds in our environment is vast, with more than 30 million compounds catalogued. Different combinations of these chemicals are emitted by foods, predators, and mates and act as signatures that animals use to distinguish among them. The chemical senses of olfaction and gustation allow for the detection of an enormous number of chemical cues and translate this information into meaningful behaviors. The identification of large families of chemoreceptors, the ability to monitor cell activity in the periphery and central nervous system and the ability to genetically manipulate chemosensory systems in model organisms are rapidly revolutionizing our understanding of chemosensory systems and beginning to elucidate the brain's mechanisms for encoding flavors and fragrances.

### TASTE

The sense of taste is involved primarily in feeding, allowing animals to identify food that is nutrient-rich and avoid toxic substances. Like the other primary

senses, the best definition of the gustatory system is that it has specialized sensory cells in the periphery and unique regions in the brain dedicated to sensory processing. The sensory cues detected by the gustatory system are soluble chemicals, limiting detection to a short range by direct contact with a chemical source. The concentration range for taste detection is broad and depends on the nature of the chemical stimulus. At one extreme, taste cells detect sugars and amino acids at very high concentrations (100 millimolar), allowing animals to detect only the most caloric foodstuffs instead of food with little nutritional value. At the other extreme, taste cells can also detect minute amounts of noxious substances or toxins, compounds that are harmful at very low concentrations. Mammals are thought to perceive only five taste modalities: sweet, bitter, sour, salty and umami (the taste of the amino acid glutamate), with several chemicals in most categories.

How the brain translates chemical detection into the perception of different taste modalities and taste behaviors is a basic problem in neural coding. Of course, the gustatory system does not work in isolation and the smell, texture, and sight of food also contribute to flavor perception. For example, without our olfactory neurons, we are unable to recognize coffee, chocolate, or wine! However, it is the gustatory system that acts as the final checkpoint controlling food acceptance or rejection and is essential for the basic recognition of taste modalities. Understanding the neural coding of taste information begins with knowledge about how taste receptor cells detect chemical cues, an area of rapid advances. How taste quality is encoded in higher brain areas is an area of active investigation that will ultimately require unraveling neural circuits and neural activity underlying taste behavior.

## Taste Cells Are Situated within Taste Buds Located in Several Distinct Subpopulations

In mammals, taste recognition begins on the tongue, where specialized cells detect chemical cues. Mammalian taste cells are derived from epithelial tissue rather than neural tissue, although they display neural properties such as depolarization and release of neurotransmitters. The apical tip of each receptor cell contains microvilli that project into the mucus of the oral environment. The microvilli are the site of taste detection, where taste ligands interact with membrane-bound receptors or ion channels. The basolateral membrane of taste cells forms chemical synapses with primary gustatory nerve fibers. The nerve fibers enter the base of the taste bud and transmit taste detection to the brain.

Groups of 50 to 100 taste cells are clustered together into onion-shaped organs called taste buds (Fig. 24.1). The apical center of the taste buds is called the taste pore, where the microvilli of taste cells interact with the environment. Groups of taste buds are located pri-

marily within papillae on the tongue although they are distributed on other parts of the oral cavity as well (Fig. 24.2). Three classes of papillae are defined based on their location on the lingual epithelium: fungiform papillae are found on the anterior part of the tongue, foliate papillae are on the posterior sides of the tongue and circumvallate papillae are located at the midline on the posterior tongue. In addition, taste cells are found on the palate and the epiglottis.

Taste buds are innervated by dendrites of neurons that travel in the facial (VIIth), glossopharyngeal (IXth), or vagus (X) nerves to gustatory nuclei in the brain stem. Different regions of the tongue are innervated by different nerves. Fungiform papillae and the foliate papillae on the anterior part of the tongue are innervated by the chorda tympani branch of the facial nerve. Taste buds on the soft palate receive fibers from the greater superficial petrosal (GSP) branch of the facial nerve. Circumvallate and foliate papillae on the posterior tongue contain taste buds innervated by the lingual-tonsillar branch of the glossopharyngeal nerve. Taste buds of the epiglottis and the esophagus are

**FIGURE 24.1** Cell types in mammalian taste buds. (A) The taste bud is a barrel-shaped structure containing approximately 50–100 taste cells. These epithelial receptor cells make synaptic contact with distal processes of cranial nerves VII, IX, or X, whose cell bodies lie within the cranial nerve ganglia. Microvilli of the taste receptor cells project into an opening in the epithelium, the taste pore, where they make contact with gustatory stimuli. (B) The characteristic spindle shape of taste receptor cells is revealed when a subset of taste cells is immunoreacted to an antibody against  $\alpha$ -gustducin, a gustatory G protein. (C) When sectioned transversely, gustducin-positive cells appear round in cross-section, as shown by  $\alpha$ -gustducin immunoreactivity (red), whereas other cells are revealed with an antibody against the H blood group antigen (green).

**FIGURE 24.2** Diagram of a tongue showing the distribution of various taste bud populations, which are found in the fungiform (F) papillae on the anterior tongue, the vallate (V) and foliate (FO) papillae on the posterior tongue. These taste buds are innervated by branches of the VIIth, IXth, and Xth cranial nerves (see text). From Chandrashekar *et al.*, 2006.

innervated by the internal branch of the superior laryngeal nerve (SLN), which is a branch of the vagus (Xth) nerve. A single nerve fiber may innervate cells in more than one taste bud, and each taste bud is innervated by several different afferent fibers.

### Turnover and Replacement of Taste Bud Cells Are Continuous Processes

Taste receptor cells arise continually from an underlying population of basal epithelial cells. In rats, the life span of a taste cell in a fungiform papilla is approximately 10 days. Although the mechanisms of renewal are unknown, processes underlying taste cell survival are becoming clear. In particular, it is well established that the nerves that synapse with taste cells are required for taste cell survival. Severing the chordate tympani nerve (CT) that innervates fungiform papillae results in rapid degeneration of taste papillae and taste buds. Thus, gustatory nerves maintain a trophic influence over taste buds, which degenerate when their nerve supply is removed. Although taste nerves are required for survival, they do not instruct the differentiation of taste cells. The electrophysiological properties of taste cells are not altered when the nerves that innervate

them are cross-wired (for example, by redirecting the chordate tympani to invade circumvallate papillae instead of fungiform papillae). Together, these experiments demonstrate that synaptic connections are necessary for cell survival but not for taste cell development.

Many interesting questions remain to be explored regarding taste cell turnover. For example, how is taste cell turnover regulated? Are all taste cells renewed with equal probability or do representations of different taste cell populations change over time? In other words, does a tongue maintain or change its taste-responsiveness over time? How does a dendrite know which taste cells to contact in the changing milieu of living and dying cells? How is synapse formation and retraction controlled? The renewal of taste cells may provide an ideal system to study tissue regeneration and stem cell differentiation as well as synapse plasticity.

### Mechanisms of Taste Detection by Receptor Cells

Recent fundamental discoveries have begun to identify the receptor molecules that detect taste ligands.

**FIGURE 24.3** Two families of taste receptors mediate detection of amino acids, sugars, and bitter compounds. The T1R family consists of three members. T1R1 and T1R2 mediate amino acid detection and T1R2 and T1R3 mediate the recognition of sugars. The T2R family of receptors consists of approximately 30 different receptors that respond to bitter stimuli.

There are two different families of G protein-coupled receptors that mediate the detection of sugars, amino acids and bitter compounds (Fig. 24.3). In addition, candidate ion channels for the recognition of salts and sour compounds have been identified. The diversity of receptor-types used by the gustatory system (different GPCRs, ion channels) suggests that mechanisms of detecting different taste modalities have evolved independently, unlike the olfactory system where one GPCR family mediates the detection of all odors. The total number of receptors used by the gustatory system is far fewer than for the olfactory system: under 50 taste receptors versus approximately 1000 odor receptors. This suggests that the gustatory system recognizes fewer chemical cues, perhaps with a greater diversity of molecular structures, than the olfactory system. The molecular mechanisms of taste detection are described next.

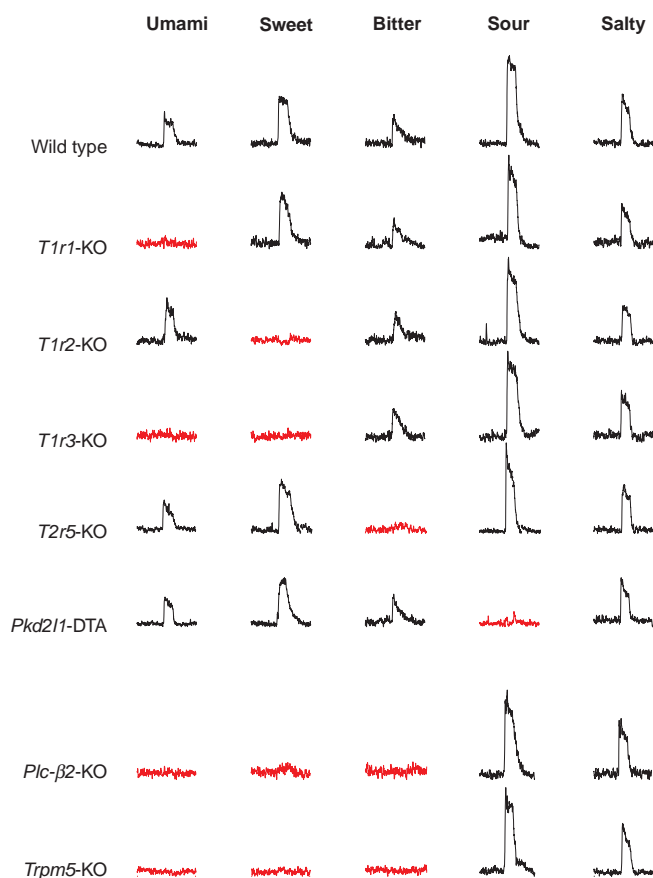

### The T1R Receptor Family Mediates the Taste of Sugars and Amino Acids

In mammals, a small family containing three genes mediates the detection of sugars and amino acids. This receptor family was identified by isolation of genes

expressed in taste tissue and by bioinformatics searches for related genes in the genome. The Taste Receptor 1 family is comprised of the T1R1, T1R2, and T1R3 receptors. These receptors are all G protein coupled receptors and contain large extracellular domains similar to the metabotropic glutamate receptors.

What constitutes proof that a protein is a taste receptor? First, the protein should be in the right place at the right time to do the job. Second, loss of the protein should lead to loss of taste detection. Third, addition of the protein into novel cells should cause these cells to respond to taste cues. These criteria have been firmly established for the T1R family of taste receptors and have demonstrated that the combination of T1R2 plus T1R3 detects sugars and the combination of T1R1 plus T1R3 recognizes amino acids.

The following evidence demonstrates that the combination of T1R2 plus T1R3 recognizes sugars. First, as expected for taste receptors, the T1Rs are expressed in taste cells on the tongue. Second, mice engineered to lack either T1R2 or T1R3 do not detect sugars, as determined by electrophysiological recordings of taste nerves (Fig. 24.4) and by behavioral taste tests. Whereas normal mice prefer sugar water to water, mice lacking these receptors do not. Given a choice between water

**FIGURE 24.4** Mice lacking specific taste receptors have specific taste defects. Shown are nerve recordings showing taste-induced activity to amino acids, sugars, bitter compounds, sour compounds, and salts. Wild-type mice respond to all compounds. Mice lacking T1R1 do not detect amino acids, mice lacking T1R2 do not detect sugars, and mice lacking T2R5 do not detect specific bitter compounds. From Chandrashekar *et al.*, 2006.

and sugar water in a short-term taste preference test, they drink equal amounts of water and sugar water. Third, heterologous cells that coexpress T1R2 and T1R3 respond to sugars, but those that express T1R2 or T1R3 alone do not. This argues that T1R2 and T1R3 act together to detect sugars. Equivalent experiments demonstrate that the combination of T1R1 and T1R3 recognizes amino acids. Thus, T1R1 is selective for amino acids, T1R2 sugars, and T1R3 is an obligate partner for both amino acid and sugar detection.

Mammals detect a wide array of sugars and amino acids only at high concentrations (10–100 mM), allowing them to recognize compounds that provide nutritional value. The three T1R receptors apparently have solved the problem of detection by having loose ligand-binding sites that recognize several ligands with low affinity. Differences in the binding sites of the T1R receptors are found in different species. For example, the taste of umami in humans is the taste of the amino

acid glutamate. The human T1R1 plus T1R3 amino acid receptor binds to glutamate with a 10-fold higher affinity than other amino acids. In contrast, the mouse T1R1 plus T1R3 receptor recognizes all amino acids with similar affinity. Thus, mice have an amino acid taste whereas humans have an umami taste. Although this may sound like humans are short-changed, it may not be the case. Because foods that have one amino acid generally contain many, the enhanced ability to detect glutamate in humans may actually enhance detection of all amino acids. The observation that T1R sequence variation underlies differences in taste detection also occurs for sugars. For example, we find aspartame (Nutrasweet) sweet, but mice and rats do not detect it. Mice have been genetically engineered to express the human T1R2 and T1R3 in taste cells and these mice are now able to detect aspartame. Interestingly, cats lack a functional T1R2 receptor, providing a plausible explanation for why they do not taste sugars. These studies highlight the role of T1Rs in sugar and amino acid taste detection in mammals and demonstrate that sequence differences in T1Rs can account for species-specific taste preferences.

Studies of the ligand-binding properties of the T1Rs argue that all T1Rs contribute to binding. Taking advantage of the observation that rat T1R2/T1R3 and human T1R2/T1R3 recognize some different sweeteners, experiments exchanging extracellular domains of the human and rodent T1R2/T1R3 receptors were used to dissect receptor domains that recognize sweeteners. For example, as mentioned earlier, human T1R2/T1R3 recognizes aspartame and rat T1R2/T1R3 does not. Importantly, a rat receptor in which the extracellular domain of T1R2 has been replaced by the human T1R2 extracellular domain does detect aspartame. This argues that the extracellular domain of human T1R2 detects aspartame. A series of these domain-swapping studies demonstrated that the T1R2 extracellular amino-terminal domain binds several sugars, the T1R2 transmembrane carboxyl-terminal domain binds the G-protein and the T1R3 transmembrane carboxyl-terminal domain binds some artificial sweeteners. Thus, different regions of T1Rs mediate taste detection and both T1R2 and T1R3 participate in ligand recognition. This strongly argues that T1R2 and T1R3 are coreceptors for sugars.

### The T2R Receptor Family Mediates Bitter Taste Detection

A common variation in human behavior is the ability to detect the bitter compound phenylthiocarbamide (PTC). In 1931, a scientist at the Dupont chemical company synthesized this compound and quickly

## BOX 24.1

## IDENTIFYING A GENETIC LOCUS LINKED TO BITTER TASTE PERCEPTION

The ability to taste the compound phenylthiocarbamide (PTC) varies drastically among humans. Approximately 75% of people find PTC intensely bitter whereas 25% do not detect it. The ability to detect PTC was linked to a small region of chromosome 7 in human genetic studies. The taste receptor gene T2R38 is located within this interval and variations in its sequence perfectly correlate with the ability to taste PTC. In the human population, there are two major sequence variations in T2R38, which differ by three amino acids. One variant (containing the amino acid substitutions AVI) accounts for the

nontasters and the other variant (containing the amino acid substitutions PAV) is the major taster allele (see Kim *et al.*, 2003). Thus, people with two AVI alleles are nontasters, those with one PAV and one AVI are tasters, and those with two PAV alleles are super-tasters. In addition, there are five other forms of T2R38 in the human population, but these are found in low frequency in the population. These studies demonstrate that humans vary in their ability to detect taste compounds because of variations in the sequence of taste receptors.

Kristin Scott

came to the realization that although it was flavorless to him, his colleague found it unbearably bitter. Since then, numerous human taste tests (often done in high school classes) have revealed that the ability to detect PTC and a related compound *n*-propyl uracil (PROP) behaves as a classic inherited recessive trait with taster and nontaster alleles (see Box 24.1). The identification of the genomic location linked to PTC detection enabled the identification of genes associated with this chromosomal interval and the seminal discovery of a large family of related mammalian bitter taste receptors.

The Taste Receptor 2 family (T2R) of bitter receptors is a family of G protein-coupled receptors whose members, unlike T1Rs, contain a small extracellular domain and most resemble the opsin family of GPCRs. There are 25 functional T2R receptors in human, 35 in mouse and rat, and only three in chicken. (Perhaps this explains why chickens will eat anything!) Most T2R genes are linked in large chromosomal arrays, suggesting rapid expansion of this gene family.

A number of lines of evidence conclusively demonstrate the T2Rs are bitter receptors. First, T2Rs are specifically expressed in taste cells on the tongue. Second, the receptors are localized to taste cell dendrites decorating the taste pore, the site of taste detection. Third, heterologous cells expressing T2Rs respond to bitter compounds; for example, cells expressing mT2R5 respond specifically to cyclohexamide, whereas cells containing mT2R8 respond strongly to denatonium and weakly to PROP. Fourth, mice lacking specific T2Rs show specific bitter taste defects (Fig. 24.4). As predicted from the expression studies of mT2R5 in heterologous cells, mice lacking mT2R5 do not detect

cyclohexamide but do detect a myriad of other bitter compounds. Even more remarkably, mice engineered to contain a human T2R that recognizes phenyl- $\beta$ -D-glucopyranoside in place of the mouse T2R now avoid phenyl- $\beta$ -D-glucopyranoside whereas wild-type mice do not detect it.

Studies of the T2R receptor family provide important insights into how animals recognize a large number of bitter compounds and are able to detect them at very low concentrations. Each T2R receptor generally recognizes only a few bitter compounds with very high affinity, allowing for very specific detection. In addition, the large number of T2R receptors ensures that animals can recognize several bitter compounds.

### Mechanisms of Taste Transduction for T1Rs and T2Rs

Activation of the T1R and T2R receptors ultimately leads to cell depolarization and neurotransmitter release. In general, signal transduction mediated by G-protein coupled receptors involves a conformational change in the receptor leading to activation of a heterotrimeric G protein, in turn activating enzymes whose byproducts regulate the activity of ion channels. Many signal transduction cascades have been proposed to mediate sweet and bitter taste detection. However, key experiments pinpoint a few critical transducers for sweet and bitter signaling (Fig. 24.5).

Gustducin is the  $G\alpha$  subunit of a heterotrimeric protein that participates in taste transduction. Gustducin is found in taste cells on the tongue that contain

**FIGURE 24.5** Taste transduction for sugars, amino acids, and bitter compounds uses a common signaling pathway. Activation of the receptor activates a heterotrimeric G protein. This activates phospholipase C- $\beta 2$  (PLC- $\beta 2$ ), producing the second messengers IP<sub>3</sub> and diacylglycerol (DAG). Activation of PLC- $\beta 2$  leads to opening of the TRPM5 ion channel and cell depolarization.

T1R and T2R receptors. Confusingly, it is not found in all T1R-containing cells, suggesting that either a subset of T1R-containing cells is nonfunctional or other G $\alpha$  subunits contribute to taste transduction. Animals lacking gustducin show behavioral and electrophysiological defects in the detection of bitter and sugar compounds, arguing that this G $\alpha$  participates in taste transduction.

Downstream of G protein activation, the enzyme phospholipase C- $\beta 2$  and the ion channel TRPM5 mediate taste transduction. PLC- $\beta 2$  and TRPM5 are coexpressed in all T1R and T2R-containing cells. Transgenic mice that lack the PLC- $\beta 2$  enzyme do not taste sugar or bitter compounds. Similarly, loss of the ion channel TRPM5 results in mice that do not taste sugars or bitter compounds. The simplest model for taste transduction is that activation of T1Rs or T2Rs leads to activation of gustducin, leading to activation of PLC- $\beta 2$  and depolarization by TRPM5. PLC- $\beta 2$  catalyzes the breakdown of phosphoinositol 1,4 bisphosphonate into inositol-1,4,5-triphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). IP<sub>3</sub> can release calcium from the endoplasmic reticulum. Whether IP<sub>3</sub>, DAG, calcium, or another second messenger activates TRPM5 is unknown. Indeed, it has not been formally demonstrated that activation of PLC- $\beta 2$  directly activates TRPM5 or that these signaling molecules are in a linear pathway. Nevertheless, the most parsimonious explanation is that gustducin, PLC- $\beta 2$ , and TRPM5 are signaling molecules that form the taste transduction cascade.

### Acids Depolarize Taste Cells by Modulating Ion Channels

Unlike sweet and bitter taste detection, which relies on activation of G-protein coupled receptors and downstream signaling molecules to regulate channel activity, the tastes of sour and salty are likely to be directly mediated by ion channels. Sour taste is produced by acids, and the degree of sourness depends primarily on proton concentration. Patch-clamp studies suggest that several different ion channels may participate in sour transduction, which is not surprising because protons are capable of modulating most ion channels. A recent study has identified a candidate sour receptor, comprised of PKD1L3 and PKD2L1, that is expressed in taste cell subsets necessary for sour detection.

PKD1L3 and PKD2L1 are cationic ion channels of the TRP family (transient receptor potential) of ion channels. TRP channels are necessary signaling molecules in *Drosophila* phototransduction, mammalian pheromone detection, *C. elegans* chemosensation, as well as thermosensation and hearing. They can be directly activated by ligands or downstream transducers of signaling. PKD1L3 and PKD2L1 are coexpressed in taste cells on the tongue that do not contain T1Rs or T2Rs. These channels are localized to the taste pore, the site of ligand binding. In heterologous cells, they act together to detect sour compounds such as citric acid, hydrochloric acid, and malic acid. Mice lacking

these channels have not yet been generated. However, transgenic mice have been produced such that the PKD2L1 promoter drives expression of a toxin gene to kill all cells that express the channel. Mice lacking these cells do not show electrophysiological responses to sour compounds, but still respond to sugars, salts, and bitter compounds. These experiments argue that cells containing PKD2L1 are necessary for sour detection and suggest that PKD2L1 and PKD1L3 are the mammalian sour detectors.

### Apically Located Na<sup>+</sup> Channels May Mediate Salt Taste Detection

Molecules that mediate salt taste are not clearly defined. The best candidate ion channel that may mediate sodium salt taste is the epithelial sodium channel ENaC. This channel, which is responsible for sodium transport in a variety of epithelial tissues, is expressed on the apical membrane of salt-sensitive taste cells, where it mediates the passive influx of sodium. Sodium simply diffuses through the open channels to depolarize taste cells, and is presumably pumped out by a NaK-ATPase on the basolateral membrane. The first evidence for a role of ENaC in taste came from experiments showing that the gustatory nerve response to NaCl was inhibited by amiloride, a diuretic drug known to block these channels in other transporting epithelial tissues. More recently, patch-clamp recordings have directly demonstrated the presence of amiloride-sensitive sodium channels in taste cell membranes. However, the taste cells that express ENaC channels have not been defined, animals lacking ENaCs in taste cells have not been generated to determine their function, and ENaCs have not been misexpressed in bitter or sugar cells and shown to confer salt detection to these cells. Thus, although ENaCs do depolarize in response to salts and are

expressed in taste cells, it has not yet been determined whether they are necessary and sufficient for salt taste detection.

### The Organization of Taste Receptor Genes on the Tongue

Taste receptors are segregated into different taste cells on the tongue. *In situ* hybridization experiments as well as immunohistochemistry have been used to determine the expression patterns of receptor mRNAs and proteins. These experiments demonstrated that T1Rs and T2Rs are not found in the same taste cells (Fig. 24.6). Among the T1Rs, T1R1 plus T1R3 and T1R2 plus T1R3 are segregated into different cells. In addition, the PKD1L3 and PKD2L1 candidate sour ion channel subunits are found in different cells than the T1Rs or T2Rs. This demonstrates that there are modality-specific taste cells on the tongue, with one taste cell population recognizing sugars, another amino acids (or glutamate for humans), a third bitter compounds, and a fourth sour cues. An important conclusion is that different taste modalities are encoded by the activation of different taste cells. Our perception of only a few different tastes may stem from the fact that there are only a few different types of taste cells on the tongue. Sugar-sensing and bitter-sensing cells also are found in *Drosophila melanogaster*, suggesting that modality-specific cells are a common principle of taste systems (Box 24.2).

Most taste receptors are expressed in subsets of taste buds on the tongue and on the palate. T1R1 plus T1R3 (amino acid receptor) are coexpressed in fungiform papillae and palate; T1R2 and T1R3 (sugar receptor) are coexpressed in the circumvallate, foliate, and palate papillae. T2Rs (bitter) are expressed on the circumvallate, foliate, and palate papillae; and PKD2L1 (sour) on the circumvallate, foliate, fungiform, and

**FIGURE 24.6** Different taste cells express different taste receptor genes. *In situ* hybridization experiments showing expression of T1Rs (green) and T2Rs (red) in mammalian tongue sections. Data from Nelson *et al.* (2001).

## BOX 24.2

## TASTE CELLS IN FRUITFLIES ARE ALSO TUNED BY TASTE MODALITY

*Drosophila melanogaster*, like mammals, recognize sugars, salts, and bitter compounds, making them a model system for comparative studies of taste recognition. *Drosophila* taste with sensory neurons on their proboscis (mouth), legs, and wings. A family of 68 candidate Gustatory Receptor genes, unrelated to mammalian T1R or T2R receptors, may mediate taste detection as some members are expressed in taste tissue and recognize taste ligands in heterologous systems. Similar to mammalian taste, multiple receptors are expressed in each *Drosophila* taste cell. Two different classes of taste cells have been identified based on the receptor subsets they contain. One

population detects bitter compounds and a second population detects sugars. Additional subpopulations of taste neurons likely recognize other taste categories. Thus, although flies and mammals are separated by more than 500 million years of evolution, they both have taste cells that selectively recognize bitter compounds or sugars. This suggests that modality-specific taste cells may be a general strategy that organisms use to distinguish nutrients from toxins.

Kristin Scott

palate papillae. This argues that different parts of the tongue are not dedicated to detecting a single taste modality. Although many textbooks include a tongue “taste map” suggesting that the front of the tongue detects sugars, the side salt and sour, and the back bitter, this is not true. Instead, the topographic distribution of taste receptors on the tongue suggests there are more subtle differences in the relative sensitivities of different tongue regions.

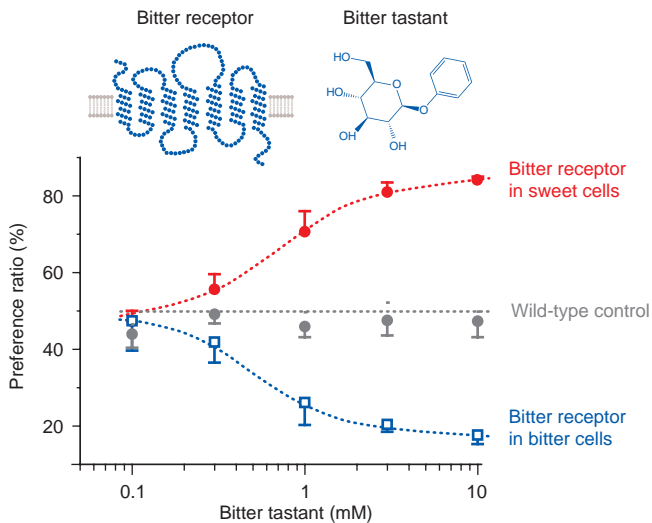

### Activation of Taste Neurons Is Sufficient to Generate Taste Behavior

The finding that different taste compounds activate different populations of taste cells suggests that activation of different cells in the periphery leads to different taste percepts and different taste behaviors. To test this, transgenic mice were engineered to express novel receptors in taste cells. In one derivation of this experiment, mice were engineered to contain a modified G protein coupled receptor activated solely by a synthetic ligand (RASSL) in all T1R2 containing taste cells. This exogenous receptor is activated only by a compound called spiradoline, which animals do not detect. These mice then were given a choice between drinking water or water with the synthetic ligand, spiradoline. The mice with the RASSL in T1R2 cells showed a strong preference for spiradoline, in contrast to normal mice. In another experiment, the RASSL was put in T2R taste cells; these mice now avoid spiradoline. In a third extremely elegant experiment, transgenic mice were engineered to contain the human bitter receptor (hT2R16) for phenyl- $\beta$ -D-glucopyranoside (a com-

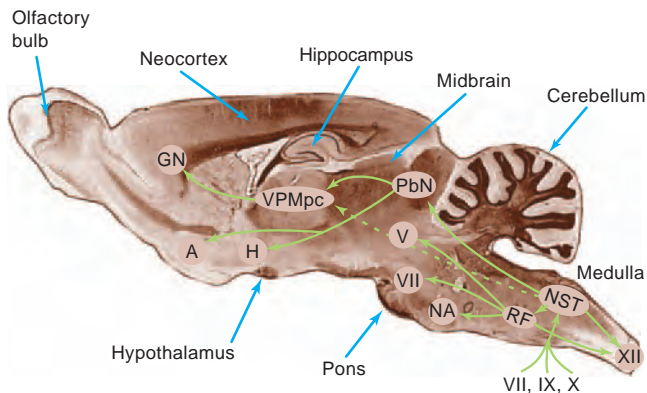

pound that humans perceive as bitter) in either T2R (bitter) or T1R2 (sugar) cells (Fig. 24.7). If hT2R16 is expressed in T2R cells, mice avoid phenyl- $\beta$ -D-glucopyranoside. If this human bitter receptor is expressed in T1R2 cells, however, mice prefer phenyl- $\beta$ -D-glucopyranoside. Thus, expression of a bitter receptor in sugar cells triggers attraction to the bitter compound. These experiments demonstrate that activation of sugar cells leads to taste acceptance behavior and activation of bitter cells leads to avoidance. This argues that the activity of different taste cells is hard-wired to different behaviors.

### Transmission of Taste Information from the Tongue to the Brain

The three nerves that contact taste cells have cell bodies in ganglia and send axons to the solitary tract nucleus (NST) of the medulla in a topographic order (Fig. 24.8). Dendrites from the chorda tympani (a branch of the facial nerve VII) contact the anterior tongue, cell bodies reside in the geniculate ganglion and axons terminate in the rostral pole of the NST. Dendrites from the lingual-tonsillar branch (glossopharyngeal nerve IX) contact the posterior tongue, have cell bodies in the petrosal ganglion, and axons invade the NST at intermediate regions. Dendrites from the superior laryngeal branch (vagus nerve X) innervate the epiglottis and esophagus, have cell bodies in the nodose ganglion, and send axons to the caudal regions of the NST. Thus information from the anterior-posterior tongue is represented from the rostral to caudal NST.

**FIGURE 24.7** Activation of different taste cells is tethered to specific taste behaviors. Mice were engineered to contain a human bitter receptor in either T1R2 sugar-sensing or T2R bitter-sensing cells. Mice avoid the specific bitter compound when the receptor is expressed in T2R cells and prefer the same compound when the receptor is expressed in T1R2 cells. This elegant experiment demonstrates that the same compound can elicit different behaviors depending on which cells detect it. Figure adapted from *Nature* (2006); 444(7117), 283–284.

**FIGURE 24.8** Schematic diagram of the ascending gustatory pathway; descending projections are not shown. Connections of the rodent gustatory system within the CNS are shown by solid lines; the projection from NST to VPMpc in primates is indicated by a dashed line. NST, nucleus of the solitary tract; PbN, parabrachial nuclei; VPMpc, venteroposteromedial nucleus (parvi cellularis) of the thalamus; GN, gustatory neocortex; A, amygdala; H, hypothalamus; NA, nucleus ambiguus; RF, reticular formation; V, VII, and XII, trigeminal, facial, and hypoglossal motor nuclei; VII, IX, and X, axons of peripheral gustatory fibers in the facial, glossopharyngeal, and vagal cranial nerves.

This segregation continues throughout the gustatory pathway to the cortex, where there are separate terminal fields for VIIth and IXth nerve inputs. From the NST, ascending fibers project in most species to third-order cells within the parabrachial nuclei (PbN)

of the pons. A thalamocortical projection arises from the PbN to carry taste information to the parvicellular portion of the ventroposteromedial nucleus of the thalamus (VPMpc) and on to the gustatory neocortex (GN), located in rodents within the agranular insular cortex. In primates, taste fibers bypass the pontine relay and project directly to the VPMpc.

Arising in parallel with the thalamocortical projection is a second projection that carries gustatory afferent information into limbic forebrain areas involved in feeding and autonomic regulation, including the lateral hypothalamus, the central nucleus of the amygdala, and the bed nucleus of the stria terminalis. Descending axons within the gustatory system arise from the insular cortex and several ventral forebrain areas and project to the PbN and NST. There are also numerous local connections among neurons within the NST and with cells of the oral, facial, and pharyngeal motor nuclei (V, VII, ambiguous, and XII), either directly (as with XII) or via interneurons in the reticular formation. These hindbrain systems form the substrate for many taste-mediated somatic and visceral responses related to ingestion and rejection of tastants.

### Gustatory Afferent Neurons Extract Several Types of Sensory Information

Three features of taste ligands are thought to be encoded by the activation of gustatory neurons: intensity, quality, and hedonic value. Intensity refers to the perceived strength of the stimulus; for example, low concentrations of sugar taste less sweet than high concentrations. Quality refers to the nature of the sensory stimulus; mammals are thought to perceive five different taste qualities—sweet, bitter, sour, salty, and amino acids. Hedonic value is the perceived pleasantness or unpleasantness of a taste ligand. Thus, gustatory afferent input provides at least three types of information that are interrelated in complex ways. How taste intensity, quality, and hedonic value are represented in the nervous system is the problem of gustatory neural coding.

Gustatory stimulus intensity, the magnitude of the evoked sensation, generally is assumed to be encoded by neural impulse frequency and numbers of responding neurons. All neurons responsive to taste stimuli show some modulation by stimulus concentration, with increased firing rates as concentration increases. In addition, at high taste ligand concentrations, more cells are responsive than at low concentrations. These studies suggest that a simple rate code, and cell recruitment at high concentrations, allow the discrimination of different concentrations of a taste stimulus.

The encoding of taste quality and hedonic value are more complicated. Taste quality and hedonic value are strongly related. Most animals find sugars pleasant-tasting and bitter compounds unpleasant. However, species-specific predispositions toward the hedonic value of a stimulus can be overcome in response to metabolic or pharmacologic manipulations. Thus, the hedonic value of taste qualities can be influenced by experience and physiologic state. Unlike gustatory intensity and quality, the issue of hedonic coding has not been addressed systematically in neurobiological studies of the taste system, probably because hedonic value is not independent of either quality or intensity and can be modified by both experience and physiologic state.

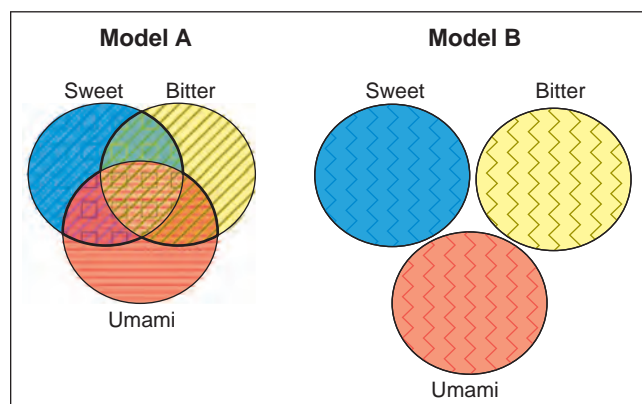

Mechanisms underlying taste quality encoding are controversial. Different models are described next.

### Models of Encoding Taste Quality

The nature of the neural coding of taste quality has been debated vigorously for many years, with considerable disagreement about whether taste quality is represented by activity in specific neural channels (a labeled line code) or by the relative activity across the responsive neurons (a population code) (Fig. 24.9).

#### Labeled Lines

The labeled line model of taste coding proposes that different taste qualities are encoded by the activation of different cells. In this model, cells respond to selective cues in the periphery and this information remains

**FIGURE 24.9** Two models of taste coding have been proposed. The left panel depicts the labeled line model in which different taste cells recognize different taste qualities, such that one cell population is activated by sugars and different cells are activated by bitter compounds. The right panel depicts the population coding model in which cells respond to multiple taste modalities. The pattern of activity across the ensemble of taste neurons encodes for specific tastes. Adapted from Amrein and Bray, 2003.

segregated in the brain. This hypothesis suggests that “sweetness” is coded by activity of neurons that respond selectively to sugars, “saltiness” by activity of neurons that respond selectively to salt, and so forth. Activity in a given cell type provides complete information about the quality of the stimulus. In this scheme, the animal then discerns different tastes by the activation of different neurons.

#### Population Coding of Taste Quality (Across-Fiber Patterning)

In this model of taste coding, each cell responds to multiple taste modalities with different activity levels for different taste ligands, such that taste quality is coded by the pattern of activity across taste fibers. In this coding hypothesis, the pattern of activity generated across the entire array of taste neurons encodes taste quality, whereas activity in any one cell cannot unambiguously represent both stimulus quality and intensity. This population approach to quality coding makes the multiple sensitivity of gustatory neurons an essential part of the neural code for taste quality; it stresses that the code for quality is given in the response of the entire population of cells, placing little or no emphasis on the role of an individual neuron. In this scenario, the animal then discerns different tastes by differences in the ensemble activity of taste neurons.

#### Taste Coding in the Periphery

The studies of taste receptor genes strongly argue for the labeled line encoding of taste information in the periphery. Different taste cells contain different taste receptor genes and respond to different taste ligands. T1R2 plus T1R3 cells detect sugars, T1R1 plus T1R3 cells detect amino acids, T2R cells detect bitter compounds, and PKD2L1 cells detect acids. There is no overlap in the expression of different receptor-types and thus no cell that detects both sugar and bitter compounds. Thus, “sweetness” is encoded by the activation of sugar cells; “bitter” by the activation of bitter-sensing cells.

Not only do different cells identify different tastes, but these different cell-types are necessary and sufficient for taste detection and behavior. Mice lacking T1R2 do not detect sugars, but still detect bitter, salts, sour, and amino acids. Similarly, mice lacking cells containing PKD2L1 do not detect sour, but do detect sugars, bitter, salt, and amino acids. Moreover, simply activating the sugar cells artificially generates taste acceptance behavior and activating the bitter cells generates avoidance behavior. These experiments are difficult to reconcile with population coding models. In population coding, the relative activity of nonselective

neurons dictates taste quality and loss of any subpopulation of taste cells would affect detection of all compounds. In addition, in population coding, activation of a subset of taste cells would be meaningful only in the context of the ensemble activity. Instead, different taste cells recognize different taste modalities and mediate specific taste behaviors, arguing that there are labeled lines of taste information from peripheral activation to behavior.

### Taste Coding in the Central Nervous System

Although the selectivity of taste cells in the periphery strongly argues for labeled lines of taste information, neurophysiological recordings of both primary gustatory nerves and central gustatory neurons typically show that individual fibers or cells respond to more than one of the stimuli representing the salty, sweet, sour, or bitter taste qualities, often to as many as three or four. Accumulating evidence suggests that there are functional classes of neurons that correspond in some way to primary taste qualities, for example, “sucrose-best” cells, “sodium-best” cells. However, analyses show that no single class of neurons in isolation can discriminate well between different taste qualities. As a result, an “across neuron pattern” theory suggesting that taste quality is coded by the relative activity across a population of neurons was proposed.

The current debate in the mammalian taste field is how to reconcile the evidence of labeled lines for different tastes in the periphery with the evidence for mixed lines in the central nervous system. One possibility is that a single nerve fiber synapses onto taste cells of many different taste qualities on the tongue, such that the labeled lines in the periphery become mixed at the first synapse. Alternatively, electrophysiological studies of single neurons with defined connections to taste cells, rather than random recordings of neurons in the solitary tract nucleus or gustatory cortex, may reveal populations of higher-order taste neurons that show selective responses to single taste qualities, supporting labeled line encoding.

### Summary

The sense of taste allows animals to recognize different chemical compounds and gives rise to a limited number of taste sensations (saltiness, sweetness, sourness, bitterness, and umami/amino acids). Two families of taste receptors, the T1R and T2R families, mediate the detections of sugars, amino acids, and bitter compounds. These receptors are G protein-coupled receptors that activate a heterotrimeric G protein, phospholipase C, and TRPM5, leading to cell

depolarization and neurotransmitter release. Candidate ion channels have been implicated in the detections of salts and sour compounds. Compared to mammalian olfaction, the gustatory system utilizes a relatively small number of receptors with very diverse structures to detect chemical compounds.

The transduction mechanisms for taste stimuli are located on receptor cells within taste buds distributed in several subpopulations, innervated by different peripheral nerves. These nerves project into the nucleus of the solitary tract in the medulla. From there, projections arise to the parabrachial nuclei in the pons and then to the thalamus and gustatory neocortex. A parallel pathway carries taste information into the ventral forebrain to areas involved in autonomic regulation. The gustatory system extracts information about taste intensity, quality and the hedonic value of the stimuli. How gustatory information is encoded in the brain is an area of active investigation. In the periphery, an individual taste cell is tuned to a single taste quality, arguing that there are labeled lines of taste information. More centrally, gustatory neurons appear broadly tuned to stimuli of different taste qualities, leading to a debate whether the labeled lines in the periphery become mixed centrally. The ability to determine the connectivity of higher order taste neurons and their taste response profiles will enhance our understanding of taste neural circuits and the coding mechanisms underlying taste perception.

---

## OLFACTION

---

The number of volatile cues in the environment that animals can detect is colossal. Humans, although not known to have particularly keen noses, can sense over 10,000 different odors, with detection thresholds in the parts per million and even parts per billion. Scent-tracking dogs, especially bloodhounds, have even more sensitive noses, approximately 10 million times more sensitive than humans, allowing them to follow scent trails a few days old. The ability to detect chemicals a distance from the source allows animals to direct their movement toward food and potential mates and away from harmful or dangerous environments. Although many animals rely on their olfactory system for survival, the sense of smell in humans is primarily an aesthetic sense, enhancing our enjoyment of foods and evoking memories of past experiences.

How does the olfactory system allow for the recognition and discrimination of thousands of different odors? A large family of 1000 olfactory receptors provides the molecular diversity necessary for recogniz-

FIGURE 24.10 Odor molecules given off by the jasmine flower that constitute the smell of jasmine as an odor object (Mori and Yoshihara, 1995).

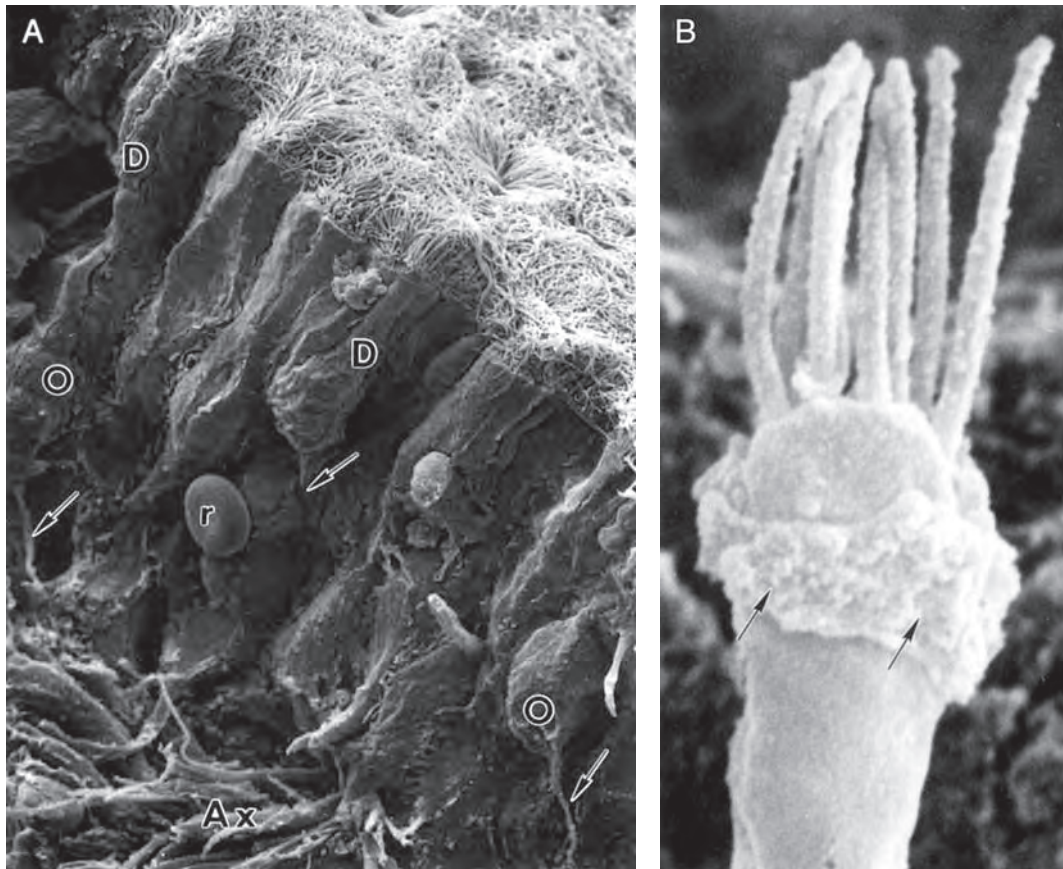

ing numerous ligands. The discovery of the olfactory receptor genes has provided molecular tools to probe the molecular underpinnings of olfactory detection. The logic of olfactory detection in the periphery is discussed next.

### Odor Stimuli Consist of a Wide Range of Small Signal Molecules

Odor signals are low molecular weight molecules that fall into several broad classes. In terrestrial animals, the molecules tend to be small (under 200 Da) and volatile so that they can vaporize readily and be

carried in the air; they also tend to be lipid soluble. Some of these are acids, alcohols, and esters found in various plant and animal foods. Some are essential oils. Others are aromatic compounds given off by flowering plants (Fig. 24.10). They may function for long distance signaling of the presence and palatability of food in the environment.

An important category consists of molecules used in reproductive activities, including signals used in attracting mates, identifying them, copulating, blocking pregnancy, facilitating nipple attachment by infants, and infant identification. Some of these activities are mediated by complex mixtures of acids, esters,

The terminal web is visible encircling the knob (arrows). From Morrison and Costanzo (1990).

and other types of common molecules; others by individual larger and more complex molecules such as musks; and still others by specific types of molecules for conspecific signaling known as *pheromones*.

### Odor Molecules Are Transduced by Olfactory Receptor Neurons

Most vertebrate animals sense odor molecules by means of olfactory receptor neurons (ORNs) located in a pseudostratified epithelium within the nasal cavity. These are bipolar neurons; a thin dendrite arises from one pole, ending in a knob with 6 to 12 cilia (Fig. 24.11). These contain the 9 + 2 pairs of microtubules characteristic of true cilia in other cells of the body. The cilia are thin ( $0.2\ \mu\text{m}$  in diameter near the knob, tapering to  $0.1\ \mu\text{m}$  near their tips) and vary in length in different species, from 5 to  $10\ \mu\text{m}$  in humans to  $200\ \mu\text{m}$  in frogs. They contain no other organelles. The knobs and cilia are embedded in the mucus overlying the epithelium.

The cilia greatly increase the surface area containing the olfactory receptors. The cilia form a dense mat within the mucus layer that provides an effective device for capturing odor molecules that are absorbed from the air into the mucus. The mucus is viscous (secreted by the supporting cells) except for a watery surface layer (secreted by Bowman's glands). From the other pole of the neuron, a thin unmyelinated axon arises and joins other axons in the submucosa to form bundles that connect to the olfactory bulb.

### G-Protein-Coupled Receptors Are the Initial Site of Odor Transduction in Mammals

The 2004 Nobel Prize in Medicine was awarded to Dr. Richard Axel and Dr. Linda Buck for their seminal discovery of a large family of mammalian olfactory receptors. Their search for olfactory receptors was based on three assumptions: first, that olfactory receptors would be G protein-coupled receptors (GPCRs)

similar to visual receptors; second, that they would be exclusively expressed in nasal epithelium; and third, that there would be a large number of receptors, given the large number of odors that mammals smell. This led Axel and Buck to search for novel GPCRs in nasal tissue and to the discovery of the odorant receptor gene (OR) family.

There are approximately 1300 olfactory genes in mouse (5% of their genome), 500 in humans (2% of the genome), and 100 in zebrafish and catfish (Box 24.4). They are members of the class A family of GPCRs, which includes opsin and  $\beta$ -adrenergic receptors. These receptors contain a short extracellular amino terminus, seven membrane spanning (TM) domains, and an intracellular carboxyl terminus. Hypervariable regions in TM 3, 4, and 5 likely form the ligand-binding pockets, based on the ligand binding domains of other GPCRs such as the  $\beta$ -adrenergic receptor. Individual human olfactory receptor genes share between approximately 50 and 95% sequence identity. Large gene families comprising olfactory receptors also have been identified in nematodes (Box 24.3), fish (Box 24.4), and insects (see later).

Olfactory receptor genes are organized in the genome in large linked arrays on several chromosomes. The size of the arrays ranges from 6 to 138 in humans and up to 15 in *C. elegans*. The *Drosophila*

genome, with fewer olfactory receptors, contains small arrays of two to three genes as well as many singly distributed genes. The large arrays in mammals and nematodes suggest that odor receptor gene families are evolving rapidly by duplication and expansion.

The identification of odor receptors provided fundamental insight into the molecular basis of odor perception. The large number of receptors dedicated to binding odor molecules provides an elegant solution to the problem of how animals detect a large number of smells. In addition, identifying receptors opened the door to examine interactions of different receptors with different odors, the organization of olfactory receptors in olfactory neurons, and the representations of olfactory receptors in the olfactory bulb.

### Evidence That ORs Detect Odors

The large number of ORs and the large number of odor molecules, as well as technical difficulties in expressing ORs in heterologous cells, has limited the ability to determine the ligands that different ORs recognize. In the first demonstration that ORs detect volatile cues, the "I7" odor receptor was overexpressed in most olfactory neurons of the rat. The electro-olfactogram (EOG) response of the epithelium to a battery of

#### BOX 24.3

### SENSING THOUSANDS OF CHEMICALS WITH A HANDFUL OF NEURONS

The nemode worm *Caenorhabditis elegans* lives in the soil, lacks a visual system, and relies largely on chemical detection to survive in the environment. This small animal has only 302 neurons, but displays complex olfactory behaviors, making it a model system to study chemosensory processing. Thirty-two sensory neurons mediate chemical detection and contain members of a large chemoreceptor gene family. These receptors are G protein-coupled receptors, but are not related to mammalian olfactory receptors. There are approximately 1500 chemoreceptor genes in *C. elegans*, comprising 7% of all its genes. Thus, of all animals whose genomes have been sequenced, *C. elegans* dedicates the most genes, and the highest fraction of its genes, to chemical sensing.

Many receptors are found in the same chemosensory cell, as might be expected given the large number of

receptors and the small number of sensory cells. This organization differs from the olfactory systems of mammals and flies, but resemble mammalian and fly gustatory systems. Parceling many receptors into a single cell allows these animals to detect many chemical compounds despite the limited number of chemosensory neurons.

*C. elegans* shows sophisticated behavioral responses to chemical cues, including attraction and avoidance of different volatiles cues, adaptation to specific odors as well as learned associations. For example, worms can learn to avoid pathogenic bacteria based on its smell after one exposure to the bacteria. This is similar to conditioned taste aversion in mammals where one encounter with a nausea-producing food leads to aversion of the smell and taste of the food.

*Kristin Scott*

## BOX 24.4

## CHEMOSENSATION IN FISH

The distinction between taste and smell may seem blurry in the fish. All chemicals that fish encounter are water-soluble, eliminating the distinction between volatile odors and soluble taste cues. Nevertheless, fish have distinct senses for taste and smell. Chemicals that aquatic animals detect include various amino acids that are important for food recognition as well as bile salts that may function as alarm signals to warn of the presence of predators.

Similar to mammals, the sensory organs for taste and smell are separate in the fish. Olfactory neurons are found in structures called olfactory rosettes in facial pits. Openings called nares lead to the external environment for smell detection. Taste cells are found on lips, gill rakers, pharynx, oral cavity, and distributed on the body surface.

Fish also contain receptors that are similar to mammalian olfactory and gustatory receptors. Zebrafish

contain approximately 143 genes with sequence similarity to mammalian olfactory receptors, type A receptors with short amino-termini. This is about 10-fold fewer receptors than in mice. In addition, zebrafish have 54 type C receptors, similar to mammalian V2R pheromone receptors. These are expressed in olfactory neurons, and one receptor has been shown to detect an amino acid in heterologous expression systems. There are 4 T1R genes in the zebrafish expressed in gustatory neurons. In addition, only 2 T2R-like genes have been identified in the zebrafish genome.

The molecular similarity of taste receptors and olfactory receptors from fish to man, and the anatomical segregation into different sensory structures, argues that taste and smell are different senses for fish.

Kristin Scott

odors was examined. Among some 80 compounds tested, only longer chain aldehydes gave increased responses over controls, with octyl aldehyde giving the peak response, and lesser responses for flanking long-chain aldehydes. This experiment demonstrated that a single OR detects a small subset of odors.

More recently, advances in the ability to express receptors in heterologous cells has resulted in the identification of receptor-ligand pairs for approximately 20 different ORs. Some ORs bind very few ligands (specialists) whereas others are broadly tuned (generalists). These receptor-ligand studies have shown that one OR will bind more than one odor and one odor will activate more than one OR. These experiments provide direct evidence that members of the large gene family of GPCR receptors are specifically sensitive to odors.

### One Olfactory Receptor Gene Is Expressed in Each Olfactory Neuron

Studies of olfactory receptor expression in mammals revealed that each olfactory neuron contains only one member of the OR gene family. OR gene expression was determined by *in situ* hybridization experiments, showing that each OR is found in approximately 0.1% of olfactory neurons. In addition, isolating OR receptor sequences from single olfactory neurons demonstrated that each neuron expresses mRNA for only one OR.

Finally, several pairs of ORs were examined to determine if two receptors were found in the same cell, but none of the ORs examined were coexpressed. Instead, receptors label nonoverlapping cell populations.

Not only is one receptor expressed per cell, but only one allele of a receptor is expressed per cell. All diploid organisms contain paired homologous chromosomes and two copies of each gene, the maternal allele and the paternal allele. For most genes, a cell that expresses the maternal allele also expresses the paternal allele. However, olfactory receptor genes show allelic exclusion. One demonstration of this came from engineering two sets of mice: one transgenic mouse contained the olfactory "P2" receptor linked to a green fluorescent protein (P2 green) and the other transgenic mouse contained the "P2" receptor linked to a second protein visualized with red fluorescence (P2 red). Offspring of these mice contained one allele of P2 green and one allele of P2 red. These mice had red olfactory neurons and green olfactory neurons, but no neurons that were both red and green. This experiment directly showed that only one allele of an olfactory receptor is expressed per cell. The consequence of allelic exclusion is that each olfactory neuron contains only genetically identical receptors. One could imagine that small changes in the nucleotide sequence of an allele might alter its ligand-binding properties, such that the maternal and paternal alleles recognize different odors. Segregating these alleles into different cells might expand the

repertoire of odors that different olfactory neurons detect.

The general rule that each olfactory neuron expresses only one olfactory receptor gene has important implications for olfactory coding in the periphery. The organization allows the activation of different olfactory receptors to be equivalent to the activity of different cells. Thus, the brain can know which odors are present by which neurons are activated.

How is the choice of olfactory receptor controlled to ensure that one and only one receptor is expressed per cell? Although the determinants of receptor choice are not yet clear, a feedback mechanism has been uncovered that ensures that once one odorant receptor is expressed in an olfactory neuron, no other receptors are expressed. Simply put, the expression of a functional OR turns off the expression of all other ORs. The main experimental support for this is the observation that neurons expressing a receptor that does not function (either by deletion of the coding region or by missense mutation) turn on the expression of a second receptor. In contrast, olfactory neurons expressing a functional receptor do not express other receptors. This argues that expression of a functional odorant receptor elicits a feedback signal that eliminates expression of other receptors.

### Odor-Binding Proteins May Link Odor Molecules to Odor Receptors

A class of secreted, soluble proteins called odor binding proteins (OBP) is abundantly expressed in olfactory sensory epithelium in mammals and flies. OBPs are small, globular proteins that are produced by support cells and released into the extracellular space. Insect OBPs are predominantly helical proteins

whereas the vertebrate OBPs have an eight-stranded barrel structure that is unrelated to the sequence and structure of the insect OBPs. Both vertebrate and invertebrate OBPs have been shown to bind odors *in vitro*. In general, vertebrate OBPs have broad odor–ligand affinities, and insect OBPs have narrower binding affinities.

Because OBP molecules have been shown to bind odorants, a number of models regarding their function have been proposed. One model suggests that OBPs function to partition hydrophobic ligands from the air to the aqueous phase. Alternatively, OBPs may directly present odors to the olfactory receptors and act as coreceptors. Third, OBPs may sequester the odor away from the site of odor recognition, mediating odor clearance. Recent studies on an odor binding protein in *Drosophila* argue that it is involved in presenting the odor to the olfactory receptor (Box 24.5). Whether different OBPs serve different functions remains to be determined.

### Olfactory Signal Transduction Utilizes Adenylate Cyclase and a Cyclic Nucleotide Gated Ion Channel

A combination of molecular biology and biochemistry has uncovered the olfactory signal transduction cascade (Fig. 24.12). Similar to other G protein-coupled signaling cascades, ligand-binding to an odorant receptor induces a conformational change that results in activation of a heterotrimeric G protein. The  $G\alpha$  subunit is an olfactory-specific  $G_s$  protein ( $G_{olf}$ ) that activates an adenylate cyclase type III (AC3). AC3 is an enzyme that catalyzes the conversion of ATP to 3',5'-cyclic AMP (cAMP). A cyclic nucleotide-gated (CNG) channel is activated in response to increases in cAMP, leading

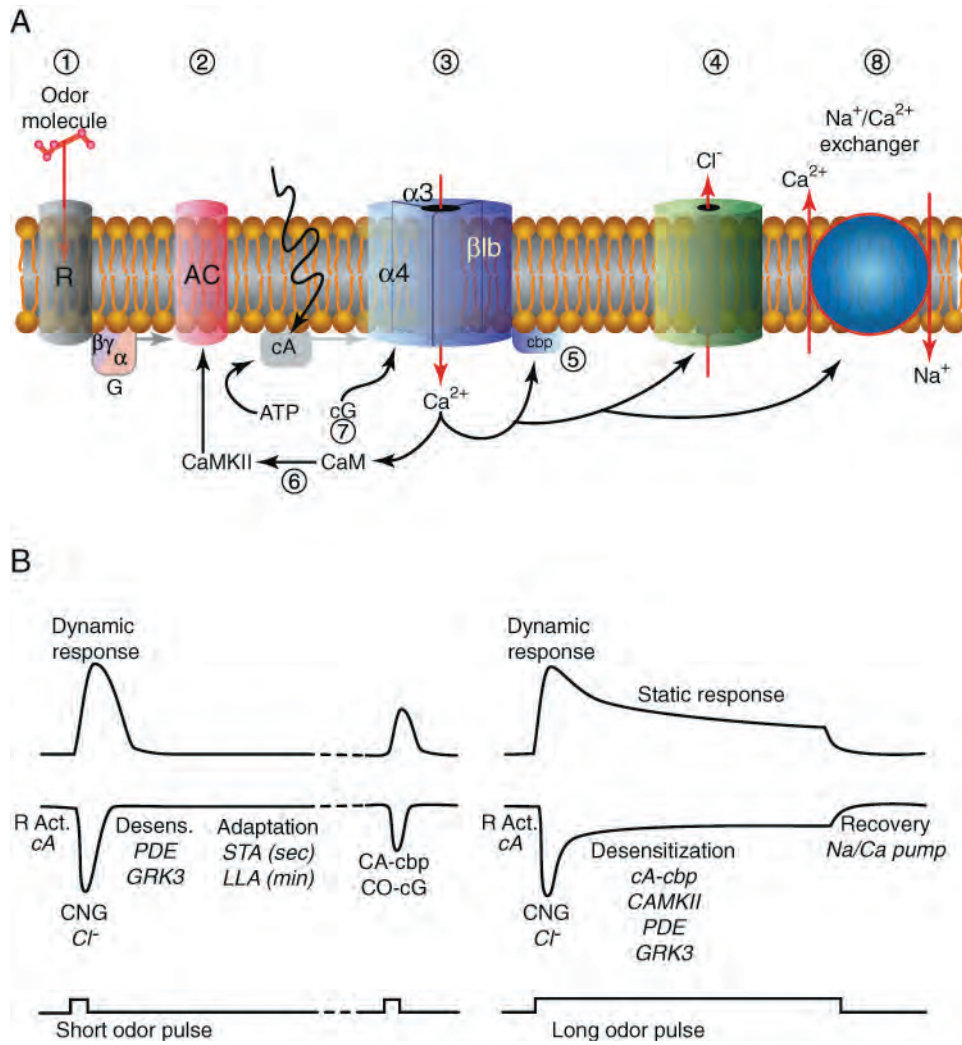

#### BOX 24.5

### A PHEROMONE-BINDING PROTEIN IN DROSOPHILA

There are 35 odor-binding proteins in the fruit fly *Drosophila melanogaster*. Each OBP is expressed in a spatially restricted region of the olfactory epithelium, suggesting that different OBPs serve different functions. One of the best studied odorant binding proteins is a *Drosophila* OBP called lush. Fly mutants lacking lush do not detect the compound 11-cis-vaccenyl acetate (cVA). cVA acts as a pheromone in *Drosophila* mediating aggregation and aspects of courtship behavior. Olfactory neurons of lush mutants do not respond to cVA, demonstrating the lush is

essential for detection of this pheromone. Remarkably, application of lush protein to the mutant olfactory neurons rescues the ability of these neurons to respond to cVA. This experiment demonstrates that lush is necessary for olfactory neurons to detect cVA. It argues that lush is involved in presenting the odor to the odor receptor and is not involved in clearance of the odor away from the receptor. For more information, please refer to Xu *et al.*, 2005.

**FIGURE 24.12** Sensory transduction of odor molecules involves a cyclic AMP second messenger pathway. Odor molecules initially are absorbed into the olfactory mucus, where they may bind to olfactory-binding protein (OBP), which carries them to the olfactory cilia. Activation of a receptor by odor molecules activates a GTP-binding protein (G); an adenylate cyclase (AC3), which produces cyclic AMP (cA); and a cationic cyclic nucleotide-gated (CNG) channel. Steps 1–3 generate the initial sensory response. Olfactory adaptation occurs in several steps. Step 4: Calcium activates a chloride conductance, which amplifies the sensory response. Step 5:  $Ca^{2+}$  activates a calcium binding protein (cbp), which produces immediate adaptation from the initial dynamic response peak. Step 6:  $Ca^{2+}$  activates a calcium/calmodulin-dependent protein kinase II, which produces short-term adaptation (LTA). Step 7:  $Ca^{2+}$  activates a cyclic GMP second messenger pathway that activates CO, which acts on the CNG channel to produce long-term adaptation (LTA). Step 8: A Ca/Na exchanger restores ion balance. Abbreviations, see text. Based on Menini (1999); Zufall and Leinders-Zufall (2000), and others.

to cell depolarization, the generation of action potentials, and neurotransmitter release.

Mice lacking the  $G_{olf}$ , the AC3, and the CNG channel have been generated and the phenotypes of these mutants highlight the critical roles of olfactory signaling. Mice lacking  $G_{olf}$ , AC3, or CNG channel generally die within one to two days of birth without milk in their stomach, unable to nurse. This reduced survival rate is consistent with the idea that olfactory cues are necessary for newborn pups to suckle. The activity of olfactory neurons in these mutant mice was monitored by extracellular recording from the nasal epithelium in

response to a panel of odors. Olfactory neurons from the AC3 mutants and the CNG channel mutants do not respond to odors. Olfactory neurons from mice lacking  $G_{olf}$  show significantly reduced odor responses, suggesting that a second  $G\alpha$  subunit found in olfactory neurons,  $G_s$ , may mediate the residual odor response in the  $G_{olf}$  mutants. These studies demonstrate that the  $G_{olf}$ , the AC3, and the CNG channel are essential components of the olfactory signal transduction cascade.

The olfactory CNG channel is structurally related to the mammalian photoreceptor transduction channel. Similar to the photoreceptor channel, the olfactory

channel is nonselective for cations. Unlike the photoreceptor, the olfactory channel is closed in the absence of sensory stimulation. When odor molecules bind to the receptor and lead to the production of cAMP, the cAMP activates the channel, causing a net inflow of cations that depolarizes the membrane toward an equilibrium potential around zero. Calcium entering through the channel acts as a second messenger activating a chloride channel to increase the outflow of chloride down its gradient from a high internal concentration; this amplifies the depolarization, thereby maximizing the amount of depolarizing sensory current while minimizing calcium inflow that would be harmful to the cilia. In addition, the chloride channel has a very small unitary conductance (less than 1 pS), and hence amplification is achieved with minimal noise.

The combined sensory current causes a depolarization that spreads through the dendrite to the cell body and axon hillock, activating voltage-gated channels that generate action potentials. In this way, the amplitude and time course of the graded sensory potentials generated by odor stimuli are transduced into a frequency code of impulses that propagate through the axon to its terminals in the olfactory bulb.

### Olfactory Adaptation Occurs in Several Stages

The decline of a sensory response during sustained stimulation is referred to as adaptation. In olfactory sensory neurons, adaptation proceeds in several stages. Experimental studies have quickly identified calcium as a key player. The first stage (step 5 in Fig. 24.12), of decline from the initial peak in the sensory response, is associated with the action of calcium; in the absence of calcium there is no decline, and patch recordings show continued channel activity with no desensitization. Single channel analysis has shown that an increase in internal calcium reduces the channel open probability. This effect appears to be mediated by an intermediate calcium-binding protein, possibly calcium-calmodulin, which binds to the channel protein to reduce its affinity for cyclic nucleotides.

The second stage of adaptation is called short-term adaptation (STA). This occurs in response to cAMP alone and suggests a feedback pathway from calcium involving calcium/calmodulin-dependent protein kinase II acting on adenylate cyclase (step 6 in Fig. 24.12). This is followed by long-term adaptation (LTA), which involves the activation of guanylate cyclase and the production of cyclic GMP (step 7 in Fig. 24.12). Another longer term contributor is a Na/Ca exchanger, which restores the ion balance (step 8 in Fig. 24.12).

Calcium ions also act externally to reduce the conductance of the channel. In the absence of calcium, the

channel has a unitary conductance of some 45 pS; in normal concentrations of extracellular calcium, calcium entering the channel induces a “flicker block,” reducing the conductance to less than 1 pS. This block is removed by depolarizing the membrane, suggesting that in normal calcium concentrations, olfactory sensory neurons act as coincidence detectors for cyclic nucleotide production plus membrane depolarization. In normal calcium and at normal resting potential, most of the channels appear to be in the blocked state. This mechanism may enhance the signal-to-noise ratio of the sensory response.

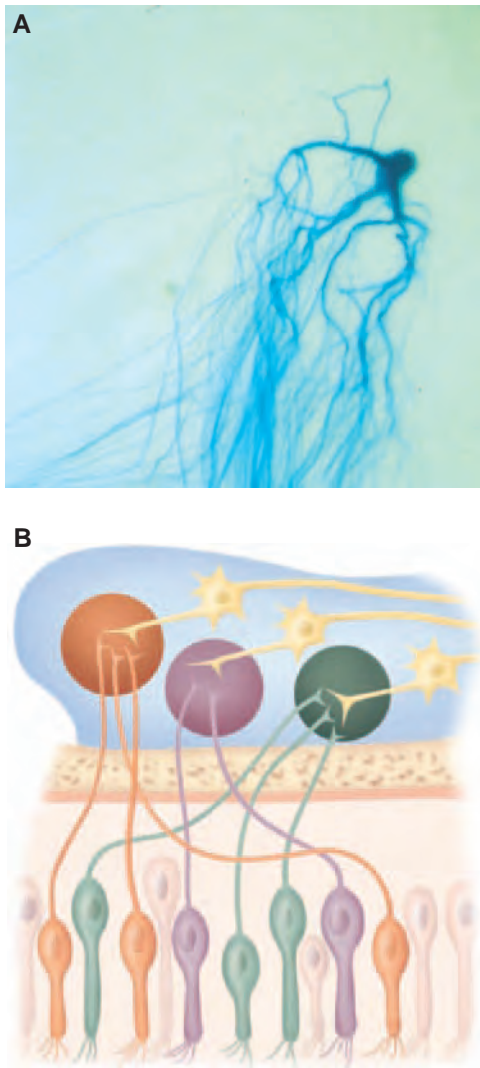

### The Spatial Organization of ORNs in the Olfactory Epithelium

The olfactory epithelium of mammals is distributed over the medial septal wall and the lateral turbinates toward the back of the nasal cavity. Each olfactory neuron expresses one of a thousand olfactory receptors. Neurons that express the same receptor are not tightly clustered together in the epithelium nor are they stochastically distributed throughout the epithelium. Instead, the ORNs that express a given receptor gene are located within one of roughly four zones that run anterior to posterior in the epithelium. Within a zone, the organization of ORNs with the same receptor appears random. The pattern of receptor expression suggests that there is positional information in the nasal epithelium that limits receptor expression to only one of four broad zones, with receptors randomly selected within a zone. How receptor expression is determined is an area of active investigation.

### Axons of Olfactory Neurons Project to the Olfactory Bulb

Olfactory neurons in the nasal epithelium send axons directly to the mammalian brain, to paired structures in the most rostral region called the olfactory bulbs (Fig. 24.13). The olfactory bulb is the primary relay station for smell. It is comprised of multiple cellular layers. Most peripheral is the glomerular layer where the axons of olfactory neurons reside, with deeper layers containing cells that synapse with olfactory neurons.

Axons of olfactory neurons terminate in the rounded regions of neuropil termed glomeruli. Anatomical studies from the time of Ramon y Cajal have shown that the glomerulus is an anatomical unit for the convergence of axons from many ORNs. In rats, the 15 million olfactory neurons converge onto 1500 glomeruli, giving an average overall convergence of some

**FIGURE 24.13** (A) Whole mount of the nose of a rat shows olfactory receptor axons converging on a single glomerulus. This subset of cells is stained for a lacZ reporter linked to mRNA for one type of olfactory receptor and the microtubule-associated protein tau. (B) Diagram of projections from the olfactory epithelium to the olfactory bulb. Neurons with the same receptor are scattered in the epithelium, but the send axons that converge onto 1–2 glomeruli in the olfactory bulb. From Mombaerts, 1999.

10,000:1. *In situ* hybridization and gene-targeting methods showed that ORNs expressing the same odorant receptor protein converge onto one or a few glomeruli in the olfactory bulb (Fig. 24.13). Neurons with different ORs send axons to different glomeruli. These experiments thus provide strong experimental evidence for the concept that subsets of ORNs expressing a single receptor gene project their axons as a labeled line onto one or a few target glomeruli. Activation of different olfactory receptors in the periphery leads to the activation of different glomeruli in the

olfactory bulb. This suggests that the animal knows what it is smelling by the combination of glomeruli that are activated.

### Different Odors Activate Different Combinations of Glomeruli

The functional significance of glomeruli is seen when an animal is exposed to an odor and the activity patterns in the olfactory bulb are observed (Box 24.6). The key observation is that different odors evoke different patterns of active glomeruli located in distinct domains within the olfactory bulb. Thus, the focal glomerular activity elicited by the odor of amyl acetate is localized in two broad zones, one medial and one lateral, within the olfactory bulb glomerular sheet (Fig. 24.14). In contrast, the activity elicited by camphor is distributed in a curving line of smaller glomerular patches. Although the two domains overlap, their overall patterns are distinct and different. These results suggest that each type of odor elicits a characteristic pattern of glomerular activation in the olfactory bulb. The patterns may be considered to constitute odor images in neural space.

These maps were obtained with the original 2-deoxyglucose (2DG) mapping method, which has been confirmed and extended by other techniques (Table 24.1). Each method has its advantages and disadvantages. Two main categories are optical methods and activity mapping methods. Optical methods give high resolution at the level of single glomeruli. Many of these studies have focused on the local architecture of relations between individual glomeruli activated by odors with related molecular structures (Fig. 24.15A). This is key for understanding the relationships of odor molecules and the glomeruli they activate. However, these methods image only a small dorsal portion (10–15%) of the total olfactory bulb. Global activity mapping methods such as 2DG are complementary in that they image the entire glomerular sheet, including areas in the 85% of the bulb not accessible to optical methods (Fig. 24.15B).

A different methodological approach has been to focus on the time course of the electrophysiological responses of olfactory cells. These studies (Laurent *et al.*, 1996) have suggested that the temporal spiking patterns contain information that itself could encode the identity of the stimulating odor molecule. This approach is still in its early stages and more information is needed, such as where in the odor maps the responses are recorded; how the temporal patterns relate to the spatial maps; and how long it takes in the temporal response for the response pattern to transmit decipherable information. This approach has thus

## BOX 24.6

## PRINCIPLES OF ODOR MAPS

Odor stimulation gives rise to spatial patterns of activity in the glomerular layer of the olfactory bulb due to the differential activation of glomeruli.

The glomerulus is the basic molecular, anatomical, developmental, and functional unit for odor mapping and odor processing.

The pattern of activated glomeruli for a given odor is relatively constant across animals for equivalent odor stimulation conditions. However, the pattern can change under different experimental conditions (e.g., anesthesia, adaptation).

The pattern for a given odor characteristically includes sites in the medial and lateral bulb, reflecting the pattern of projections of olfactory sensory neuron subsets. The patterns are characteristically bilaterally symmetrical, dependent on equivalent stimulating conditions on the two sides of the nose.

Identified glomeruli can be correlated with specific odors. This is true of the modified glomerular complex in mammals, and particularly true of identifiable glomeruli in the insect.

Different odors elicit activity in different, often overlapping, patterns. It is hypothesized that processing of the differing patterns by olfactory bulb circuits provides the basis for olfactory discrimination.

A given homologous chemical series (such as alcohols, acids, aldehydes) activates overlapping shifted patterns, reflecting similarities of chemical structure in the series.

At a weak concentration, an odor elicits activity in the single or small group of glomeruli receiving input from the olfactory receptor neuron subset whose receptor type is most sensitive to that odor. Higher odor concentrations activate increasing numbers of glomeruli. Changes in odor pattern with increasing concentration may be correlated with perceptual changes. It is therefore hypothesized that the odor patterns also are involved in the encoding of odor concentration. For references, see Xu *et al.* (2000).

### How Do Olfactory Neurons Target to the Appropriate Glomerulus?

Neurons with the same olfactory receptor are scattered in the sensory epithelium, yet all target to only one of a thousand possible glomeruli in the olfactory bulb. Axon targeting of olfactory neurons is a very complicated wiring problem. One model for targeting

is that concentration gradients of axon guidance receptors in the nasal epithelium and gradients of guidance cues in the olfactory bulb direct targeting. This approach is used in the formation of the topographic map of retinal projections in the visual system, where neurons that occupy nearby positions in the periphery (and express similar levels of guidance molecules) synapse at nearby locations. Varying the concentration of a guidance cue or guidance receptor along a sheet of tissue is unlikely to be sufficient to direct targeting the olfactory system, as neurons containing the same receptor are found at very different positions yet project to the same glomerulus. An alternative model is that neurons with the same olfactory receptor express the same axon guidance receptor, and the matching of a thousand different guidance cues and a thousand different guidance receptors is used to direct each neuron to its appropriate glomerulus. This begs the question: how are the expression of an odorant receptor and a guidance receptor coordinately controlled? An elegant solution that is emerging is that the olfactory receptors themselves may participate in axon guidance.

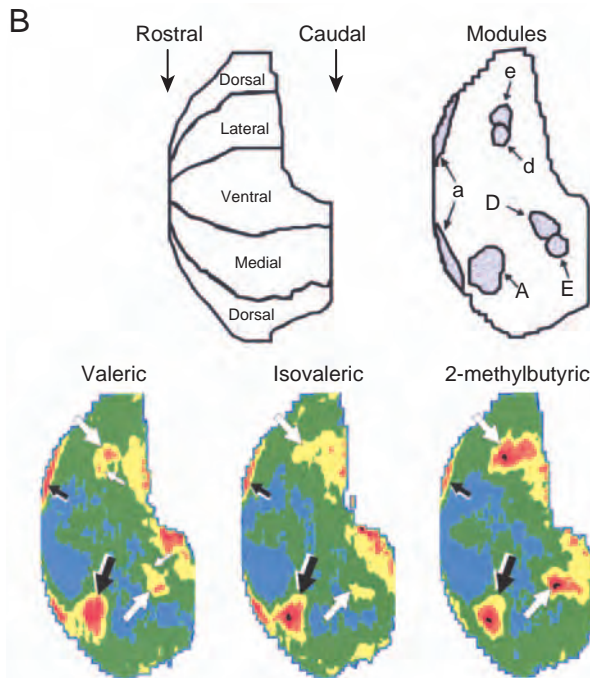

A number of lines of evidence argue that the olfactory receptors participate in axon guidance. First, olfactory receptor protein is localized to the axon

**FIGURE 24.14** The 2-deoxyglucose (2DG) method reveals the functional organization of the olfactory glomerular sheet. (A) Patterns of 2-deoxyglucose utilization in an X-ray film autoradiograph of a frontal section through the olfactory bulb of a rat exposed to a low concentration of the odor of amyl acetate. A single focus associated with one glomerulus or a small group of neighboring glomeruli is seen in one of the olfactory bulbs. (B) With a moderate concentration of amyl acetate, the activity induced in the glomerular layer is characterized by activation of several glomeruli or groups of glomeruli (white lines outline the histological layers). (C) With a high concentration of odor of amyl acetate, the induced activity consists of broad regions of increased 2DG uptake, centered on the glomerular layer in medial and lateral regions of the olfactory bulb, that are roughly bilaterally symmetrical.

termini as well as to the dendrites, in the right place to detect guidance cues. Second, olfactory neurons in which the OR has been deleted do not go to a single glomerulus. Third, transgenic mice have been generated that misexpress olfactory receptors and they show specific olfactory targeting defects. As an illustration,

mice can be genetically modified to express OR B in neurons that usually express OR A. Remarkably, these neurons no longer go to the A glomerulus. Instead, they go to a novel glomerulus or the B glomerulus. Because the neurons do not go to the A glomerulus, this argues that olfactory receptors are involved in

**FIGURE 24.15** Odor maps. (A) Visualization of odor-elicited activity in glomeruli of the dorsal olfactory bulb by intrinsic imaging. From Belluscio and Katz (2001). (B) Global maps of odor-elicited activity patterns in the glomerular layer by 2-deoxyglucose. From Johnson and Leon (2000).

guidance. Because the neurons do not necessarily go to the B glomerulus, other factors besides the olfactory receptor must also be involved in axon guidance (Fig. 24.16).

Recent experiments suggest that activation of signaling molecules directs axon guidance. Like many G protein-coupled receptors, the odor receptors contain a three amino acid motif (Asp-Arg-Tyr (DRY)) at the cytoplasmic loop between transmembranes 3 and 4, implicated in coupling to G proteins. Olfactory neurons containing a receptor that lacks this domain do not target to a single glomerulus. Expression of a constitu-

**FIGURE 24.16** Diagram showing the olfactory epithelium with neurons expressing the M50, P2, or P3 receptors in the periphery and the glomeruli they project to in the olfactory bulb. Replacing the P2 receptor with the P3 receptor (P3→P2) results in a novel glomerulus very near the original P3 glomerulus. This argues that the P3 receptor can direct targeting to the P3 glomerulus, and that the receptor is instructive for guidance. Replacing the P2 receptor with the M50 receptor (M50→P2) results in a novel glomerulus in between the P2 and M50 glomeruli. This argues that factors other than the receptor also influence guidance. From Wang *et al.*, 1998.

tively-activated G protein (always ON) rescues this defect, arguing that coupling of the receptor to the G protein is necessary for axon targeting. Interestingly, the G protein is not  $G_{olf}$ , the G protein that is involved in olfactory transduction, but rather  $G_s$ , another G protein expressed in olfactory neurons. The use of different G proteins may allow activation of the same odor receptor to produce different responses for signal transduction and axon guidance. Increasing or decreasing the levels of cAMP production also changes the position of the glomerulus, such that neurons with the same receptors but different cAMP levels project to different glomeruli. The model that emerges from these studies is that activation of olfactory receptors on axon termini activates  $G_s$  and increases cAMP levels, leading to glomerular targeting. Although this model still requires rigorous testing, the implication is that activity of each odor receptor produces a unique level of cAMP, and that different cAMP levels ensure the proper targeting of neurons containing 1000 different receptors to 1000 glomeruli. Whether and how receptor activity generates different cAMP levels remains to be determined.

### The Olfactory Bulb Is the Primary Relay for Smell

The olfactory bulb provides the first stage of synaptic processing of the sensory information in the olfac-

**FIGURE 24.17** Layers of the mouse olfactory bulb. The most superficial layer is the glomerular layer (blue) containing olfactory axons and periglomerular cells. Next (in red) is the external plexiform layer containing fibers and the mitral/tufted cell layer, containing neurons that synapse with olfactory sensory neurons. In the deep layers of the bulb (green) are the fiber-filled internal plexiform layer and the cell bodies of the granule cells, which make inhibitory connections with the mitral/tufted cells.

tory pathway. The olfactory bulb is comprised of several cell layers (Fig. 24.17). The most superficial layer is the glomerular layer, where the axons of olfactory neurons with the same odorant receptor converge onto one or two glomeruli. This layer also contains periglomerular cells, inhibitory interneurons that make connections within and between glomeruli. Next is the external plexiform layer, which contains axons and dendrites. Third is the mitral/tufted cell layer, containing the cell bodies of mitral/tufted cells, which synapse onto the olfactory axons within the glomerulus and relay information to the olfactory cortex. Fourth is the internal plexiform layer, which contains axons and dendrites. The final cell layer is the granule cell layer. Granule cells are interneurons that synapse onto mitral/tufted cells. The synaptic connections of different cell types in the olfactory bulb serve as the initial stage for olfactory information processing (Fig. 24.18).

**FIGURE 24.18** Diagram summarizing the synaptic organization of the glomerular layer. Olfactory neurons with the same receptor project to the same glomerulus. Mitral/tufted cells synapse onto a single glomerulus. Periglomerular cells are inhibitory interneurons that synapse within and between glomeruli. Granule cells are inhibitory interneurons that synapse between mitral/tufted cells.

Within a glomerulus, olfactory axons make glutamatergic excitatory synapses onto the dendrites of the mitral/tufted neurons. Each mitral/tufted cell sends dendrites to one glomerulus, and thus relays the activity of one olfactory receptor to the brain. The dendrites of mitral/tufted cells also form reciprocal synapses with the periglomerular cell. The mitral/tufted dendrites make glutamatergic connections onto periglomerular cell dendrites, and dendrites of periglomerular cells form both GABAergic and dopaminergic synapses onto mitral/tufted cell dendrites. These connections are believed to mediate numerous types of interactions, including serial excitatory synapses (which spread excitation widely within a glomerulus), as well as recurrent and lateral inhibitory synaptic circuits.

In addition to intraglomerular processing, there is interglomerular processing. The axons of the periglomerular cells make synapses onto periglomerular cells in neighboring glomeruli and onto the dendritic shafts of neighboring mitral/tufted cells. One action of these synapses may be to inhibit periglomerular cells

and mitral/tufted dendrites, thus providing contrast enhancement between neighboring glomeruli.

The second level of synaptic processing in the olfactory bulb occurs through inhibitory connections between granule cells and mitral cells. Reciprocal dendrodendritic synapses that mediate mitral/tufted-to-granule excitation and granule-to-mitral/tufted inhibition cause activated mitral/tufted cells to mediate feedback inhibition on themselves and lateral inhibition on their neighbors. Granule cells may participate in lateral inhibition onto a large population of neighboring cells that belong to neighboring glomerular units. It has been postulated that this inhibition contributes a more complex, more contextual type of contrast enhancement between cells belonging to different glomerular modules.

The current model is that the main function of the dendrodendritic synapses present at both the glomerular and granule cell levels is to mediate lateral inhibition and the role of this lateral inhibition is to enhance contrast between different odors.

### Olfactory Bulb Output Goes Directly to Olfactory Cortex

The output of the olfactory bulb is carried by the axons of mitral cells and their smaller counterparts, the tufted cells. These axons project directly to olfactory cortex in the forebrain, the only sensory system to have this immediate access to the forebrain. The olfactory cortex has a three-layer structure that represents the primitive anlage of forebrain cortex found in fish, amphibia, and reptiles (Fig. 24.19). The principal neuron is the pyramidal cell, with apical and basal dendrites bearing spines and recurrent collaterals connecting both to inhibitory interneurons and directly to other pyramidal cells. Mitral/tufted axons make excitatory connections to spines on the distal apical dendrites. Processing in the cortex takes place by means of the intrinsic excitatory and inhibitory synaptic circuits. Together these neural elements and their connections constitute a basic, canonical circuit. This type of circuit is present in other types of cortex, such as the hippocampus and neocortex, suggesting that it represents the simplest type of cortical circuit, which is adapted and elaborated in the other types to carry out different or more complex types of functional operations.

Like cortical regions in other systems, the olfactory cortex is differentiated into several different areas. The main area is the pyriform (sometimes called the pre-pyriform) cortex. This area receives input from mitral/tufted cells. It projects to the mediodorsal thalamus, which in turn projects to medial and lateral orbitofron-

tal areas of the neocortex. It is at this level that conscious perception of odors presumably takes place. Second is the olfactory tubercle, which receives input mainly from tufted cells. Third is the cortico-medial group of amygdalar nuclei, which receive specific input from the accessory olfactory bulb. Fourth is the lateral entorhinal area, which projects to the hippocampus. Last is the anterior olfactory nucleus, a sheet of cells just posterior to the olfactory bulb in subprimates.

### Stem Cells and Olfactory Function

There is much current interest in stem cells and the possibilities they raise for maintaining or repairing brain function. The olfactory system is unique in the adult brain in being supplied by two sources of stem cells.

First is the olfactory epithelium, where new ORNs arise from basal stem cells during development and throughout the adult life of the animal. During development, new ORNs expressing specific ORs differentiate from basal cells in the olfactory placode. During early life the process of neurogenesis is activated by dying ORNs, leading to a constant turnover of ORNs.

The second example is the anterior migratory stream. Stem cells in the ventricular epithelium of the basal forebrain give rise to neural progenitor cells, which migrate in an anterior direction to the olfactory bulb, where they differentiate and become incorporated into the populations of granule cells and periglomerular cells. This process also occurs throughout adult life. Migration involves homotypic interactions between migrating cells, rather than migration along radial glia as in the cerebral cortex. Current studies are aimed at understanding how the new cells are incorporated into the processing circuits of the bulb.

Almost nothing is known about the mechanisms controlling these processes. Further work is thus needed to understand the relevance of these mechanisms to olfactory processing, as well as gaining insights into the fundamental problems of stem cell functions in the brain.

### The *Drosophila* Olfactory System

The olfactory system of *Drosophila* shares many common principles with the mammalian olfactory system, although scaled down to size. The smell organs of the fly are its antennae and maxillary palp (Fig. 24.20). Olfactory neurons have dendrites that are exposed to the external environment for the detection of odors and axons that travel to the antennal lobe, the

**FIGURE 24.19** Summary of main projection pathways in the olfactory system. AON, anterior olfactory nucleus; PC, pyriform cortex; OT, olfactory tubercle; AMYG, amygdala; TEC, transitional entorhinal cortex; NHLDB, nucleus of horizontal limb of diagonal band; MD, mediodorsal.

insect equivalent of the olfactory bulb. A family of approximately 60 *Drosophila* odorant receptors (dOR) detects volatile cues. Because the number of odor receptors in *Drosophila* is relatively small, it has been possible to unambiguously determine the expression pattern of each OR in the periphery. About 44 dORs

are expressed in the adult and 20 are expressed in larvae. Each receptor is expressed in a small subset of olfactory neurons, except for one receptor that is found in nearly all olfactory neurons. This receptor, dOR83b, is necessary to localize other odor receptors to the dendritic membrane and is essential for olfactory

Current Opinion in Neurobiology

**FIGURE 24.20** The fly olfactory system. The left panel shows a diagram of the fly head, highlighting olfactory regions. The antenna containing olfactory neurons is in light blue, and the first relay, the antenna lobes, in dark blue. Neurons with the same receptor project to a single glomerulus. A single projection neuron innervates one glomerulus and sends axons to the protocerebrum. Olfactory neurons containing Or47a (blue) in the antenna. The projections of Or47a neurons (green) in the antennal lobe. The projection neuron that synapses onto Or47a neurons arborizes in a stereotyped fashion in the protocerebrum of the fly brain. From Keller and Vosshell, 2003.

function. Each olfactory neuron contains dOR83b as well as one other specific olfactory receptor.

Neurons with the same specific receptor project to a single glomerulus in the antennal lobe. Consistent with the number of receptors, there are 49 glomeruli in the adult and 21 glomeruli in larvae. A complete map of the larval and adult antennal lobes has been made, identifying each receptor by the glomerulus that innervates it. Thus the organization of the olfactory system in *Drosophila* is remarkably similar to the mammalian system where neurons with different receptors project to different glomeruli.

Because the numbers of receptors are much smaller, it has been possible to examine the selectivity of receptors to different odors. To determine the selectivity of different receptors, the responses of 24 different odor receptors to 110 different chemicals were examined. These studies revealed that approximately 70% of the

odor-receptor combinations did not show increased firing rates, 30% showed increased firing rate, and 10% showed inhibitory responses. The number of odors that a receptor recognizes (out of the 100 tested) varied from none to thirty, with receptor response profiles ranging continuously from very narrow to broadly tuned. In general, receptors that are broadly tuned respond to structurally similar compounds. A single odor activated from one to 16 different receptors. Overall, these studies demonstrate that a given odor is sparsely encoded by the activation of a few receptors.

Is there a chemotopic map in the *Drosophila* antennal lobe? Knowing the odors that different receptors recognize as well as the glomeruli associated with all receptors has made it possible to map the distribution of odor responses in the antennal lobe. These studies argue that broadly tuned receptors occupy medial regions of the antennal lobe, and narrowly tuned receptors occupy more lateral regions. However, there is no obvious chemotopic organization: neurons responding to the same stimuli are not clustered together.

Olfactory receptor neurons send axons to the antennal lobe. The second order neurons are projection neurons and local inhibitory interneurons. Each projection neuron sends dendrites to a single glomerulus and axons that branch to terminate in the protocerebrum and mushroom bodies (involved in associative learning) of the fly brain. The pattern of projections is invariant: each projection neuron sends dendrites to a specific glomerulus and has a characteristic, defined axon branching pattern in the protocerebrum and mushroom bodies that is invariant from individual to individual. These arborizations occur in the absence of olfactory neurons. Studies of the development of projection neurons argue that projection neuron identity is defined by the birth-order of the neuron. The picture that has emerged from these studies is that the connectivity of projection neurons is hard-wired.

In general, although flies and mammals are separated by approximately 400 million years in evolution, the principles of olfaction are conserved in these organisms. In fly olfaction, as in mammalian olfaction, one receptor is expressed per cell and neurons with the same receptor project to the same glomerulus. Moreover, the simplicity of the *Drosophila* system allows a complete description of the ligand-binding properties of ORs and their targeting in the olfactory bulb. Comparative studies of the olfactory systems of different organisms highlight the general strategies that animals use for chemical recognition. Interestingly, even organisms without a nervous system may have a sense of smell (see Box 24.7).

## PHEROMONE DETECTION

### The Accessory Olfactory System May Mediate Pheromone Detection

In addition to the main olfactory pathway, an accessory olfactory pathway exists for the detection of pheromones in many species. Pheromones are species-specific and gender-specific chemical cues emitted by an individual and detected by other members of the species that provide information about the individual's social, sexual, and reproductive status. In general, pheromones cause stereotyped and innate changes in conspecifics' behavior, either by direct, short-term effects on animal behavior or longer-term changes that alter the endocrine state. For example, one of the few vertebrate pheromones isolated is the sex pheromone of the red-sided garter snake. Female snakes produce this substance that is sufficient to induce courting behavior in males. Another well-described pheromone is made by slave-maker ants. They emit a blend of chemicals that serve as an alarm signal, causing the slave-makers to attack other ants' nests, and the resident ants to flee. An uncharacterized pheromone is thought to be responsible for the Bruce effect in mice: a behavior in which the scent of a novel male will terminate the pregnancy of a recently inseminated female, providing the novel male the opportunity to produce offspring.

The sensory structure for pheromone detection is the vomeronasal organ (VNO), also referred to as Jacobson's organ (Fig. 24.21). The VNO is a cigar-shaped cavity in the anterior nasal septum surrounded by bone. Openings in the anterior cavity contact either the oral cavity or the nasal cavity, depending on the species, for the detection of pheromonal cues. The sensory epithelium of the VNO is divided into anterior and posterior layers. Each layer contains sensory neurons that detect soluble and volatile cues. Different

**FIGURE 24.21** The accessory olfactory system of the mouse. The vomeronasal organ in the nasal cavity contains two layers. The apical layer expresses the V1R family of pheromone receptors and the basal layer contains the V2R family. These neurons project to the accessory olfactory bulb (AOB) where they form several glomeruli. From Dulae, 2000.

receptors and signaling molecules are found in the two layers, suggesting that they serve different functions.

Axons of sensory neurons travel from the VNO to the accessory olfactory bulb (AOB), which is located at the dorsal posterior surface of the main olfactory bulb (MOB) in rodents. Projection neurons then send axons to the bed nuclei of the accessory olfactory tract and stria terminalis, and the posteromedial cortical and medial nuclei of the amygdala. These projections do not overlap with projections from the main olfactory bulb, demonstrating that there is segregation of processing from the two systems.

### Information Flow from the VNO to the AOB

The sensory epithelium of the VNO is divided into an apical and a basal layer. Neurons in the apical layer express V1R receptors and those in the basal layer express V2R receptors (see next). In general, each sensory neuron expresses one receptor, similar to the olfactory system of mammals. This suggests that each sensory neuron detects a small subset of chemical cues.

Neurons from the apical layer project to the anterior region of the AOB and neurons from the basal layer project to the posterior AOB. Unlike the olfactory system, neurons with the same receptor do not project to one or a few glomeruli (Fig. 24.21). Instead, neurons with the same receptor converge onto multiple glomeruli (from 6–30) in spatially restricted domains forming a complex pattern that is loosely conserved from animal to animal. Dendrites of mitral cells synapse onto several glomeruli in a complex fashion. Mitral cell dendrites have been reported to contact glomeruli from neurons with the same receptor as well as from neurons with different receptors. Thus unlike the olfactory system, a single mitral cell does not synapse onto a single glomerulus. The complex connectivity suggests that integration of different sensory inputs occurs in the AOB. One hypothesis is that this organization allows the animal to respond only to the relevant mixture of pheromone cues. For example, the simultaneous activity of different sensory receptors may be necessary to activate mitral cells, such that mitral cells respond to specific blends of pheromones. In this model, only the right mix of pheromones will trigger stereotyped innate behavior.

### Signal Transduction in the VNO

Different signaling molecules reside in the apical and basal compartments of the VNO. In the apical layer, the V1R family of candidate pheromone receptors is expressed. There are approximately 165 full-

length V1R genes in mice, 106 in rat, and only two in humans. These G-protein coupled receptors all contain a short amino-terminus extracellular domain and are distantly related to the T2R family of mammalian bitter receptors. Only one receptor-ligand pair has been identified for this gene family: the receptor V1Rb2 recognizes heptanone in isolated VNO neurons. Mice lacking 12 V1Rs do not detect a subset of candidate pheromones by electrophysiology studies of VNO field responses. These mice also show behavioral defects in stereotyped behaviors thought to be mediated by pheromones: for example, the female mice do not show maternal aggression (normally, nursing mothers fend off intruders). These findings argue that the V1R family detects pheromones and mediates behavior. Neurons that express V1Rs also contain the *Gα2* alpha subunit of heterotrimeric G proteins and the ion channel TRPC2 as shown by *in situ* hybridization and immunocytochemical staining. This suggests that these molecules transduce information from the activation of V1Rs to cell depolarization.

The V2R family of chemoreceptors is expressed in the basal layer of the VNO. This receptor family has a long amino-terminal extracellular domain and shares sequence similarity with the mammalian T1R family of taste receptors. There are approximately 60 intact V2R receptor genes in mice and rats. All genes are expressed exclusively in the VNO suggesting that they mediate pheromone detection. However, no ligands have been identified for these receptors and mice lacking V2Rs have not yet been engineered. The *Gαo* subunit of heterotrimeric G proteins is expressed in the basal layer along with V2Rs. In addition, the TRPC2 ion channel that is expressed in the apical layer also is found in the basal layer.

### Mice Lacking TRPC2 Show Behavioral Defects

Because the TRPC2 ion channel is expressed in both the apical and basal layer of the VNO, it may act as an ion channel mediating detection of pheromones. To test this, mice were generated that lack the TRPC2 channel. The VNO is not activated by candidate pheromones in these mice by electrophysiological recordings, demonstrating a deficit in VNO function. If the VNO is not functional, one prediction would be that these mice would lack pheromone-driven social behaviors such as mating and aggression. Consistent with this, mice lacking TRPC2 do not show aggressive behavior. Surprisingly, male mice without TRPC2 indiscriminately mate both females and males. The simplest interpretation of these studies is that mating does not require the VNO; instead, the VNO is required

to inhibit male–male courtship behavior and promote discrimination between the sexes. One caveat with these studies is that it is not clear that loss of TRPC2 eliminates all VNO function; therefore it will be important to generate mice specifically lacking the VNO to determine its role in social and sexual behavior.

### Pheromone Detection in Humans?

Although evidence is accumulating that the VNO participates in pheromone-driven behavior in mice, the role of the VNO in human behavior is far less certain. Anatomical studies of the vomeronasal organ argue that this structure exists but lacks sensory neurons and nerve bundles in the adult. The accessory olfactory bulb exists in the fetus but regresses and is not present in the adult. Genomic studies demonstrate the TRPC2 gene is a nonfunctional pseudogene in humans. Moreover, almost all V1R pheromone receptors are pseudogenes (115/117). There are only two intact V1R sequences and no functional V2R sequences in the human genome. Taken together, these studies strongly argue that the accessory olfactory system does not function in humans.

The loss of VNO in humans can be interpreted in two ways. One possibility is that humans do not detect pheromones and have evolved other strategies to ensure appropriate detection of mates and attackers. Alternatively, it is possible that humans detect odors through the main olfactory system that act as pheromones to elicit innate, stereotypical behaviors involved in reproduction and aggression.

### Comparison of the Main Olfactory System and the Accessory Olfactory System

Although the accessory olfactory system has been classically thought to detect pheromones and the main olfactory system to detect a vast array of volatile cues, the distinction between the two noses is blurred both in terms of the compounds they detect and the behaviors they mediate. For example, electrophysiological studies show that sensory neurons in the VNO respond to volatile and nonvolatile compounds. Similarly, olfactory neurons depolarize in response to compounds classified as pheromones. Mice that have a defective VNO (lacking TRPC2) lack many pheromone mediated behaviors, but not all. For example, pup suckling is a stereotyped behavior that is normal in TRPC2 mutants. Mice with a defective MOE (lacking the olfactory cyclic nucleotide-gated channel) do not mate, fight, or suckle, showing that the olfactory system also is required for innate stereotyped behavior. Thus, the best ways to distinguish the main and

## BOX 24.7

## DO PLANTS HAVE A SENSE OF SMELL?

Plants have devised a number of strategies to detect information about the outside world, and have mechanisms for detecting light, nutrients, and mechanical stimulation. Recent studies suggest that they might have a sense of smell as well (Runyon *et al.*, 2006). The dodder (also called strangletread or witches shoelaces) is a small parasitic plant that does not contain machinery for photosynthesis. Instead, this major agricultural pest must attach onto host plants such as tomatoes for nutrients. In order to examine how the dodder finds its way to its host, experiments were done to test the sensory cues necessary to direct growth. A dodder plant directs its growth toward

a tomato plant, and the scent, but not the sight, of a tomato is sufficient to direct dodder growth. Several individual volatile compounds were also able to direct growth, suggesting that dodders can sense multiple odors. Whether it is a general principle that plants recognize odors remains to be seen. The diversity of odors recognized by plants and the mechanism are also unknown. However, it is interesting to consider that plants also have primary senses and translate information about the outside world into behavior, even without a brain.

Kristin Scott

accessory olfactory systems are not by the ligands they recognize or the behaviors they mediate, but by their anatomical segregation in the periphery and central nervous system.

### Summary

The olfactory system enables animals to detect and discriminate between thousands of different odors. The enormous number of olfactory receptors allows for the ability to detect a vast array of odors. Each olfactory receptor recognizes a subset of chemical cues, with one odor activating more than one receptor and one receptor recognizing more than one odor. In the periphery, each olfactory neuron expresses only one olfactory receptor. Neurons with the same OR are distributed randomly in the nasal epithelium but they all project to the same glomerulus in the olfactory bulb. Thus, the activation of different olfactory receptors leads to the activation of different glomeruli in the central nervous system. Different combinations of activated glomeruli represent different smells. In *Drosophila* as well as mammals, one receptor is expressed per cell and neurons with the same receptor project to the same glomerulus, demonstrating that the logic of olfaction has been maintained through evolutionary time. In addition to the main olfactory pathway in vertebrates, a parallel accessory pathway exists for transmitting signals from less volatile odorous compounds called pheromones.

Higher order processing begins in the olfactory bulb, where mitral/tufted cells synapse onto olfactory neurons and transmit this information to the

olfactory cortex. Periglomerular cells and granule cells provide inhibitory connections in the bulb that shape olfactory responses. Information is then relayed to five different brain regions where it is ultimately translated into different odor percepts and behavior.

## Somatosensory System

The somatic sensory system is burdened with many responsibilities. Beyond the obvious need to bring to consciousness events that occur along the skin surface, this system provides an organism with knowledge of where it is in space and it provides the motor system with feedback to control and coordinate action. Those are functions so diverse that minute variations on a common theme cannot accomplish them all. That is, the many demands on the somatosensory system cannot be met by subtle changes in gene expression or pattern of synapses or location of cell bodies. As a result, single neurons, large ensembles, and groups of interconnected regions use different tactics and strategies to achieve a final goal.

### PERIPHERAL MECHANISMS OF SOMATIC SENSATION

#### All Somatic Sensation Begins with Receptors and Ganglion Cells

Neurons of the dorsal root and trigeminal ganglia are the only routes by which mammals receive information from the periphery of the body and of the face. These are pseudo-unipolar cells, with a single process—an axon—that divides close to the cell body and sends separate branches out to the periphery and into the central nervous system (Fig. 25.1). Under normal circumstances neurons in the 31 pairs of dorsal root ganglia and the single pair of trigeminal ganglia receive no synapses. That situation can change, however, when the peripheral branches of ganglion cells are cut and axons of neurons in nearby sympathetic ganglia are attracted to enter and innervate. In the absence of

this pathology, the cell body of a somatic sensory ganglion cell is properly considered a factory for all that must be made to keep its two branches functioning properly. Its major function is to keep a very long axon healthy enough to avoid conduction failures, particularly at the T junction near the cell body. This is a function large ganglion cell bodies do very well, as the incidence for conduction failures in their axons is reported to be zero. Even where failures at the T-junction are reported, as in the small ganglion cell bodies of some vertebrate species, the effect appears deliberate and is tied to the difference in action potential shape seen in large and small cells.

Neuronal cell bodies in the dorsal root and trigeminal ganglia vary in size and in gene expression (Fig. 25.2). Although the details of size vary among species according to differences in body size, all species examined to date include two populations, one at least half again larger than the other. Variations in the density of Nissl staining combined with the size difference lead to a simple division of ganglion cells into large light and small dark neurons. The group with the larger somata is outnumbered by at least 3-to-1 by those with the smaller somata.

Peripheral branches of dorsal root ganglion cells enter peripheral nerves. Those of the trigeminal ganglion enter the trigeminal nerve. In a mixed nerve, with both sensory and motor axons, the ganglion cells provide more than a fair share of the large, myelinated axons and all of the thinly myelinated and unmyelinated axons. Conduction velocities vary because of these differences in axon diameter and degree of myelination. Classic studies divide the sensory axons in human peripheral nerve into the following groups with conduction velocities in parentheses: Group I or  $A\alpha$  (70–120 meters/second), Group II or  $A\beta$  (40–70

**FIGURE 25.1** A dorsal root ganglion cell is a pseudo-unipolar neuron with an axon that divides at T-junction into a peripheral branch and a central branch. At the tip of the peripheral branch are receptor proteins that, through opening of cation channels, produce a depolarization called a generator potential. With sufficient depolarization, voltage-gated  $\text{Na}^+$  channels open to initiate action potentials. These action potentials are conducted down the axon and into the central branch that innervates second-order neurons in the spinal cord (in this case) or in the medulla.

**FIGURE 25.2** A somatosensory ganglion (center) is populated by a broad range of neurons that differ in size, gene expression, and receptive field properties. Mechanoreceptors (in blue) differ in how they respond to a sustained stimulus. Rapidly adapting (RA) afferents of the glabrous skin and D-hair receptors or hair follicle receptors generate short bursts of action potentials at stimulus onset and offset. Slowly adapting (SA) afferents respond to a sustained indentation of skin with a prolonged series of action potentials. Nociceptors (in red) also vary in size and conduction velocity of their axons ( $A\delta$  vs. C) and in their response to noxious mechanical stimulation, such as a hard pinch. Some receptors respond specifically to this stimulus (AM nociceptors and C-mechanocceptors) whereas others respond to a broad range of noxious stimuli (C-mechanoheat nociceptors). From Lewin, G. R. and Moshourab, R. (2004).

meters/second), Group III or  $A\delta$  (12–36 meters/second), and Group IV or C (0.5–2.0 meters/second). These groups correspond to functional classes that carry proprioceptive, mechanosensory, thermoreceptive, or nociceptive information from muscles, tendons, and skin to the spinal cord (Table 25.1).

What sets apart ganglion cells of the somatosensory system from all other neurons carrying the name ganglion cell is the requirements for double duty. As ganglion cells of the somatosensory system they carry into the brain and spinal cord all the information about skin and deep tissues the CNS will ever have. Unlike

TABLE 25.1 Summary of Primary Afferent Fibers and Their Roles

Modality	Submodality	Receptor	Fiber type	Conduction velocity (ms <sup>-1</sup> )	Role in perception
Mechanoreception	SAI	Merkel cell	A $\beta$	42–72	Pressure, form, texture
	RA	Meissner corpuscle	A $\beta$	42–72	Flutter, motion
	SAII	Ruffini corpuscle	A $\beta$	42–72	Unknown, possibly skin stretch
	PC	Pacinian corpuscle	A $\beta$	42–72	Vibration
Thermoreception	Warm	Bare nerve endings	C	0.5–1.2	Warmth
	Cold	Bare nerve endings	A $\delta$	12–36	Cold
Nociception	Small, myelinated	Bare nerve endings	A $\delta$	12–36	Sharp pain
	Unmyelinated	Bare nerve endings	C	0.5–1.2	Burning pain
Propioception	Joint afferents	Ruffini-like and paciniform-like endings, bare nerve	A $\beta$	42–72	Protective function against hyperextension
	Golgi tendon organs	Golgi endings	A $\alpha$	72–120	Muscle tension
	Muscle spindles	Type I	A $\alpha$	72–120	Muscle length and velocity
		Type II	A $\beta$	42–72	Muscle length
	SAII	Ruffini corpuscle	A $\beta$	42–72	Joint angle?

the ganglion cells of auditory, vestibular, visual, and gustatory systems (and much like the olfactory sensory neurons that carry information about odors into the brain), ganglion cells of the trigeminal and dorsal root ganglia also transduce all forms of somatosensory stimulation. Somatosensory ganglion cells are also receptors. Inserted at the peripheral tips of the ganglion cells' axons are two types of cation channels. One is either physically tethered to peripheral tissue (and is therefore a mechanoreceptor protein) or responsive to changes in temperature, pH, or the concentration of circulating factors that signal tissue damage (thermoreceptors and nociceptors). By way of these channels the tips of ganglion cells are depolarized to produce generator potentials. In addition, near the peripheral terminals of all sensory axons are voltage-gated Na<sup>+</sup> channels, responsible for initiation and conduction of action potentials. The best evidence suggests these voltage-gated channels are present at the first node of Ranvier in myelinated axons or at a similar distance from axon tip in unmyelinated axons (Fig. 25.1).

### Many Types of Somatosensory Receptors Innervate Skin and Deep Tissues

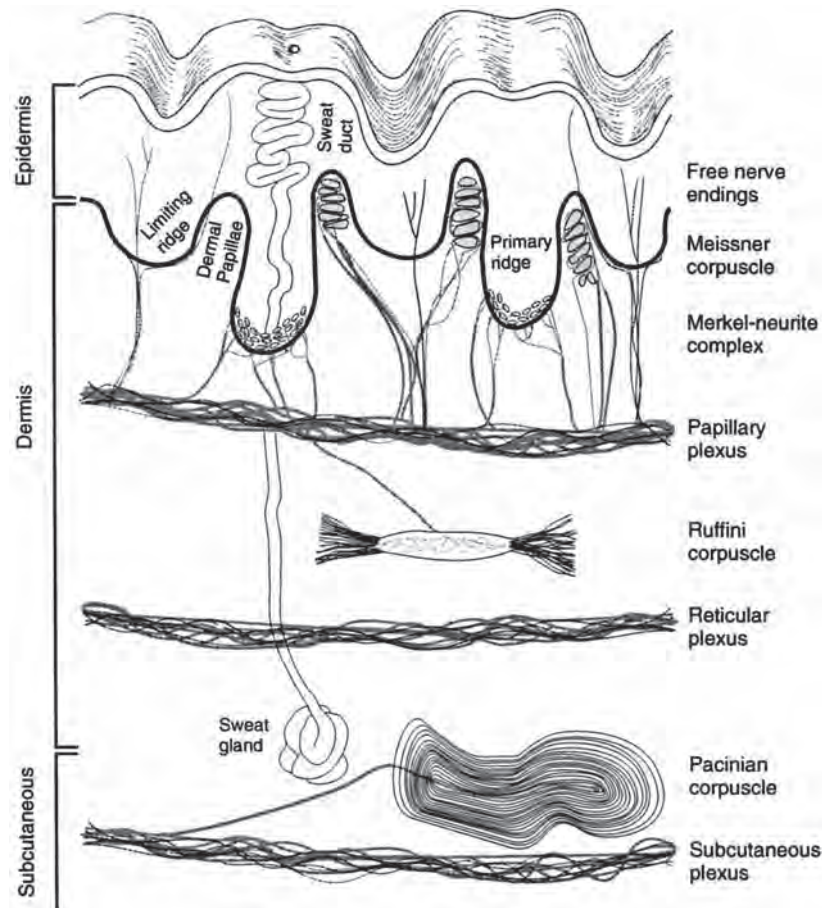

The modern tradition breaks up the axons of sensory ganglia into 13 varieties of receptors. These include four types of proprioceptors, three types of nociceptors, two groups of thermoreceptors (one each for

cooling and warming), and four types of mechanoreceptors. That is a decidedly conservative point of view. At a minimum it leaves unmentioned the class of D-hair receptor or hair follicle afferent and it recognizes only the major type of nociceptors. Molecular and functional distinctions among the nociceptors alone add enough additional types to make the list approach 20. The point here is not to split peripheral receptors into the greatest number of types, but to emphasize the unusual nature of somatosensory transduction.

### Mechanosensory Axons of Glabrous Skin Are Split into Four Types

Four types of mechanosensory axons are found in the hairless or glabrous skin and immediately adjacent deeper tissues of the human body (Fig. 25.3). Whereas a decade ago it would have seemed a radical thought, we now recognize the four receptors are responsible for specific functions. These include peripheral events that lead to perception of form and texture, detection of object slip leading to adjustment of grip, sensory feedback necessary for the use of tools, perception of vibration, and perception of hand shape and limb position (Table 25.1).

All mechanoreceptors conduct action potentials in the A $\beta$  (type II) range, so no distinction can be made among them in that property. Rather it is in the response of the axon to a ramp-and-hold stimulus that

**FIGURE 25.3** Peripheral receptors of the hairless (glabrous) skin are present in dermis, epidermis, and subcutaneous tissue. Superficial receptors at the dermis-epidermis border include the free nerve endings of nociceptors and thermoreceptors, the rapidly adapting afferents associated with Meissner's corpuscle, and the type I slowly adapting afferents that end as Merkel's disks. Deep receptors include a rapidly adapting receptor enclosed by a Pacinian corpuscle and a type II slowly adapting afferent in some species. Those SAI afferents are associated with Ruffini corpuscles in domestic cats but appear to have some other arrangement in most of the human hand. SAI afferents are missing from the skin of macaques and mice. From Johnson, K. (2002).

the four types become clear. Two types of afferents respond at elevated rates for as long as a blunt mechanical stimulus is applied to its receptive field. These are slowly adapting (SA) afferents, and they can be further divided into SAI and SAI types based on differences in their response to the applied stimuli (Fig. 25.1). Two other types of mechanoreceptor afferents are frequently called rapidly adapting (RA) or sometimes fast adapting or quickly adapting because their response to a prolonged indentation of skin is a spike or two at onset of the stimulus, perhaps a single spike at offset and nothing in between. They, too, are split into two varieties, RA and PC, differing principally in their sensitivity and response to vibrating stimuli (see later). We should also point out some investigators object to the use of the term, adaptation, to describe this change in a mechanoreceptor axon's response because, as we

will see, it is not the axon that adapts but the tissue around it. Nevertheless, the terms rapidly adapting and slowly adapting are illustrative and are in common usage, so will we use them here.

### *Pacinian Corpuscles*

The work of Iggo and Muir in the late 1960s established a consistent relationship between the four types of peripheral mechanoreceptor axons and the morphology of axon tips, or more properly of the axons' relationship with nonneural cells. For three of the axons this structure-function relationship has held up well. The clearest example is that of the PC afferent, the unmyelinated tip of which ends as part of a Pacinian corpuscle. Unmistakable in its onion skin-like structure, the Pacinian corpuscle serves as a connective tissue filter of low frequency mechanical

stimuli such as sustained pressure applied to the skin (Fig. 25.3).

PC afferents are exquisitely sensitive to vibration. They display a peak response near 200 Hz with skin indentations of no more than 10 nm. Yet as pointed out earlier, a single indentation of the skin surface produces only a couple of spikes from these axons. Careful dissection of the connective tissue that surrounds the PC axon shows the axon itself is capable of generating a steady burst of action potentials with continued application of a blunt probe. The axon does not adapt. Rather, a change in structure of the fluid-filled capsule carries the energy of a continually applied probe away from the axon tip and closes the cation channels responsible for mechanical transduction. By contrast, repeated application of a mechanical stimulus, such as occurs with a tuning fork vibrating at 200 Hz, produces a series of discrete transduction events and a series of action potentials. We can say with great confidence, then, that PCs are responsive to high frequency vibration at even the smallest magnitude. This extreme sensitivity to vibration turns the PC afferent into a detector of remote events. These are the receptors, for example, that respond as hands gripping a steering wheel vibrate when a car travels over a rough road. As a more common and practical matter the minute vibrations transduced by PC afferents provide information about the texture of surfaces during the manipulation of tools.

### *Meissner's Corpuscles*

Lower frequency vibration, sometimes called flutter, produces a maximal response in RA afferents. As is the case of PCs, the correlation between this type of response and the structure of the afferent axon and its surrounding tissue is consistent. Each RA afferent ends as a stack of broad terminal disks within a Meissner's corpuscles. Both divergence and convergence is seen in the relationship between corpuscle and axon. Two RA afferents end in a Meissner's corpuscle whereas each afferent innervates anywhere between 20 and 50 separate corpuscles. In addition to the  $A\beta$  axons, C fibers are also present in Meissner's corpuscles of monkey glabrous skin. Whether these axons play a role in mechanosensation or provide the Meissner's corpuscle with nociceptive and thermoreceptive properties is not yet known.

The anatomy of the RA afferent says a great deal about what this mechanoreceptor does. Meissner's corpuscles are found in dermal pockets of the adhesive ridges, as close to the epidermis as any dermal structure can be (Fig. 25.3). And their density is extraordinary, approaching  $50\text{mm}^2$  in the index fingertip of a young adult. The result is an afferent very sensitive to even the slightest stretch of skin, as happens when a

slippery object moves in the hand. Yet the levels of divergence and convergence from a single RA afferent lead to large receptive fields ( $5\text{mm}^2$ ). That feature and the filtering properties of the connective tissue capsule make them inappropriate for form and texture perception. RA afferents are responsible, instead, for the detection of objects slipping across the hand and fingers. They provide the sensory information that leads to the adjustment of grip force.

### *Merkel's Disks*

Of the two slowly adapting afferents, SAIs end in a manner that prompts no arguments. A single SAI axon breaks into several branches that end in several closely packed dermal ridges. Each branch ends in a series of axon terminals and each terminal is enfolded by an epidermal Merkel cell. This confluence of dozens of axon terminals and their Merkel cells produces a surface elevation called a touch dome in the skin of cats and in the hairy skin of humans.

Years of study have brought us little closer to answering the question of what the Merkel cell does. Merkel cells contact the tips of SAI afferents by what look to be chemical synapses, and vesicles in the Merkel cell are filled with the amino acid neurotransmitter, glutamate. There are as yet, however, no clear indications that Merkel cells are capable of transducing a mechanical stimulus or that SAI afferents respond to chemical agents Merkel cells might release. Most data point to the axon tips of the SAI afferent as the site of mechanical transduction and so the prevailing wisdom at this time suggests Merkel cells work as supporting elements only.

### *SAI Afferents Are Responsible for Form, Texture, and Curvature*

Studies by K. Johnson and S. Hsiao and their colleagues established the SAI afferent as the source of peripheral information used by the CNS to perceive both form and texture. Parallel studies by R. LaMotte and T. Goodwin and their colleagues documented a role of SAIs in the perception of object curvature. Form perception is approachable by a combination of psychophysics and neurophysiology because its dimensions are readily quantifiable. When the performance of individual receptors on the surface of a monkey's finger pad is compared with the performance of the monkey itself, only one type of afferent is sensitive enough to account for the animal's ability to discriminate the form of a mechanical stimulus. That receptor is at the tip of SAI afferents ending in Merkel's disk. One example is seen in the response to the type of dots used in Braille (Fig. 25.4). Only the SAI afferents respond to the minute edges present in these embossed

**FIGURE 25.4** Response of peripheral axons to a Braille pattern of dots scanned over the surface of a human fingertip at a rate of 60 mm/s, with 200- $\mu$ m shifts in position after each pass. Dots represent individual action potentials. Only the response of the SAI afferents (Merkel disk receptors) follows the Braille pattern faithfully, whereas RA afferents and Pacinians (PC) produce a response that distorts the input. SAIs display little response to this stimulus. Adapted from Phillips *et al.* (1990).

dots (6.0 mm high or greater) so accurately as to account for the ability a monkey or a human has in telling one pattern from the next.

Peripheral factors contribute significantly to the SAI's contribution to form and texture perception. One of these factors is the unique sensitivity of SAI afferents to strain energy density, a term that Johnson describes as "the energy required to produce local deformation" per unit volume of skin. Thus rather than responding to the total energy generated by application of a uniform stimulus, SAI afferents respond to even the slight imperfections in that surface and the local deformation of skin they produce. Movement of the skin across a surface, as in scanning Braille, greatly increases the energy produced by any imperfection and leads to a greatly enhanced response by SAI afferents. This finding has a strong intuitive feel to it, given the much greater tactile acuity each of us has when we move a fingertip along a surface with even slight imperfections.

A second peripheral factor is that of surround suppression. Skin mechanics lead not only to local peaks in strain energy density but also to broader troughs. The result for any single SAI afferent are hot spots in its receptive field surrounded by tissue that, when simultaneously probed, leads to a reduction in the response of that afferent. An average terminal domain for an SAI afferent on the finger tip may be as much as 5 mm<sup>2</sup>, but the presence of hot spots and surround

suppression permits these afferents to signal the presence of a stimulus (such a gap between two elevations) of as little as 0.5 mm.

In contrast to tactile form, texture has relatively few dimensions (rough-smooth, hard-soft, and sticky-slippery are the most prominent) but they are difficult to quantify. Nevertheless, a series of careful studies has documented that for variations in roughness, only the response of SAI afferents matches human perceptual ability. That is, the variation in firing rates among SAI follows precisely the perception human subjects have of surface roughness. Much the same can be said for the detection of surface hardness. Only the response of SAI afferents can account for human perception of how hard or soft is the surface of an object scanned by the fingertips. In summary, a combination of physiological and psychophysical studies leads one to conclude that SAIs provide the central somatosensory system with all the information it needs to detect the shape, hardness, and roughness of objects pressed or scanned across the skin.

#### *SAII Afferents*

A second slowly adapting afferent in human skin, the SAI afferent, differs from an SAI in the greater size of its receptive field, the reduced sensitivity to simple indentation of the skin, and the greater sensitivity to skin stretch. One surprising feature of these afferents is the less than universal presence of SAIs across the

short range of well-studied mammals. Direct recordings from the peripheral nerves of humans and of domestic cats show these afferents to be a commonly encountered feature of both species, but they do not exist in monkeys or mice. Just as perplexing is the poor correlation between structure and function with this receptor. The original correlative work in cats found SAI responses to arise from axons terminating in skin as Ruffini endings. These structures were first described in human skin at the turn of the twentieth century, but a twenty-first century study by M. Pare and colleagues found true Ruffini endings in human skin very rarely and only in the bed of fingernails. These findings indicate SAI responses over most of the human hand arise from some other arrangement of mechanoreceptor axon and connective tissue sheath. Recent recordings from human peripheral nerves have added to the conundrum by documenting the presence of a third SA variety—labeled SA3—that has properties intermediate between the other two slowly adapting types. A conservative conclusion from these findings is that some arrangement of nonneural cells, perhaps a classic Ruffini in cats but another configuration in humans, leads to the cardinal feature of SAI afferents, namely a robust response to skin stretch. That configuration could vary from one species to another and from one area of skin surface to the next, but in the end the nonneural tissue serves as a mechanical filter. Given the task of subtracting from the activity of a SAI afferent a response to simple deformation of the skin, the nonneural tissue leaves behind an unambiguous response to anything that stretches the skin.

### Hair Follicle Afferents

In addition to receptor types found in glabrous skin, hairy skin is innervated by a separate receptor, called the D-hair receptor or hair follicle afferent (HFA). It is the most sensitive receptor in hairy skin. The HFA threshold is said to be one-tenth that of any other afferent in mouse skin, and displacement of a hair follicle by as little as  $1\mu\text{m}$  produces robust responses in this population of receptors. Single afferents innervate more than one hair follicle and as a result, the receptive field of an HFA is large ( $>10\text{mm}^2$  in mice). Unlike other mechanoreceptors, HFA's conduct action potentials in the  $A\delta$  range, which translates into a velocity of 20–25 m/s for humans but a much lower velocity in mice.

### Receptor Density

A plot of SAI and SII receptors along the human skin surface shows receptive field size and density varies by a factor of four in the short distance from the fingertip to the wrist. As is the case for other sensory

systems, wherever receptor density declines receptive field size ascends. This inverse variation in receptive size and density is reflected in the ability of a human subject to discriminate the two-dimensional shape of an object. Human performance in this area has been measured classically as two-point discrimination (Fig. 25.5). Two blunt probes applied to a skin surface can be moved together to produce a perception of a single probe. How close they can be and still produce the percept of two separate probes says something about the receptive field size and density of receptors that underlie the function referred to as fine touch. Normal human subjects are able to detect two probes separated by as little as one millimeter on the surface of the distal pad of the index finger and face. Acuity declines in other regions of the body and is poorest on the back where two points cannot be distinguished from one until they are about 70 mm apart. Regions of high spatial acuity (the hand and face) are where form perception is greatest and are analogous to the fovea of the retina.

## Muscle Spindles and Golgi Tendon Organs Are Proprioceptors

The most prominent receptors fulfilling the function of sensing position and movement are muscle

**FIGURE 25.5** Variation in two-point limen (threshold) across the body surface. The graph plots the distance necessary for a human subject to detect two blunt probes as separate stimuli. That distance is lowest for the fingertips and mouth (approximately 10 mm) and highest for the legs, shoulders, and back (as much as 70 mm). From Patton, H. D., Sundsten, J. W., Crill, W. E., and Swanson, P. D. (eds.) (1976). "Introduction to Basic Neurology," p. 160. Saunders, Philadelphia.

receptors and tendon receptors. These two have in common their sensitivity to stretch and the large diameter of the axons that carry the receptors' activity into the CNS. The manner in which they are arranged, however, makes all the difference in the world. Muscle receptors are arranged in parallel with the muscle fibers and as a result, these afferents respond when the muscle is stretched. As a common occurrence, muscle fibers stretch when load is added to them in the form of weight or resistance. The resulting stretch of the extrafusal or work muscle fibers produces a simultaneous stretch of the much smaller intrafusal muscle fibers. The intrafusal fibers have their own motor

innervation and a sensory innervation from the largest diameter axons in a sensory nerve (Fig. 25.6). These sensory axons are called Ia afferents and they end in one of two configurations around the noncontractile portion of an intrafusal muscle fiber, where they signal the static or dynamic aspects of muscle stretch. All of these—sensory axons, intrafusal muscle fibers, and motor axons—are surrounded by a connective tissue capsule to form a muscle spindle. The contribution of the motor axons to all this is rather simple to envision—by adjusting the contractile state of the intrafusal muscle fiber, they adjust the sensitivity of the muscle afferent. When the intrafusal fiber is contracted

Copyright © 2002, Elsevier Science (USA). All rights reserved.

**FIGURE 25.6** Proprioceptive afferents. (A) Golgi tendon organs and their termination along collagen fibers of the tendon capsule. These afferents respond when the entire capsule is stretched, usually by overvigorous contraction of the muscle. (B) Muscle spindle afferents (Ia and II) terminate on the noncontractile portions of intrafusal muscle fibers. They are arranged in parallel with work muscle fibers and respond to stretch of the entire muscle. Specialized motoneurons ( $\gamma$ ) provide the motor innervation of the intrafusal muscle fibers and control the overall sensitivity of the muscle spindle.

the spindle is at its most sensitive and when the intrafusal fiber is relaxed, the spindle is least sensitive.

Much as muscle receptors are sensitive to muscle stretch, tendon receptors (referred to as Golgi tendon organs) are sensitive to tendon stretch and provide information about muscle force. Because tendons are arranged in series with the muscles, so too are tendon receptors. What stretches the tendon is muscle contraction. In this regard, muscle spindles and Golgi tendon organs signal the opposite trends. Spindles fire when a muscle is relatively inactive and stretched whereas tendon organs fire when the muscle is most active and contracted.

### Proprioception Involves More Than Proprioceptors

By a definition of proprioception as an awareness of the position of the body and limbs, the two most prominent proprioceptors are necessary but not sufficient. More than just muscle and tendon receptors are at work. The related sense of kinesthesia, or awareness of position of moving body parts, is equally complex. Often used interchangeably for position sense, these two are complex percepts that require the contribution of receptors in muscle, skin, and joints as well as a sense of muscle exertion. Studies of the 1950s and 1960s focused on the contribution of joint afferents to a sense of limb position. The connective tissue and bones of joints are richly innervated and would seem to be in an ideal location to signal limb position. Yet a series of findings in the 1970s made clear that a sense of position survived joint removal; and the joint afferents, themselves, responded only at the extreme limits of joint flexion. With no response in the usual, midrange of joint movement, these afferents could not signal position under most circumstances.

Studies of more recent vintage have dealt principally with muscle spindle afferents as a major source of the position signal. Since all muscles are organized as antagonistic pairs, contraction of one delivers a robust stimulus to afferents of the antagonistic, stretched muscle. From these sorts of inputs, limb position and movement would appear to require a simple neural computation. That position sense is significantly affected by stimulation, anesthesia and disengagement of spindle afferents adds weight to the argument that the burden of signaling limb position and movement falls on these receptors. Perhaps the most convincing data are from studies of illusory movements produced by tendon vibration. This type of stimulus selectively activates spindle afferents and leads to the perception of limb movement when none has occurred. Illusory

movement is muscle specific, so that activation of arm flexors gives rise to the percept of an arm that has extended (a movement that normally produces activation of flexor muscle afferents). The illusion is so strong it gives rise to the Pinocchio effect: if arm flexor afferents are activated when a subject is touching his or her nose with an index finger, the nose itself, is perceived to grow.

Only in the past several years has proper attention been paid to the role of cutaneous receptors in position sense. In recording from peripheral nerve axons of human subjects, B. Edin has made a strong case for a unique response by an ensemble of SAII afferents to any position a limb or digit might adopt. Particularly compelling is the role these skin stretch receptors play in signaling the position of fingers. For the hand and fingers, therefore, a conscious sense of position appears to arise from the cooperative activity of SAII afferents, muscle afferents, and (at the extremes of movement) joint afferents.

## NOCICEPTION, THERMORECEPTION, AND ITCH

### Nociceptors Respond to Noxious Stimuli

For most purposes anything that has produced tissue damage or that threatens do so in the immediate future can be defined as noxious and the type of axon that responds selectively to the noxious quality of a stimulus is, by definition then, a nociceptor. These are not pain receptors because nociception is not pain just as sensitivity to the wavelength of light is not color perception. Both are CNS constructs of peripheral events. Unlike color, pain has not only a perceptual component that involves comparison across receptors but also rich psychological and cognitive components. We will deal with those elements of pain perception but for now the most important principle to grasp is also intuitively obvious: the range of stimuli that are perceived as painful is very broad, from heat above 42°C to acids below pH6, from a sharp pinch on the fingertip to a swollen ankle. Each of these is tied to the activity in a variety of nociceptors.

True for all nociceptors is the simple morphology of their axon terminations. These are usually described as free nerve endings because unlike mechanoreceptive afferents, nociceptors end in no specialized capsule of nonneuronal cells. Another way of looking at this relationship is to notice that nothing extraneuronal serves as a filter or buffer between the nociceptive axon tip and its immediate environment. The only thing that

determines the response of a nociceptor, then, is the type of protein receptor it inserts into its membrane.

Nociceptors also differ from mechanoreceptors in how broadly the terminals of the peripheral axon branch as they reach target. Take the tip of the human index finger as an example. An individual SAI and SAI axon ends in a well-confined cluster of terminals over a distance as small as a few millimeters. Terminals of a single C fiber, by contrast, end over an area of more than a dozen millimeters. This is the first of several anatomical features along the nociceptive pathway that, together, produce a much coarser spatial sense for pain than exists for mechanosensation. Only the simultaneous activation of mechanoreceptors as occurs with puncture wounds or damaging compression permits a person to accurately detect the location of a nociceptive stimulus.

The afferents that make up the nociceptive population can be subdivided into groups that are named by their axon conduction velocity ( $A\delta$  vs. C) and the response to noxious mechanical stimuli and noxious heat. Thus, an AM receptor conducts in the  $A\delta$  range and responds to intense mechanical stimuli whereas a CMH receptor conducts in the C range and responds to both noxious mechanical energy and noxious heat (Fig. 25.1). Other permutations of conduction velocity and response type are evident in the peripheral nerves of humans and other mammals, but these two are most common. They are frequently referred to as specific mechanical nociceptors and polymodal nociceptors.

### First and Second Pain

Many afferents responding specifically to a mechanical stimulus (AM receptors) carry the more rapid signals into the CNS, whereas those responding to the broad range of noxious stimuli (CMH receptors) conduct action potentials more slowly. These are the peripheral components to the two very different qualities of pain perceived by humans (Fig. 25.7). First pain or epicritic pain is rapidly perceived and carries with it much that is discriminative. A person can quickly and with some ease figure out what has happened and where it has happened when he or she drops a heavy object onto a toe or touches a hot stove surface with a couple of fingers on the right hand. First pain is informative and the peripheral component of it is the population of  $A\delta$  nociceptors. What follows later is second pain or protopathic pain. This is agonizing pain that carries much less information about location or source of energy. Second pain is punishing pain that serves to change the behavior of a person. Its peripheral component is the population of C nociceptors.

FIGURE 25.7 The two classes of nociceptors that conduct action potentials in the C and  $A\delta$  ranges are peripheral components for two types of pain. First pain carried by  $A\delta$  axons reaches consciousness rapidly and is discriminative. Both the location and the subjective intensity of the stimulus can be judged with relatively good precision in first pain. Second pain, in contrast, is much slower and is agonizing pain, with greatly reduced discriminative value.

Two varieties of C nociceptors are found in mammalian skin. One of these is characterized by the presence of fluoride-resistant acid phosphatase (FRAP) in its cytoplasm and cell-surface glycoproteins recognized by the isolectin I-B4 and the monoclonal antibody LA4. As none of these proteins is known to contribute to the physiological features of this C fiber type their presence is currently a convenient feature that allows anyone studying them to recognize and target them. The situation is very different in the second type of C nociceptor. Present in its cytoplasm are two neuroactive peptides, calcitonin gene-related peptide (CGRP) and substance P. These play major roles in the function of the peptide-containing type of C nociceptor.

### The Axon Reflex

Release of neuropeptides from the second type of C nociceptor is responsible for the axon reflex (Fig. 25.8). Injury to the skin surface is often well confined, as happens with a paper cut, for example. Yet within a short time of that injury, tissue surrounding the cut becomes reddened in what is referred to as flair and edema or swelling sets in as the tissue fills with fluid. Most importantly, the region surrounding a punctate wound becomes painful to touch even though it is outside the zone of direct damage.

**FIGURE 25.8** The axon reflex is a mechanism by which a class of C fibers communicates with both the spinal cord and peripheral cells. Action potentials are generated at one branch of a peptide-containing C fiber through tissue damage and the release of chemical signaling factors, including bradykinin and prostaglandin. Those action potentials invade not only the central branch of the axon but also the other peripheral branches. Substance P and CGRP released from the terminals of the C fiber induce mast cells to release histamine and promote swelling by widening arterioles and shrinking the diameter of venules.

Recall that an individual C fiber terminates over a wide area in skin, and so it is very likely that a punctate wound directly affects only a fraction of all that fiber's many branches. Action potentials generated at those directly affected branches invade all the peripheral branches as well as the parent axon that conducts the signal to the CNS. At all the peripheral terminals, substance P and CGRP are released onto two principal targets, the smooth muscle surrounding peripheral blood vessels and histamine-rich mast cells. By causing the arterial smooth muscles to relax, the peptides increase the flow of blood into the neighborhood of damaged tissue and produce a flow of water and electrolytes out of capillaries and into extracellular space. This process is referred to as extravasation. Histamine released from mast cells leads to a pronounced inflammatory response. All of this is important for the infiltration of damaged tissue with cellular elements that will protect against infection and promote repair. Yet what is most salient about the axon reflex is the much greater sensitivity of the tissue surrounding a wound to anything that might be noxious. This primary hyperalgesia is a direct result of the axon reflex, produced because the protein receptors inserted into nociceptive axons are sensitive to chemical changes produced by that reflex.

Both the histamine released by mast cells and the edema resulting from extravasation affect the response of nociceptors. Histamine's effects are more selective,

as only a subclass of the most slowly conducting C fibers insert histamine receptors into the membranes of their axon terminals. A considerable body of evidence suggests these are peripheral receptors whose activity leads to the unpleasant percept of itch. A parallel system for itch that operates independently of histamine release has been discovered recently but the population of afferents involved is not yet known.

Edema causes a general reduction in pH of extracellular fluid from 7.4 to below 6.0. As outlined later, a general feature of protein receptors inserted into nociceptive axons is their sensitivity to the concentration of  $H^+$ . By this path, activation of one branch of a C fiber leads to increased sensitivity of all its branches and all neighboring nociceptors to noxious stimulation. At least some of those neighboring nociceptors are likely to be silent nociceptors, so named because they are unresponsive to intense mechanical stimulation under normal circumstances. When activated by changes in pH or the presence of factors that signal the presence of tissue damage (see later) the silent nociceptors become responsive to noxious stimuli.

### Chemical Sensitivity of Nociceptors

Two of the most powerful pain-inducing chemicals that can be delivered to a human observer are natural products of tissue damage. They are lipids of the prostaglandin family and the nonapeptide bradykinin

(Fig. 25.8). Prostaglandins are derivatives of the membrane fatty acid, arachidonic acid, which is itself a major component of the lipid bilayer. Damage to tissue and the resulting disruption of cell membranes releases arachidonic acid into extracellular fluid, where it is broken down by the enzyme, cyclo-oxygenase (COX), to form prostaglandin. Inhibitors that target both forms of COX or more specifically target the COX-2 enzyme are taken by the hundreds of thousands every day to relieve pain. These are referred to as nonsteroidal anti-inflammatory drugs (NSAIDs) and they include over-the-counter drugs such as aspirin and ibuprofen. Their popularity is a powerful indication of effectiveness in suppressing pain by interfering with the production of prostaglandins.

### Nociceptor Proteins

Polymodal nociceptor activation occurs by way of a widespread family of receptor channels referred to as transient receptor potential (TRP). Relevant to the function of nociceptors is the subfamily of TRP-V channels, particularly of the channel protein TRPV-1 (Fig. 25.9). The V in the channel's name refers to its sensitivity to vanilloids, the active ingredients of chili peppers. TRPV-1 is a nonspecific cation channel with

**FIGURE 25.9** The receptor protein, TRPV-1, provides a nociceptor with the ability to respond to many noxious stimuli. In addition to heat, TRPV-1 is directly gated by a reduction in pH (the presence of H<sup>+</sup>) produced in response to tissue swelling. Either or both opens a nonspecific cation channel that, through an influx of Na<sup>+</sup>, depolarizes the nociceptor axon. Circulating agents that signal the presence of tissue damage (ATP and bradykinin) bind to a G-protein coupled receptor (GPCR). Through a series of steps PKC $\epsilon$  is activated and TRPV-1 subunits are phosphorylated, leading to a sensitization of the receptor. One result of that cascade is an opening of the cation channel at body temperature. Adapted from Caterina, M. J. and Julius, D. (2001).

approximately 10 times more permeability to Na<sup>+</sup> than to Ca<sup>2+</sup>. Like other members of the TRP-V subfamily, TRPV-1 is a molecular thermometer that opens in response to increased temperature. What makes TRPV-1 a receptor responsive to other noxious stimuli is the effect these stimuli have on the threshold for channel opening. When exposed to high concentrations of H<sup>+</sup> or to agents such as prostaglandins or bradykinin the threshold temperature at which the channel opens descends to normal body temperature. By this mechanism, each of several distinct noxious stimuli elicits the same neural response by opening the same depolarizing channels in the population of polymodal C nociceptors.

### CNS COMPONENTS OF SOMATIC SENSATION

The central paths taken by large diameter afferents and small diameter afferents tell two stories worth paying attention to. The first is that the path for mechanosensation and proprioception are separate and largely distinct from the path for nociception and thermoreception. These separate paths continue through the CNS to cerebral cortex and represent one of the clearest divisions of labor seen in any sensory system. The second story is seen in the multiple targets contacted by each population of axons. Here the lesson repeats a statement made at the beginning of this chapter. The somatosensory system has many tasks to perform, from the input side of motor reflexes to the higher order functions of perception, comprehension, and emotion. To accomplish them, mechanosensory/proprioceptive and nociceptive/thermoreceptive axons send information along several pathways performing separate functions.

### An Outline of Ascending Paths to Perception (Fig. 25.10)

Primary afferents in the somatosensory system terminate on second order neurons in either the spinal cord (nociceptors and thermoreceptors) or medulla (mechanoreceptors and proprioceptors). Second order neurons in the spinal cord and medulla send their axons across the midline to terminate in thalamus. Convergence is kept to a minimum so that second order mechanosensory and nociceptive neurons end in separate nuclei and subnuclei of the thalamus. In addition, axons of particular submodalities (e.g., muscle spindle afferents vs. cutaneous afferents) end in different subnuclei of the thalamus. The major thalamic

**FIGURE 25.10** Anatomy of ascending somatosensory paths. (A) Organization of the dorsal column-medial lemniscal system from entry of large-diameter afferents into the spinal cord to the termination of thalamocortical axons in the first somatosensory area of the cerebral cortex. An obligatory synapse occurs in the gracile and cuneate nuclei, from which second-order axons cross the midline and ascend to the ventral posterolateral nucleus of the thalamus (VPL) by way of the medial lemniscus. (B) Organization of the spinothalamic tract and the remainder of the anterolateral system. Primary axons terminate in the spinal cord and brain stem. Second-order axons cross the midline and ascend through the spinal cord and brain stem to terminate in VPL and other nuclei of the thalamus. Collaterals of these axons terminate in the reticular formation of the pons and medulla.

nuclei involved are the various parts of the ventral posterior complex (referred to as ventral caudal in human studies). The lateral and medial subnuclei of VP, logically named VPL and VPM, are the recipients of discriminative inputs from the body and face, respectively. Both innervate the first somatosensory cortex (SI) and a third subnucleus, VPI, sends its axons to the second somatosensory area (SII).

SI and SII are recognized in the cerebral cortex of all mammals that have been examined (Fig. 25.11). Yet the organization of each appears to vary considerably

across that class. If we take human cerebral cortex as a starting point, SI is traditionally divided into four structurally distinct areas named (from rostral to caudal) areas 3a, 3b, 1, and 2. The same is seen for the best-studied genus of monkeys, the macaques. What stands out in the organization of these four is the combination of serial and parallel processing. Parallel processing is seen in the types of thalamic neurons that innervate each area and the receptive field properties displayed by those cortical neurons. Areas 3b and 1 most often are characterized by the response of neurons to cutaneous

**FIGURE 25.11** Functional organization of the ventrobasal complex and first somatosensory cortex (SI). (A) Location of SI in the postcentral gyrus and its relationship to SII and the somatosensory association cortex in the posterior parietal lobe. (B) Cross-section through the postcentral gyrus, cut orthogonal to the central sulcus. SI is divided into four anatomically and functionally distinct areas. They are bordered by area 4 of the precentral motor cortex and by area 5 of the parietal association cortex. (C) Relationship between regions of cutaneous and deep input to VPL and the termination of thalamocortical axons in SI. The serial processing of somatosensory inputs also is indicated by the projections from one area of SI to others and from all areas in SI to the second somatosensory area (SII). Adapted from Jones and Friedman (1982).

inputs, SAs and RAs, whereas neurons in area 3a are found to respond exclusively to stimulation of deep receptors and neurons in area 2 respond to both.

Serial processing of information is evident in both the physiology and connectivity of these areas. Area 3b is much more richly innervated by VPL and VPM than any of the other three areas of SI and, in terms of its structure and connectivity appears much more of a primary sensory area. Comparative studies suggest that area 3b of rhesus monkeys and humans is in most ways equivalent to all of SI in other mammals and so this area often is referred to as SI Proper. The principal outputs of area 3b are directed caudally to areas 1 and 2; and in a similar fashion, area 1 sends its own rich set of axons to area 2. From these considerations, a hierarchy emerges, with area 2 at something of a pinnacle, in that it receives a direct deep receptor input from the thalamus, indirect deep input from 3a and an indirect cutaneous input from areas 3b and 1.

The output of SI as a whole is in two directions (Fig. 25.12):

- A ventral path to SII and from there to caudal insula, areas of the temporal lobe and to premotor and prefrontal cortical areas. Eventual convergence of somatosensory, auditory, and visual information in medial temporal lobe is viewed as the path toward shape and form processing. This ventral path is vital for inserting new information into declarative memory and accessing established memories for comparison with ongoing events.
- A dorsal path to superior parietal lobule, providing areas in that lobule with somesthetic information for control of voluntary movements, selective attention and information about how to perform different tasks, sometimes known as the “how” pathway.

**FIGURE 25.12** Schematic representation of the path taken by mechanoreceptor input to eventually reach three cortical targets. All relevant information reaches the ventrobasal complex and most is relayed to the areas of SI. From there, by steps through SII and the posterior parietal areas, somatosensory information reaches (1) the limbic system (entorhinal cortex and hippocampus), as a means for becoming part of or gaining access to stored memories; (2) the motor system (primary and supplementary motor cortex), where the continuous sensory feedback onto motor system occurs; and (3) the polysensory cortex in the superior temporal gyrus, in which creation of a complete and abstract sensory map of the external world is thought to occur. Adapted from Wall (1988), with permission.

With these essential elements in mind we will consider separately the paths for mechanosensation and nociception from the entry of primary afferents into the spinal cord to the areas of cortex in which the elements of sensation are brought together into a perceptual whole.

### The Path for Mechanosensation for the Body

Dorsal columns are the principal routes for spinal mechanoreceptor axons. All axons of sensory ganglion cells enter the CNS by way of dorsal roots and the trigeminal nerves. At a gross level the spinal cord is

segmented by the existence of separate dorsal root ganglia. Because the peripheral tissue innervated by any one dorsal root ganglion is restricted, the entire innervation of the body surface can be seen as a series of overlapping bands. These are the dermatomes (Fig. 25.13). As a practical matter, then, a mechanical stimulus applied to a restricted region of the body surface leads to action potentials conducted in one or at most two dorsal roots.

### *Mechanosensory and Nociceptive Axons Enter the Cord Along Different Paths*

The dorsal roots divide after they have penetrated the dura mater but before they have entered the spinal cord itself. A medial division of large-diameter, heavily myelinated axons enters at the dorsal funiculus of the cord and the majority of those axons turn at right angles after they have entered the cord and ascend

**FIGURE 25.13** Classic dermatomal map showing the distribution of spinal nerves and the segments from which they arise. Despite extensive overlap between nerves arising from adjacent segments, this map permits localization of injuries and other conditions that give rise to restricted sensory deficits.

toward the brain. From level T7 of the cord to the terminal coccygeal segment, the large diameter axons enter one fiber tract called the gracile fasciculus. And as they do so they stack up as thin sheets with the earliest entering axons (coccygeal) occupying the most medial part of the funiculus and the last entering (7th thoracic) occupying the most lateral part. That same medial-to-lateral pattern continues with large axons that enter from T6 up to the first cervical segment but at those levels the axons form a separate fasciculus, called the cuneate fasciculus. Together the gracile and cuneate fasciculi are called the dorsal columns. The orderly pattern established by the axons of the dorsal columns as they ascend means there is a body map or somatotopy to the ascending mechanosensory system. Large diameter axons ascend on the same side of the spinal cord as the one they entered to reach the lowest levels of the medulla.

### *Dorsal Column Nuclei*

In a path toward sensory perception, the majority of axons in the dorsal columns ascend to reach the dorsal column nuclei at the junction of the spinal cord and medulla. The dorsal column nuclei are neither simple nor homogeneous. At the grossest level, each nucleus is divided into at least three regions in which group I afferents (mainly muscle spindle afferents), PC axons, and SA axons terminate separately. In some species the neurons receiving spindle inputs are sufficiently distinct to be given their own name (nucleus Z). All this serves to accent the role played by subcortical somatosensory nuclei in keeping segregated the input from different functional classes of receptors. At a finer level the dorsal column nuclei are broken up into clusters of large relay neurons separate from one another by bundles of axons and groups of small cells. These also serve to keep afferents segregated since, as seen in one example, mechanosensory axons from adjacent toes terminate in adjacent but separate clusters.

Despite an anatomical convergence of primary afferents onto single neurons of the dorsal column nuclei, convergence and comparison of receptor input appears minimal. Studies in the laboratory of M. Rowe have shown that the coupling between a single neuron in the gracile or cuneate nucleus and a single afferent axon is extremely tight. As a result of this coupling, a single action potential in the afferent axon reliably produces an action potential in the postsynaptic cell. That phenomenon is seen for RA, PC and SAI afferents of the glabrous skin and hair follicle afferents of the hairy skin. These findings indicate that for a neuron in the gracile and cuneate nuclei receptive field locations, sizes and properties are a matter of which primary afferent innervates that neuron.

### *Role of Inhibition in the Dorsal Column Nuclei*

The dominant input from a single afferent leaves room for synaptic processing to play a role in the function of the dorsal column nuclei. An anatomical basis for this inhibition is the significant population of inhibitory interneurons scattered among the clusters of relay neurons. Several studies suggest inhibition suppresses a response to any input other than the most powerful afferent ending on a relay neuron. Thus, the convergence of multiple afferents on a single neuron is whittled down to the contribution of one dominant afferent by a powerful synaptic inhibition, mediated by GABAergic synaptic transmission. The peripheral source of this suppressive inhibition appears to be nociceptors, so that when C fiber activity is eliminated, receptive fields in neurons of the dorsal column nuclei grow. The route by which nociceptive input reaches the dorsal column nuclei is indirect, most likely through a population of spinal cord neurons that receive convergent mechanosensory and nociceptive innervation. Because axons of these spinal cord neurons enter the dorsal columns they are called postsynaptic dorsal column axons.

### *The Lateral Cervical Nucleus*

A cluster of mechanosensitive relay neurons is found in the lateral neck of the dorsal horn at cervical segments 1 and 2 and extends into the caudal one-third of the medulla. This is called the lateral cervical nucleus. Innervated by mechanosensory neurons in the dorsal horn throughout all segments of the spinal cord, the neurons in the lateral cervical nucleus display predominantly cutaneous receptive fields that cover large patches of hairy skin and usually some part of glabrous skin. In addition, responses to intense mechanical stimulation such as that carried into the cord by A $\delta$  mechano-nociceptors, are common in the lateral half of the nucleus. Most axons of cells in the nucleus decussate immediately and reach the contralateral VPL by way of the medial lemniscus. In VPL, the cervicothalamic axons responding to low-threshold mechanical stimulation of skin or hair appear to converge with axons that arise in dorsal column nuclei.

Nociceptive inputs to the lateral cervical nucleus are relayed not only to thalamus (VPL and POM) but also the periaqueductal gray (PAG) region in cats. The PAG is a complex region of the midbrain, populated by neurons that control functions as diverse as defense responses and sexual behavior. As outlined next, some neurons in this region are an essential part of a descending system for control of pain. The innervation of PAG

by lateral cervical neurons that respond to intense mechanical stimulation is one route by which this descending system is informed of damaging events along the surface of the skin. Moreover, this input appears to end on PAG neurons that drive a flight response and can be seen, then, as the afferent side of a reflexive response to danger.

Unlike other nuclei of the somatosensory system, the lateral cervical nucleus is an inconstant feature of the mammalian nervous system. Whereas it is a robust part of the spinal cord and medulla in rodents and carnivores and has been found consistently in nonhuman primates, it is present in only half the humans studied and is well defined in very few of them. Comparison across species also shows a marked difference in the density of cervicothalamic terminations in VPL, with the density in cats far exceeding that in rhesus monkeys. These findings lead to the assumption that functions parceled out to the lateral cervical nucleus in rodents and carnivores are sequestered in the dorsal column-medial lemniscal system of primates, and particularly of humans.

## THALAMIC MECHANISMS OF SOMATIC SENSATION

---

### Segregation of Place and Modality Continues in Thalamus

Medial lemniscal axons terminate on large neurons of VPL and VPM. As in the dorsal column nuclei, the synaptic means to generate lateral inhibitory influences exists in the thalamus but evidence for robust lateral inhibition is seldom found in these nuclei. Where inhibition has been detected, its strength across the neuron's receptive field matches that of the excitation so that the region of greatest inhibition is also the region of greatest excitation. Missing from this stage of somatosensory processing, then, is the synaptic means to produce contrast, by which activity produced by stimulation of one spot on the skin surface is compared with activity produced by stimulation of surrounding regions.

Neurons in VPL and VPM display a cluster of features labeled as lemniscal properties. Static lemniscal properties are place and modality specificity. Thalamic circuits maintain these features much as they exist in the lemniscal afferents, themselves. As a result, mixing of inputs is avoided and the specific properties of where on the body surface something has occurred and what exactly has occurred are kept anatomically distinct. Dynamic properties characteristic of these

cells include the ability to follow a rapid train of stimuli as well as the incoming lemniscal afferent. Here the synaptic organization of the thalamus favors the ability to behave much like the lemniscal afferent. Axons of the medial lemniscus terminate as a series of very large axon terminals that form synaptic contacts with broad active zones on the primary dendrites of thalamocortical neurons. These synaptic arrangements in VPL and VPM insure a faithful transfer of information.

Anatomical and physiological studies demonstrate that as lemniscal afferents terminate in VPL they do so as clusters of axon terminals elongated in the rostro-caudal dimension. They are referred to as rods. This appears to be the major organizing principle to somatosensory thalamus as lemniscal axons carrying information of the same type (e.g., SAI input) from the same part of the body terminate in a rod-like formation. On the output side, thalamocortical neurons that send axons to a 1 mm-wide patch in SI occupy the same sort of formation. Thus, thalamic rods are the anatomical basis for the most salient feature of somatosensory thalamus, the strict segregation of place- and modality-specific responses.

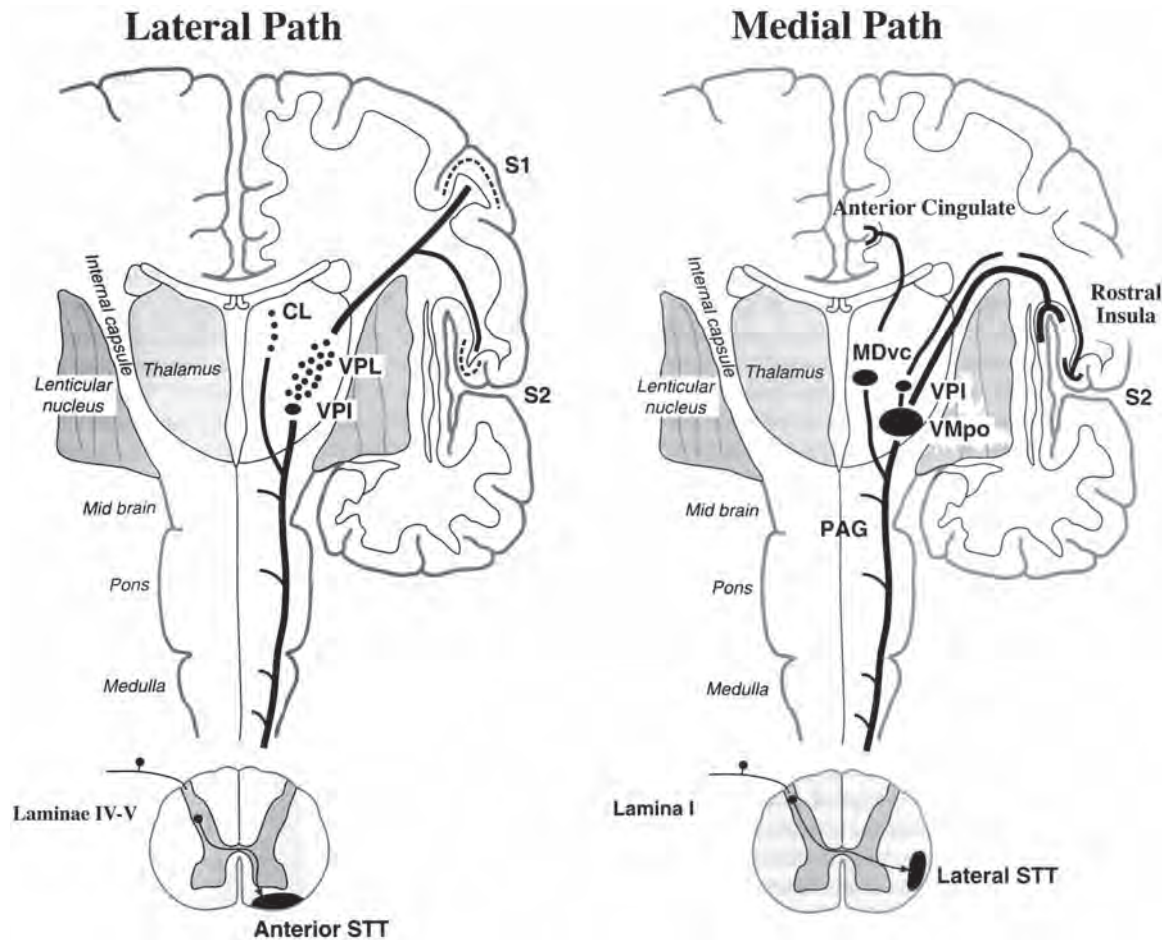

## THE PATH FROM NOCICEPTION TO PAIN

---

### Spinal Cord Pathways

In stark contrast to the pattern of input by mechanosensory axons, nociceptive axons terminate in the dorsal horn of the spinal cord. These lightly myelinated and unmyelinated axons enter the cord by way of a lateral division of the dorsal root and divide to send branches up and down the cord for a segment or two. The tract they form is a cap on the surface of the dorsal horn called Lissauer's tract. Nociceptive axons terminate, therefore, on dorsal horn neurons across four or five segments and a single dorsal horn neuron is innervated by nociceptors that cover a broad swath of the body or limb surface. A majority of second-order neurons innervated by the nociceptive axons then decussate and ascend in the anterolateral quadrant of white matter to reach the brainstem and thalamus.

Spinal cord circuits for nociception form two ascending routes with distinct functions (Fig. 25.14). Recall the peripheral basis for first and second pain is the division of nociceptors into relatively fast-conducting A $\delta$  axons and slow-conducting C fibers. Yet the discriminative versus agonizing components of pain is a CNS construct, produced by the difference in central circuits driven by A $\delta$  and C fibers. To appreciate that

**FIGURE 25.14** The path taken by spinothalamic neurons in lamina I (driven by C fibers) differs from that taken by neurons in laminae IV and V (driven by C and  $A\delta$  nociceptors and  $A\beta$  mechanoreceptors). Anterior spinothalamic tract axons are given off by the deeper neurons and terminate in lateral thalamus (VPL and VPI and the centrolateral nucleus). Lateral spinothalamic tract axons given off by lamina I neurons innervate medial thalamus, including the ventral caudal division of the mediodorsal nucleus (MDvc) and a region in posterolateral thalamus. In this figure, the region is labeled a separate, nociceptive/thermoreceptive-specific nucleus called VMpo, but several lines of evidence indicate lamina I neurons also innervate VPL and VPM, as well as VPI. From this varied thalamic innervation, nociceptive information reaches S1 and S2 for discriminative aspects of pain and temperature and the anterior cingulate and rostral insula for the affective, punishing aspects of pain. Modified from Craig, A. D. and Dostrovsky, J. O. (1999).

difference it is best to start with the population of spinothalamic neurons.

### Spinothalamic Neurons

Spinal cord neurons that directly innervate thalamus (therefore, spinothalamic neurons) occupy several laminae in rhesus monkey spinal cord. The major populations, however, are found in the most superficial layer of dorsal horn (lamina I) and a second region deeper in the dorsal horn (laminae IV and V). Nociceptive innervation of these two populations differs fundamentally. Lamina I neurons are innervated pre-

dominantly by C fibers, both directly and indirectly by way of excitatory interneurons in the immediately adjacent superficial half of lamina II. They also receive an indirect innervation from  $A\delta$  fibers by those same interneurons and can be thought of as nociceptive-specific cells. Laminae IV and V neurons, on the other hand, are innervated predominantly by  $A\delta$  fibers that end deep in lamina II on a population of excitatory interneurons. Many of these deeper spinothalamic neurons also receive a convergent input from mechanosensory axons ( $A\beta$  axons). Because they respond to both nociceptive and mechanosensory stimulation these neurons often are referred to as wide dynamic range cells.

## Ascending Paths to Thalamus

Axons from both lamina I neurons and laminae IV/V neurons decussate and enter fiber tracts in the anterolateral quadrant of spinal cord, but the tracts they enter differ from one another in location and termination (Fig. 25.14). Neurons of laminae IV and V enter the anterior spinothalamic tract and terminate in lateral parts of the thalamus, including VPL and VPI, and an intralaminar nucleus, the central lateral nucleus. The innervation of ventral posterior thalamus does not mean nociceptive and mechanosensory information converge in the thalamus. The two remain segregated as medial lemniscal axons terminate on groups of large neurons that express the calcium-binding protein parvalbumin whereas the spinothalamic axons innervate clusters of smaller neurons that express a second calcium binding protein, calbindin. Response properties of the calbindin-rich neurons in VPL are much like those of the wide dynamic range neurons that innervate them, both in the type of stimuli to which they respond and the size of their receptive fields.

Nociceptive specific neurons of lamina I enter the lateral spinothalamic tract and terminate in several nuclei of the thalamus, including two that receive few deep lamina inputs (Fig. 25.14). Targets in which convergence of lamina I and lamina IV–VI inputs are strongly suspected or known to occur are the nucleus of the ventral posterior complex. Although the most compelling data in support of convergence has been reported for VPI, several careful studies have documented termination of lamina I inputs in the calbindin-rich clusters of VPL and VPM. This represents what has become a traditional view of the nociceptive pathway, that discriminative pain is driven by nociceptive inputs to both lamina I and laminae IV–VI and through a relay in the ventral posterior nuclei, that nociceptive information reaches SI and SII.

Outside the ventral posterior complex are two sites of spinothalamic terminations predominantly from lamina I (Fig. 25.14). One of these is a subnucleus of the mediodorsal nucleus (M<sub>dv</sub>c) in which spinothalamic terminations are surprisingly rich. The other is posterior to the classically drawn borders of VP and includes the medial nucleus of the posterior group (POM). Neurons in this region are innervated by spinothalamic axons and display the same chemical signature (calbinding immunoreactivity) as spinothalamic-recipient neurons of VPL and VPM.

Considerable disagreement exists with the source and meaning of the spinothalamic innervation in posterolateral thalamus of monkeys and humans. One part of the disagreement deals with the propor-

tion of lamina I afferents that end inside the bounds of VPL and VPM and those that end caudal and medial to it. A. D. Craig and his colleagues indicate a majority of lamina I output targets a neurochemically distinct region outside VPL and VPM. They have given this region the name VM<sub>po</sub> in apparent recognition of the data suggesting it is a nucleus separate and distinct from VPL and VPM. E. G. Jones and W. D. Willis and their colleagues hold to the traditional view that termination of axons from lamina I neurons is widespread, and includes VPL, VPM, and other thalamic nuclei, including POM. Jones, in addition, argues that what has been called VM<sub>po</sub> is simply the most medial tip of VPM. That disagreement is not minor in its implications. An exclusive lamina I innervation of the region labeled VM<sub>po</sub> turns it into a nociceptive- and thermoreceptive-specific relay nucleus, whereas the traditional view sees a major role for VPL and VPM in nociceptive and thermoreceptive relay. Resolution of this question has not been a simple matter, as studies favoring and refuting the central premise of a nociceptive- and thermoreceptive-specific VM<sub>po</sub> are common in the experimental and clinical literature. If the most conservative conclusions are adopted, we are left to recognize spinothalamic innervation of four thalamic regions, each with its own cortical target. Spinothalamic terminations in VPL and VPM are relayed to SI and those in VPI to SII. Together, they can be seen as a lateral path to first or discriminative pain. A second medial path to anterior cingulate by way of MD<sub>vc</sub> and to the insula by way of POM and the neurons of the region designated VM<sub>po</sub> appears to be the central route for second or punishing pain.

## SI and Pain

Nociceptive responses in SI have been difficult to record and where neurons responding to noxious stimuli have been encountered, their location (e.g., area 3a) has not been easy to fit into a general scheme of what these areas do. Nevertheless, ablation studies in monkeys show SIs involvement in pain perception and studies of human cerebral cortex (see later) regularly show SI responds to stimuli judged to be painful. Perhaps the most compelling story can be told for area 1 of SI in monkeys, where evidence exists of clustered organization for nociceptive neurons. Yet these neurons do not form columns. They are largely confined to layer IV of that area and are intermixed with mechanosensory neurons. These data suggest that nociceptive and mechanosensory inputs converge in area 1, perhaps as a means to accurately locate the source of pain.

## The Human Axis of Pain

Functional imaging studies of the human brain indicate four areas of cerebral cortex are active during (and often just prior to) the application of a painful stimulus. Activation of SI and of SII occurs as part of a discriminative component to painful stimuli. A subject's ability to report the location and grade the intensity of a stimulus is correlated with activity in these areas. Two other areas appear tied to the cognitive and emotional content of pain. These are the rostral half of the anterior cingulate gyrus and the rostral insula, both of which display elevated activity during the anticipation of painful stimuli and the infliction of pain on a loved one (empathetic pain). And it is these areas that show a reduction in activity when the administration of a placebo produces reports of lessened pain. As a group, then, studies of the cortical representation of pain point to a distributed network of four main areas (SI, SII, rostral anterior cingulate, and rostral insula) in which the noxious stimulus applied to some peripheral region becomes a painful sensation with both discriminative and punishing components.

## Nonperceptual Elements of Nociception

Several paths are taken by first- and second-order nociceptor axons that reach neither spinothalamic neurons nor regions of the thalamus. Targets of these axons include the following: (1) spinal interneurons that mediate the withdrawal and crossed-extensor reflexes; (2) the pontine reticular formation, where the startle reflex is generated; and (3) the midbrain periaqueductal gray (PAG) as a means to control pain. The last of these is a well-studied mechanism (Fig. 25.15). Neurons of the PAG are innervated by second-order nociceptive neurons in laminae IV and V. They provide PAG neurons with an indication of the source and intensity of nociceptive input. By way of a relay from serotonin neurons in nucleus raphe magnus and norepinephrine neurons in the locus coeruleus, activity in PAG drives a population of interneurons in the lamina II of the spinal cord. Two characteristics of those interneurons are worth some consideration. First, they end not only on the populations of spinothalamic neurons, but also on the axon terminals of C and A $\delta$  axons. Through postsynaptic inhibition these inhibitory interneurons are able to suppress the response of spinothalamic cells and through presynaptic inhibition they are able to suppress primary nociceptive afferents. The combination of pre- and postsynaptic inhibition reduces activity in the population of spinal neurons that carries nociceptive information to the brain. Second, the inhibitory neurons release the pentapep-

**FIGURE 25.15** Descending control of pain. Serotonergic axons arise from neurons in the nucleus raphe magnus and adrenergic axons from neurons in the lateral tegmental nucleus. Neurons in each nucleus are innervated by neurons of the periaqueductal gray area and both form excitatory synapses onto spinal interneurons (E). Those interneurons use opiate-like peptides (enkephalins) as neurotransmitters; release of enkephalins inhibits both the incoming nociceptive axons and the spinothalamic neurons (S) on which they synapse.

tide, met-enkephalin as a neurotransmitter. Met-enkephalin is an opioid peptide that binds to a member of the opiate receptor family. Its actions are mimicked by the administration of morphine and synthetic opiates accounting for at least part of the analgesic properties those compounds possess.

Pain is such a rich experience with an obvious impact on the well-being of a person that unusual phenomena associated with pain have been studied in

considerable depth. Among the best studied are referred pain, secondary hyperalgesia/allodynia and phantom limb pain. Each has been explained by referring to the circuitry and chemistry of normal nociceptive processing. Referred pain is the experience in which noxious stimuli in the viscera (e.g., ischemia of cardiac muscle) is felt as pain in a peripheral location such as the shoulder. A classic explanation for referred pain notes the widely branching nature of C and A $\delta$  fibers as they enter the cord, so that lamina I neurons innervated by nociceptors of the shoulder are also innervated by nociceptors of the pericardium. When the latter are driven to fire a series of action potentials the percept is one of a more common occurrence, shoulder pain.

Central or secondary hyperalgesia and allodynia are related phenomena that occur in response to synaptic plasticity at the level of the spinal cord. Secondary hyperalgesia is a phenomenon in which a greater degree of pain is felt upon application of a noxious stimulus. Allodynia, by contrast, is the perception of pain when the stimulus itself is not noxious. Each occurs when the application of an intense or prolonged noxious stimulus leads in spinal circuits to a rearrangement in synaptic strength, much like long-term potentiation. With secondary hyperalgesia, the potentiation is homosynaptic, leading to a greater postsynaptic response in spinal neurons to a noxious stimulus. Plasticity with allodynia is thought to be heterosynaptic. Under normal circumstances, activity in A $\beta$  fibers to a benign mechanical stimulus (e.g., the movement of a cotton swab across the skin) modulates a response to noxious stimuli but fails to drive spinothalamic cells. Yet when the synapses formed by the A $\beta$  fibers are potentiated in response to an intense or prolonged barrage of C fiber activity spinothalamic neurons are driven by that mechanical stimulus. The result is perception of pain where only nonnoxious mechanical stimulation has occurred.

Unlike allodynia, phantom limb pain appears to involve synaptic plasticity at each of several levels in the somatosensory system. Removal of a digit or limb in experimental animals and in humans leads to a robust functional plasticity. In cases first documented by J. Kaas and M. Merzenich and their colleagues, surgical removal of digits produces a short-lived silent zone in the somatotopically appropriate part of SI. Quickly thereafter, the previously silent region becomes responsive to tactile stimulation. Yet the newly acquired response is to adjacent body parts, as the activity evoked in neighboring receptors fills in the zone where the cortex had been silent. Subsequent work has shown that following amputation of a digit or limb, this process of filling in takes place through

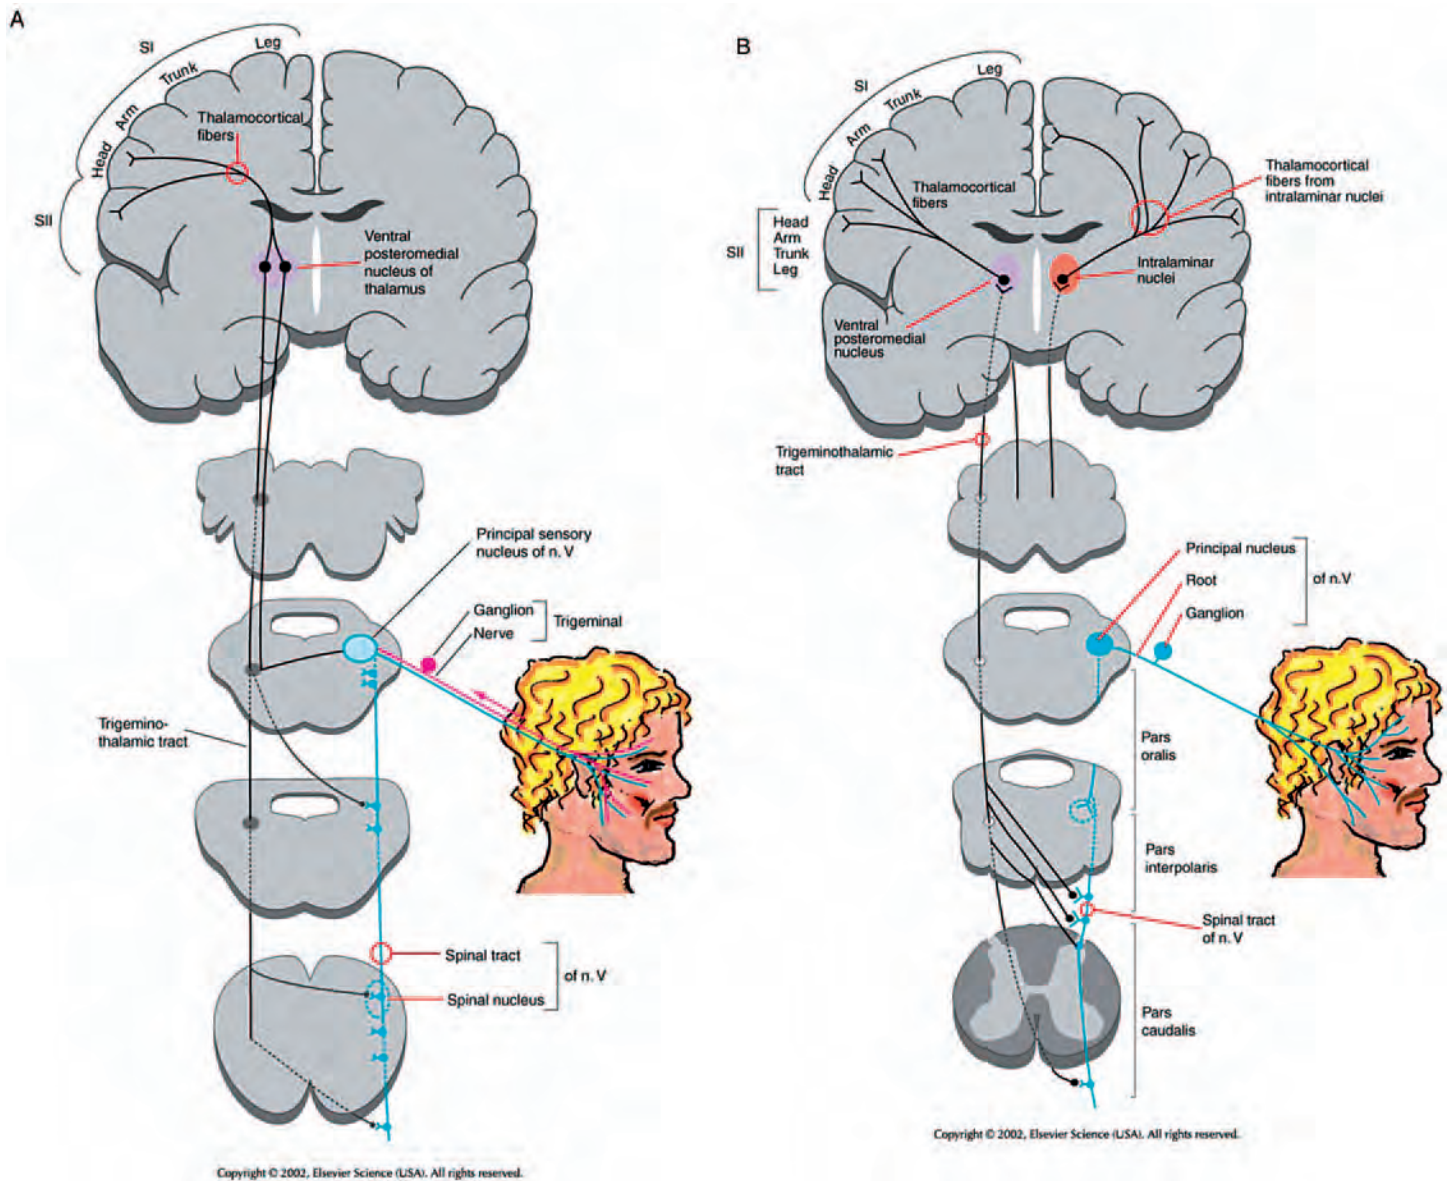

synaptic changes in the spinal cord, medulla, and thalamus, as well as in cerebral cortex. It is assumed that phantom limb pain works much the same way. Thus, stimulation of the shoulder and chest in amputees drives regions of cerebral cortex that had been responsive to stimulation of an arm prior to its amputation. The result is the percept of arm pain even in the absence of an arm.

## THE TRIGEMINAL SYSTEM (Fig. 25.16)

Mechanoreceptive, nociceptive, and thermoreceptive afferents for the face have their cell bodies in the pair of trigeminal ganglia. The central processes of trigeminal ganglion cells enter the mid-pons as the trigeminal nerve. In many ways, the central trigeminal system is organized along parallel lines with the spinal somatosensory system.

Three nuclei make up the somatosensory part of the trigeminal system. The largest of these is the principal or main sensory nucleus, the cell bodies of which are in mid-pons, at the level of entry for the trigeminal nerve. Acting much like the dorsal column nuclei, the principal sensory nucleus is innervated by large diameter afferents of the ipsilateral half of the face. Its neurons respond to skin indentation and to vibrotactile stimuli. Most of these neurons send their axons across the midline in the pons, where they join the fibers of the medial lemniscus. The trigemino-thalamic axons ascend in the most medial part of the lemniscus (next to the axons that carry information about the hand) and terminate in VPM.

The spinal trigeminal nucleus is an elongated nucleus, split into three subnuclei distinguished geographically by reference to the obex. Pars oralis occupies the lower pons and upper medulla to the level of the obex. It gives way to the pars interpolaris at the obex and then to pars caudalis through the lower medulla and into the first two cervical segments of the spinal cord. Borders between these subdivisions are hardly distinct as afferents innervating a restricted part of the face may end across two or all three parts of the spinal trigeminal nucleus. The traditional subdivision of the spinal nucleus into functional units accents the mechanosensory functions of pars oralis, the deep receptor functions of pars interpolaris, and the nociceptive and thermoreceptive functions of pars caudalis. In this context, the relay of input from pars caudalis to VPM is viewed as the equivalent of the spinothalamic system for the face. Yet studies of C fibers that innervate tooth pulp find these afferents terminate in a long, continuous sheet from the caudal

**FIGURE 25.16** Sensory components of the trigeminal system. (A) Path for discriminative touch. Large-diameter afferents from the face innervate second-order neurons in the spinal trigeminal nucleus (pars oralis) and the principal sensory nucleus. Neurons in these nuclei give rise to axons that cross the midline, ascend in the trigeminothalamic tract, and terminate in the ventral posteromedial (VPM) nucleus of the thalamus. (B) Path for pain and temperature in the trigeminal system. Small-diameter afferent axons descend in the spinal trigeminal tract and terminate in the pars caudalis of the spinal nucleus. Second-order axons cross the midline and ascend to the thalamus.

half of the principal nucleus to the caudal-most aspect of pars caudalis. These data indicate a great deal more intermixing of mechanosensory neurons and nociceptive neurons takes place in the trigeminal system than is seen for the spinal somatosensory system.

The third nucleus of the sensory trigeminal system is the most unusual. Incorporated into the CNS as the

mesencephalic nucleus of the trigeminal system is a collection of ganglion cells that give rise to muscle spindle afferents. This nucleus is one of only two in the CNS to contain neurons of neural crest origin. The central processes of the ganglion cells innervate several targets, the most prominent of which is the motor trigeminal nucleus.

## CORTICAL REPRESENTATION OF TOUCH

### Neurons of SI Are the First in the Somatosensory System to Show Clear Signs of Lateral Inhibition

Between the level of the peripheral afferent, where skin mechanics produces surround suppression and the level of the cerebral cortex, the somatosensory system is unusual in the sparseness and weakness of lateral inhibition. As discussed earlier, the synaptic means to generate lateral inhibition exist in the dorsal column nuclei and thalamus, but the response of a single neuron in those regions appears very much like the response of the one axon that drives it best. Neurons in SI, however, display true inhibitory surrounds (Fig. 25.17). For area 3b in monkeys such surrounds are one-third larger than the central excitatory region and can occupy one or more (but rarely all four) sides of the excitatory center. Many neurons in area 3b also exhibit a strong temporal component to their response. Application of a peripheral stimulus produces an initial excitatory response that evolves over a 25ms period into inhibitory response, referred to as replacing inhibition. Receptive fields in area 3b neurons possess three distinct components: (1) a central region of excitation that comes on rapidly following application of a stimulus; (2) a rapidly occurring lateral inhibition that diminishes the response to a stimulus that is applied to it and the excitatory center; and (3) a delayed inhibition that overlaps the central excitatory region in part or in whole. These properties of spatial and temporal inhibition in area 3b are emergent properties—ones found in cerebral cortex but not earlier in the somatosensory system—that produce responses tied to the spatial details of a tactile stimulus.

#### *Spatial and Temporal Inhibition* (Fig. 25.14)

Spatial inhibition maintains the response selectivity of neurons when objects scanned across the skin surface at different speeds (as in reading Braille). In short, the receptive fields of neurons in area 3b are velocity insensitive. An increase in the velocity of scanning strengthens the response of a neuron but that increased response occurs in both the excitatory and the inhibitory subfields and it occurs without a change in the geometry of either field. The result is a population of neurons in SI more responsive to an ideal stimulus but no less tightly tuned to the spatial features of the stimulus. Temporal inhibition performs a parallel function by producing a progressive increase in response rate to surface elements that are scanned

**FIGURE 25.17** Receptive fields of neurons in area 3b. Examples of receptive fields displayed by neurons in area 3b of an alert rhesus monkey show clear signs of lateral inhibition (A). In this figure, black represents regions of excitation and white regions of inhibition. An inhibitory part of the receptive field is rarely missing in neurons of this area, as most neurons have inhibitory regions on one or more sides of the excitatory center. Below each subplot is the percentage of times each neuron type was observed in the population. In (B) a hypothetical example is shown illustrating the velocity invariance of a neuron's spatial receptive field. In the top of this figure, overlapping regions of excitation and inhibition are shown at two velocities. The degree of overlap decreases as scan velocity increases, but the spatial profile of the RF is unchanged. Part A is adapted from DiCarlo, Johnson and Hsiao, 1998 and DiCarlo and Johnson 1999.

**FIGURE 25.18** The receptive field of a neuron in area SII from a macaque monkey is overlaid on the glabrous surface of a human hand. On each finger pad are rasters showing the response of the SII neuron to a bar indented at 8 orientations. Histograms are also shown for the most responsive and least responsive orientation. Shown on the palm are tuning curves for each finger pad. These results demonstrate that neurons in SII have large receptive fields so that tuning to orientation of a bar on one finger pad is the same as the tuning across other pads. Adapted from Cover illustration of *J. Neurosci.* vol 26 2006.

more quickly. The lag between the initial excitatory response and the delayed inhibitory one liberates more activity when the velocity of scanning increases. This more than makes up for the reduction in contact time between peripheral receptor and surface feature that accompanies any increase in scanning velocity.

### **Orientation Selectivity**

As a result of circuits in cerebral cortex, the roughly circular receptive fields that enter SI by way of thalamocortical axons become orientation-selective responses in 70% of cortical neurons. The synaptic

mechanism for generating a receptive field tuned to the orientation of a stimulus could be convergence of excitatory inputs, much like the mechanism proposed originally for orientation tuning in visual cortex. Yet examination of spatial-temporal response of neurons in SI indicates orientation selectivity is best explained by the presence and spatial distribution of inhibitory regions.

### **Serial Processing in SI**

Area 3b is considered an early step in the cortical processing of tactile information. Much of the data

supporting that conclusion come from studies in the lab of Randolph and Semmes, showing that ablation of area 3b produces a general decline in tactile discrimination behavior whereas ablation in other areas of SI leads to losses that are more selective. These include difficulties in discriminating the texture of a surface following ablation of area 1 and deficits in three-dimensional form perception with ablation of area 2. From these data come the conclusion that areas of SI are organized as a hierarchy. A similar conclusion is seen in physiological properties of SI neurons as receptive fields become larger and their properties become more complex in going from area 3b to one of the more caudal somatosensory areas. One example is selectivity for the direction of object movement across the skin. Neurons in area 3b show no sign of direction selectivity but in areas 1 and 2 this property emerges from the cortical circuitry. For example, a neuron in areas 1 and 2 with a receptive field on the palmar surface of a monkey's hand show tuned responses to movements over a 90° range but respond poorly and often not at all to movements over the remaining 270°. The ability of subjects to detect movements with much finer detail than that of single neurons occurs through a population code much like the directions of arm movement are encoded by a group of broadly tuned neurons in the precentral motor area.

### *Columnar Organization*

Responses of like type are organized as columns in SI. The original description of cortical columns was made by V. Mountcastle in his 1953 study of cat somatosensory cortex. For SI in macaques one of obvious place for columnar processing is in the RA and SA responses. As expected neurons in monkey area 3b directly innervated by thalamocortical axons show strong specificity for either RA or SA inputs. These neurons are in layer IV and deep layer III. Yet superficial to this layer, where neurons of layer IV send their axons, the response is predominantly slowly adapting. In other words, the response of neurons outside layer IV makes it appear as though rapidly adapting inputs are incorporated into a slowly adapting output.

Nevertheless neurons in areas 3b and 1 are clearly involved in the discrimination of vibrotactile stimuli at low frequencies, such as those carried into the CNS by RA afferents (Meissner's corpuscles). The work of R. Romo and his colleagues documents a response of SI neurons in macaques that is tied to the frequency of a stimulus applied to the fingertips. A monkey's ability to discriminate between two stimuli of different frequencies is only as good as an SI's neuron's ability to signal that difference. And when electrical stimula-

tion of SI is used as a replacement for one of those vibratory stimuli (e.g., electrical stimulation at 30 Hz is used instead of a 30 Hz vibrotactile stimulus), a monkey will indicate that he perceived a stimulus of that frequency. This perceptual ability is not tied to the frequency of the SI neuron's response but to the number of spikes generated in the first 250 milliseconds. Thus, not only does a population of SI neurons contribute to the perception of flutter but also the neural code used by those neurons is an intensity code.

## **The Role of SII in Somatic Sensation**

### *Several Body Representations in SII*

At first glance the division of labor that is a hallmark of SI contrasts strongly with the presence of a single area called SII. Recent functional and anatomical studies show, however, that across the 10 mm in the upper bank of the lateral fissure that normally defines SII in macaques are multiple functionally distinct areas. In monkeys three separate regions have been described, referred to as SIIa, SIIc, and SIIp (some researchers prefer the terms SII, PV and PR). Anatomical studies in humans suggest there are also four separate regions called OP1-OP4, yet how the human studies relate to the monkey studies is not known.

Ablation studies in monkeys reveal three features of SII's role in somesthesia:

- Removal of all SII leaves a macaque incapable of discriminating the shape and texture of a tactile stimuli. These data show any or all subdivisions of SII play a pivotal role in tactile behavior.
- Removal of SII has no effect on the response of neurons in SI. So, even though SII provides feedback projections to SI, the dominant input to SI comes from neurons of VPL and VPM.
- Removal or cooling of SI eliminates the tactile responses in SII.

These results extend to modality-specific loss in SII following ablations restricted to one area in SI. A modern view of SII suggests it is a complex of at least three functionally distinct areas. The anterior and posterior portions (SIIa and SIIp) are involved in integrating proprioceptive inputs with cutaneous input as a means for representing the size and shape of objects held in the hand. In addition, a central field (SIIc) responds to cutaneous inputs and is important for processing information about 2D shape and texture discrimination.

### *SII Receptive Fields*

Receptive field properties of neurons in macaque SII support the conclusions that SII is part of a serial

processing scheme (Fig. 25.18). Unlike the partially isomorphic responses to raised patterns that are seen in many neurons of SI, neurons in SII appear selective for more complex features of a stimulus. They are anything but isomorphic. Moreover, orientation selectivity is seen in fewer than one out of three neurons in SII as receptive fields of single neurons grow to encompass over two or more fingers. Neurons such as these appear to represent a sparse code for objects such as the edge of a keyboard or large curved shapes that span several digits.

### SII and Attention

Whereas only a small percentage of neurons in SI are affected by attentional focus of animals, practically all the neurons in SII show attention modulated responses. Psychophysical studies show attention is a spotlight with finite boundaries that can improve performance on each of many tactile discrimination tasks. These studies raise questions as to the targets and mechanism of an attentional effect. Single unit studies show SII to be one of the major targets as the response of individual neurons changes with shifts in attention. Mechanisms by which attention appears to exert its effects include a change in the response rate (about 90% of SII neurons in macaques increase their response to a tactile stimulus) and a shift to synchronous activity. Pairs of neurons in macaque SII recorded at the same time are found to become more synchronous in their response to a tactile stimulus when an animal has been cued to pay attention to that stimulus. As the task becomes more difficult, when the difference between two stimuli is deliberately reduced, the degree of synchrony increases by a factor of four. These data show that not only is SII a nodal point for the discrimination of form and texture but it is also a site at which cognitive mechanism like selective attention are likely to exert their greatest influence.

# Audition

The auditory system detects sound and uses acoustic cues to identify and locate sounds in the environment. The auditory system shares functional and evolutionary similarities with other mechanoreceptive systems, such as the vestibular system and the lateral line system of lower vertebrates. All these systems use the same type of receptor cell—the hair cell—and all are specialized to detect an external stimulus that eventually causes the stereocilia of the hair cells to be displaced. Unlike other mechanoreceptive systems, the auditory system is sensitive to sound. This chapter explores the characteristics of the auditory system that make it sensitive to sound and that make it capable of localizing a sound source. The generalized mammalian auditory system is emphasized, but examples also are taken from studies of animals with specialized auditory systems, such as those of bats and owls, which have greatly advanced our knowledge of audition.

## EXTERNAL AND MIDDLE EAR

The peripheral auditory system is divided into the external, middle, and inner ears (Fig. 26.1). The external ear is composed of the pinna and external auditory canal. These structures convey sound to the middle ear, but not without influencing it. This influence emphasizes and deemphasizes certain sound frequencies, resulting in peaks and notches in the sound spectrum. Because positions of the peaks and notches depend on the location of the sound source, they provide information about location, even when using only one ear (monaural sound localization). Such information is especially important for determining

the elevation of a sound source because spectral peaks and notches are one of the few cues that depend strongly on elevation.

Mechanosensitive organs in lower vertebrates, such as the lateral line of fish, are sensitive to vibrations in aquatic environments. When vertebrates evolved onto land, they faced the problem of converting sound in air to sound in fluid, as the inner ear of vertebrates remains fluid filled. Sound at an air–fluid interface is almost completely reflected back into the air, rather than being transmitted into the fluid. The function of the middle ear is to ensure efficient transmission of sound from air into the fluid of the inner ear (reviewed by Geisler, 1998).

The middle ear begins at the tympanic membrane (eardrum), continues with the three middle ear ossicles (malleus, incus, and stapes), and ends at the footplate of the stapes, which contacts the inner ear fluids at the oval window of the cochlea (Fig. 26.1). The middle ear also has air spaces and two middle ear muscles. There are several ways in which the middle ear increases the transmission of sound into the inner ear. Most importantly, because the area of the eardrum is larger (by about 35 times) than the area of the stapes footplate, there is a corresponding increase in pressure from the eardrum to the stapes footplate. Additionally, there may be small contributions from a lever action of the ossicles and a buckling motion of the tympanic membrane, both increasing the force applied to the footplate. Together, these mechanisms provide a pressure gain of about 25 to 30 dB in the middle frequencies over what would be achieved by sound striking the oval window directly. This amount of gain means that for middle frequencies, most of the acoustic energy that strikes the eardrum is transmitted through the middle ear. For lower and higher frequencies, however,

**FIGURE 26.1** Drawing of the auditory periphery within the human head. The external ear (pinna and external auditory canal) and the middle ear (tympanic membrane or eardrum, and the three middle ear ossicles: malleus, incus, and stapes) are indicated. Also shown is the inner ear, which includes the cochlea of the auditory system and the semicircular canals of the vestibular system. There are two cochlear windows: oval and round. The oval window is the window through which the stapes conveys sound vibrations to the inner ear fluids. From Lindsey and Norman (1972).

energy is lost. When sound conduction through the middle ear is compromised, a person has a conductive hearing loss.

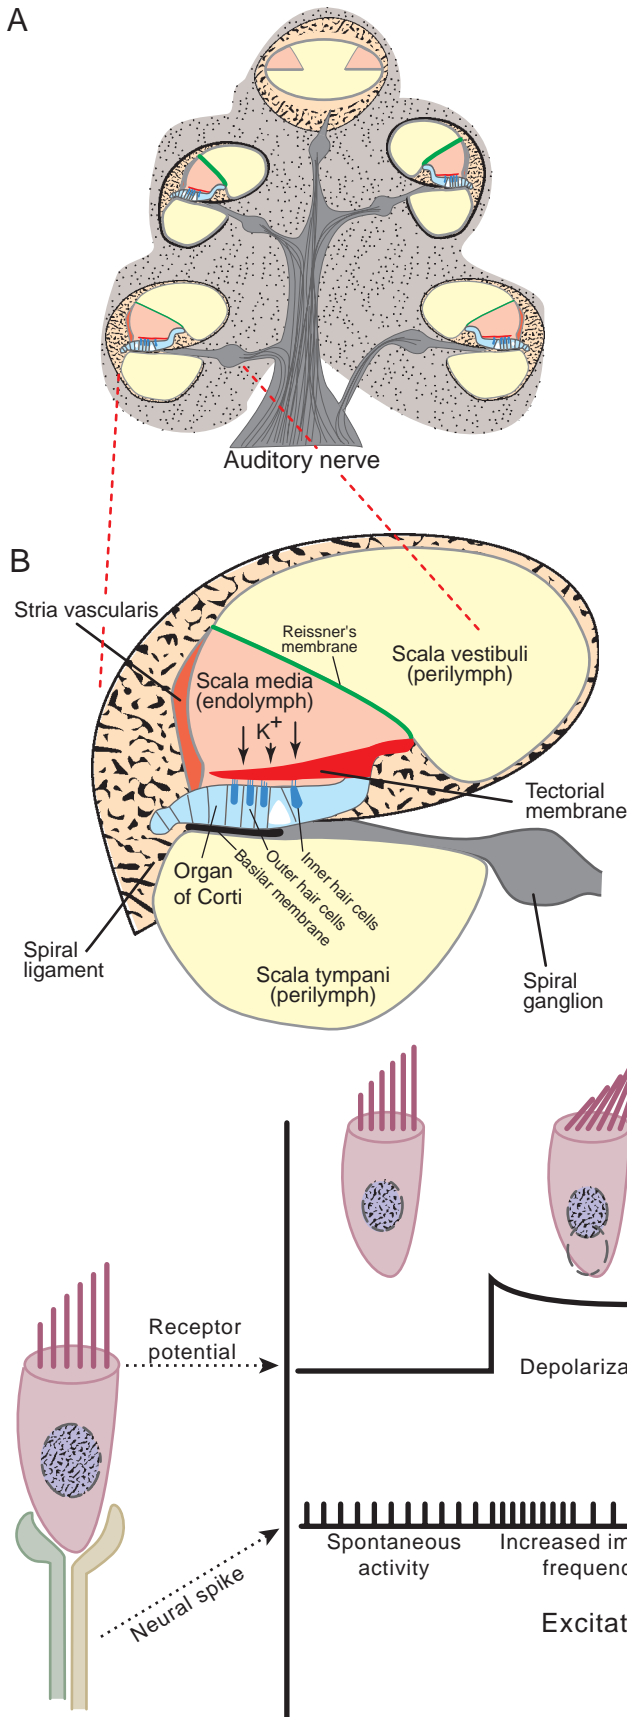

One disease that causes a conductive hearing loss is otosclerosis, in which bony growths around the stapes cause it to adhere to surrounding bone and lessen its transmission of vibration. A surgical procedure called a stapedectomy usually restores hearing by replacing the native stapes with a prosthetic one.

## THE COCHLEA

The inner ear is located deep within the head (Fig. 26.1). The inner ear contains the cochlea, which is the sensory endorgan for the auditory system. It also contains the utricle, saccule, and cristae of the three semicircular canals, which are the sensory end-organs for the vestibular system (see Chapter 33). The word cochlea comes from the Greek word *kokhlias*, meaning

“snail,” as the cochlea is coiled like the shell of a snail. In most species, the long spiraled tube of the cochlea has two to four turns (depending on species), which are visible in cross-section (Fig. 26.2A). The sensory organ, the organ of Corti, contains the receptor cells (hair cells) and supporting cells. The organ of Corti rests on the basilar membrane and is covered by the tectorial membrane (Fig. 26.2B). Hair cells are of two types: inner hair cells and outer hair cells. Their names are derived from the position of the hair cells along the cochlear spiral: inner hair cells are located innermost along the spiral and outer hair cells are located outermost. There is one row of inner hair cells and usually three rows of outer hair cells. In the human cochlea, there are about 3500 inner hair cells and about 14,000 outer hair cells.

**FIGURE 26.3** Illustration of hair cell stimulation, receptor potential response, and afferent fiber discharge. From A. Flock. ►

**FIGURE 26.2** (A) Cross-section through the cochlea. The cross-section shows that there are approximately three turns in this human cochlea and that they spiral around a central core (modiolus) that contains the auditory nerve. (B) Cross-section through one cochlear turn to illustrate important cell groups (organ of Corti, spiral ligament, stria vascularis, and spiral ganglion) and the main fluid compartments (scala vestibuli, scala media (shaded orange), and scala tympani). Within the organ of Corti, sensory cells (inner and outer hair cells) are shaded dark blue and are situated between the basilar and tectorial membranes, which move when sound stimulates the cochlea. When these membranes cause motion of the stereocilia of the hair cell, the receptor current, a potassium ( $K^+$ ) current, flows into the hair cells from the endolymph. The high  $K^+$  concentration and high electrical potential of the endolymph are created by the stria vascularis, and these factors increase the driving force for the receptor current. Supporting cells in the organ of Corti are shaded light blue; these cells form a network that is coupled by gap junctions and may recycle  $K^+$  back to the stria vascularis. Also shown is the spiral ganglion, which contains cell bodies of the auditory nerve fibers.

### Hair Cells Transduce Mechanical Energy Directly into Electrical Energy

Hair cells (Fig. 26.3) are polarized epithelial cells whose major functions are partitioned into apical and basal cellular compartments. The apical end of the cell is specialized for the reception and translation of mechanical energy into receptor currents, whereas the basal end is specialized for the transmission of information to the central nervous system via synaptic contacts with the primary afferent neuron. Stereocilia are modified microvilli, a fraction of a micrometer in width, that project from the cell apex and contain an

abundant supply of tightly packed actin filaments, bound by fimbrin, coursing along their length. Depending on which specific organ the hair cells reside in, their lengths range from a fraction (in the bat cochlea) to tens of micrometers (in vestibular organs). The number of stereocilia per hair cell ranges from about 10 to 300. Together the stereocilia from one cell form a "hair bundle" and are bundled together by extracellular filamentous linkages. They taper rapidly as they insert into the hair cell's cuticular plate, an actin-rich apical cytoplasmic structure. Because the stereocilia are stiff, rod-like structures, they pivot at their insertion when deflected.

### Receptor Potentials Are Evoked by Mechanically Gated Ion Channels within Stereocilia

With the hair bundle in its resting, unperturbed position (Fig. 26.3), a standing inward current exists through a small proportion (10–25%) of mechanically activated channels. Because these channels are nonselective for cations, this inward, positively charged flux tends to depolarize the hair cells. In many hair cell sensory systems, including the organ of Corti, the ionic milieu surrounding the hair bundle is richest in potassium (Fig. 26.2B); thus, the major charge carrier for the transduction current is potassium. However, small amounts of calcium are also required to sustain stereociliar channel activity. Displacement of the hair bundle toward the tallest stereocilium increases the proportion of open channels, thereby producing an increase

of the inward resting current. The subsequent flow of current across the basolateral membrane produces a depolarizing voltage change, a receptor potential, capable of activating a variety of voltage-dependent conductances in that membrane. Conversely, closure of transduction channels during bundle movement away from the tallest stereociliar row reduces the inward current, effectively hyperpolarizing the basolateral membrane. Several lines of evidence indicate that the flow of transduction current into hair cells occurs near the top of the hair bundle, i.e., channels are located near the tips of the stereocilia. Maximal transducer conductance changes up to about 10 nS have been observed. Single channel conductances on the order of 20–200 pS either have been measured or estimated and may increase along the tonotopic axis of the cochlea. From such conductance measures, the number of channels per stereocilium has been computed to be one to two.

The relationship between degree of bundle deflection and receptor potential magnitude is neither linear nor symmetric (Fig. 26.4). Bundle displacements in the depolarizing direction produce larger responses than equal displacements in the opposite direction. The displacement–response function is sigmoidal and shifted from its midpoint. Thus, symmetrical sinusoidal deflections of the bundle (as might occur with acoustic stimuli) will produce both sinusoidal (ac) and superimposed depolarizing steady-state (dc) changes in membrane potential. Saturating electrical responses are evoked by deflections as small as 300 nm (Hudspeth and Corey, 1977).

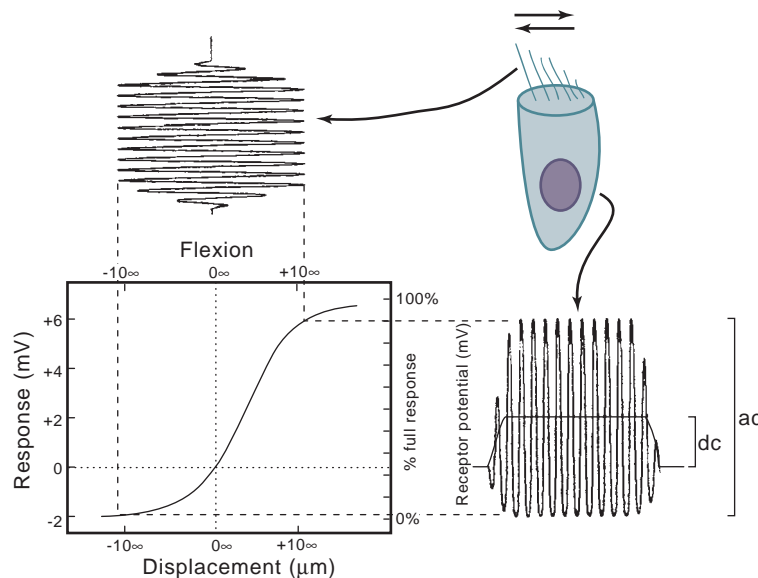

FIGURE 26.4 Sigmoidal input-output function of hair cell. Symmetrical sinusoidal displacement of stereocilia produces ac and dc receptor potential components. From Hudspeth and Corey (1977).

## Stereocilia Tip Links May Underlie Transducer Gating

The molecular basis of the hair bundle's response polarity appears to reside in specialized structural attachments at the tips of stereocilia (Pickles *et al.*, 1984) (Fig. 26.5). These "tip links" are elastic filaments ("springs") that link the top of each stereocilium with a dense membranous plaque on the upper side of the adjacent taller stereocilium, and occur in line with the axis of maximal bundle sensitivity. They are believed to provide the tension required to open transduction channels during bundle deflection, with one end of the filament being anchored and the other pulling on the channel gate. As the hair bundle tilts during deflection in the excitatory direction, adjacent stereocilia shear

against one another, stretching and increasing the tension of tip links, thereby increasing the probability that transducer channels will open. When the deflection is in the hyperpolarizing direction, tip link tension slackens and the channels tend to close. In line with tip link or gating spring hypothesis, destruction of the tip links by enzymatic (elastase) or chemical (calcium chelators) treatments can abolish mechanical transduction. In addition, if tip link tension accounts for much of the bundle's stiffness, as expected, bundle compliance varies with the extent of deflection. The deflection versus bundle compliance function is bell-shaped, with maximum compliance occurring when half the transduction channels are open. Furthermore, compliance changes are abolished by blocking stereociliar transduction channels with aminoglycoside antibiotics.

**FIGURE 26.5** Gating spring model of hair cell transduction. (A) Tip links connecting channel gate to adjacent taller stereocilium tense during displacement toward the taller stereocilium, thus increasing the probability that the channel will open (B). From Pickles and Corey (1992).

## Electrical Properties of the Basolateral Membrane Shape Receptor Potentials

The speed of the hair cell transduction process is incredibly fast compared to transduction in other sensory systems, such as vision, olfaction, and the taste modalities of sweet and bitter. The delay between a bundle deflection and the onset of receptor current is estimated to be about  $10\mu\text{s}$  at  $37^\circ\text{C}$  (Corey and Hudspeth, 1983). This rapid response is a consequence of direct gating of transduction channels, and such speed is essential for auditory hair cells to detect sound frequencies in the kilohertz (thousand per second) range. Humans can detect sound frequencies up to about 20 kHz, and some mammals, such as bats, can hear above 100 kHz. Although receptor currents may be generated without attenuation across frequency, receptor potentials, which ultimately are responsible for the release of neurotransmitter at the hair cell synapse, are susceptible to the RC filter characteristics of the basolateral membrane. The RC time constant of hair cell membranes ranges from a fraction of a millisecond to a few milliseconds at the resting potential. This translates in the frequency domain to a low-pass filter whose cutoff frequency ( $f_c$ , the frequency at which the response energy is halved) ranges from tens of hertz to about 1 kHz. This filtering reduces the ac receptor potential in half for every octave increase in frequency above the cutoff. Ultimately, at very high frequencies, ac responses will be negligible, but the dc component will remain unperturbed—a process termed rectification (Fig. 26.6). The actual cutoff frequency may be considered dynamic because receptor potentials themselves may activate voltage-dependent ionic conductances in the basolateral membrane that will modify the resistive component of the RC product. In outer hair cells from the organ of Corti, the capacitance

of the basolateral membrane is also highly voltage dependent (Santos-Sacchi, 1992), and therefore in this cell type variations in both resistive and capacitive components may influence the membrane filter.

The mammalian organ of Corti rests upon an acellular basilar membrane (Fig. 26.2B) that extends along the coiled cochlea. Cells at the basal end of the organ of Corti have high characteristic frequencies, whereas those at the apex have low ones. Von Bekesy, who won the Nobel prize in 1968, discovered that different regions of the basilar membrane are tuned to particular frequencies; low-frequency tones cause maximal vibrations of the basilar membrane near the apex, whereas higher-frequency tones cause vibrations more basally. This tuning results from the mechanical characteristics of the basilar membrane, which becomes stiffer and narrower with distance from the apex to the base. As demonstrated in early experiments, the intrinsic frequency selectivity afforded by basilar membrane tuning is not great enough to account for the very selective responses observed in hair cells and auditory nerve fibers. Later experiments demonstrated that active mechanisms are necessary to achieve this high frequency selectivity.

### Active Mechanical Properties of the Outer Hair Cells Drive the Mammalian Cochlea Amplifier

Outer hair cells (OHCs) are cylindrically shaped and decrease in resting length by a factor of about four

from the apical to the basal ends of the cochlea. When an isolated OHC is stimulated electrically, it responds by altering its length (Brownell *et al.*, 1985). No other auditory cell type responds in this manner. The mechanical response is voltage dependent; depolarizing stimuli induce contractions and hyperpolarizing stimuli induce elongations. The length change versus voltage ( $dL$  vs  $dV$ ) function (Fig. 26.7) is sigmoidal, and like the stereocilia transducer function, it is operatively offset from its midpoint; the midpoint voltage is near  $-30$  mV (OHC resting potential is near  $-70$  mV). The slope of the function ( $dL/dV$ ; Fig. 26.7) indicates the sensitivity of the mechanical response to voltage change, and responses as large as  $30$  nm/mV have been found. *In vitro*, at least, this maximum sensitivity or gain resides at a voltage that is depolarized relative to the resting potential of the cell. The mechanical activity of the cell is not akin to any other known form of cellular motility and is governed directly by voltage-dependent, integral membrane protein motors, recently identified as the gene product of Prestin (Zheng *et al.*, 2000), one of a family of sulfate transporter genes (SLC26). *In vivo*, the motor action of OHCs probably is responsible for otoacoustic emissions (Box 26.1).

Through a variety of experimental approaches, motor activity has been shown to be restricted to the lateral membrane of the OHC. As might be expected for a voltage-dependent process that resides within the membrane, a charged voltage sensor must exist, just as voltage-dependent ion channels have voltage sensors. The existence of an OHC motility voltage

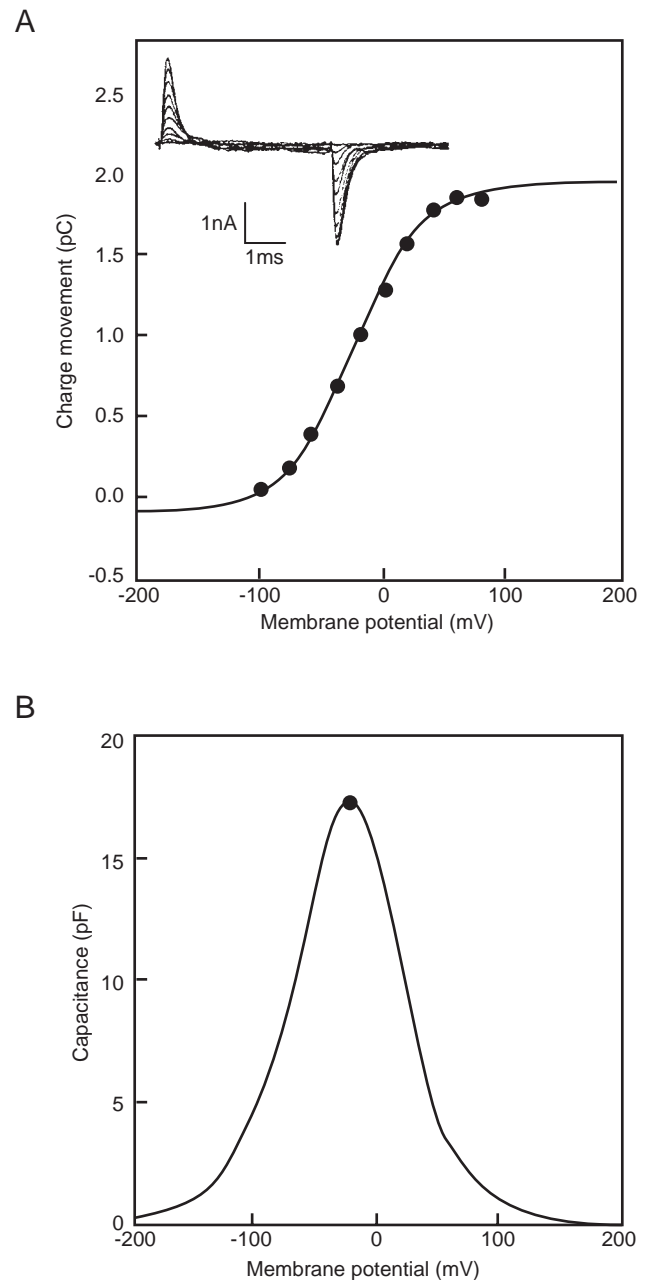

**FIGURE 26.6** Receptor potentials from the mammalian inner hair cell in response to acoustic bursts of increasing frequency. Because of the cell's  $RC$  time constant, the ac component diminishes as frequency increases. However, the dc component remains intact. From Russell and Sellick (1983).

**FIGURE 26.7** Mechanical response of mammalian outer hair cell (OHC) under voltage clamp. The OHC changes its length when the cell is held at different membrane potentials (A). The slope of the sigmoidal input-output function defines the cell's sensitivity to membrane potential change (B). From Santos-Sacchi (1992). Used with permission.

sensor is confirmed by measuring gating charge movements (capacitive-like currents) under voltage clamp while blocking ionic conductances. These gating currents represent the restricted movement of the charged voltage sensor within the plane of the lateral membrane; increasing voltage will move more charge (thus activating more motors) according to Boltzmann statistics. Maximum charge moved is about  $7500e/\mu^2$ . This value also is believed to characterize the density of motor molecules in the lateral plasma membrane. The plot of charge versus voltage ( $Q/V$ ) is sigmoidal (Fig. 26.8A) and has the same shape and characteristics as the  $dL$  versus  $dV$  function. The slope of the  $Q/V$  function is defined as capacitance, and thus the capacitance of OHC is a bell-shaped function of voltage (Fig. 26.8B). This nonlinear capacitance rides atop the cell's intrinsic linear membrane capacitance of  $1\mu\text{F}/\text{cm}^2$ . Thus, in an OHC of about  $70\mu\text{m}$  in length, at the point where motile gain is maximum (i.e., where half the motors are activated), the capacitance peaks at about double the cell's linear capacitance. As mentioned

**FIGURE 26.8** Gating charge associated with OHC motility voltage sensor. When the membrane potential is stepped with increasingly larger depolarizing voltages from a negative holding potential, nonlinear capacitive currents are generated and are obvious after linear capacitive currents are subtracted (inset). Integrating the onset currents, a measure of the amount of charge moved within the membrane can be obtained (A). The function is sigmoidal and has characteristics similar to the mechanical response. The first derivative of the charge with respect to membrane voltage defines the cell's nonlinear capacitance (B). From Santos-Sacchi (1991).

earlier, such nonlinear capacitance may have significant effects on membrane-filtering characteristics. Although the mechanical response is voltage dependent and is not evoked by activation of any particular

## BOX 26.1

## OTOACOUSTIC EMISSIONS

In 1978, David Kemp made a surprising discovery: the ear can sometimes *emit* sounds. These “otoacoustic emissions” are now the focus of much interest because basic researchers can use them to study the function of the ear and because clinicians can use them as tests of hearing (reviewed by Shera, 2004). Emissions are almost always so low in level that they are inaudible unless the individual is in an exceptionally quiet environment. Thus, measurement of emissions requires a sensitive, low-noise microphone that is placed in the external ear canal. Many studies indicate that the cochlea (inner ear) is the source of emissions. Within the cochlea, the outer hair cells are likely to be the generators of emissions. After these movements are generated, they travel in reverse of the normal pathway for sound into the inner ear: the emissions propagate from their point of generation along the basilar membrane to the oval window, then through the middle ear via the ossicles, and finally they move the tympanic membrane to result in airborne sound.

There are two main types of emissions—spontaneous and evoked—the latter are evoked in response to an externally presented sound. Spontaneous emissions are detected from the ears of about one-third of normal hearing humans, but these emissions are rare in laboratory animals. They are almost always pure tones. Transient-evoked emissions are evoked by a short sound such as a click and appear several to tens of milliseconds later. These emissions were first called the “cochlear echo,” but

they are not a real echo because more energy can appear in the emission than was present in the evoking sound. Distortion product-evoked emissions (Fig. 26.9) are evoked by two tones (“primaries” of frequencies  $f_1$  and  $f_2$ ) and occur at combinations of the primary frequencies (such as at frequency  $2f_1-f_2$ ). The two primary tones each produce traveling waves along the basilar membrane, and a likely point of generation of the emission is where these waves overlap maximally.

Otoacoustic emissions can be used clinically as a screening tool in hearing tests, as subjects with sensory hearing losses greater than 30 dB typically lack emissions. Transient-evoked or distortion product-evoked emissions are used in such tests. Emission-based tests are especially valuable for individuals such as infants who are otherwise hard to test by conventional audiometry. Otoacoustic emissions only rarely are the cause of tinnitus, the sensation of ringing in one’s ears. Most individuals who have tinnitus do not have emissions corresponding to the tinnitus. Thus, tinnitus arises by some other mechanism, almost certainly within the nervous system.

**FIGURE 26.9** Distortion product otoacoustic emission from a human subject measured with a microphone placed in the ear canal. The microphone records the sound pressure of the two primary tones (frequencies  $f_1 = 3.164$  kHz and  $f_2 = 3.828$  kHz, each 50 dB SPL) that were used to evoke the emission at  $2f_1-f_2$  (2.5 kHz at 12 dB SPL). From Lonsbury-Martin and Martin (1990).

voltage-dependent ionic conductance, the activity of the voltage sensor requires intracellular chloride, and in intact OHCs a stretch-activated chloride conductance appears crucial for maintaining and modulating motor activity (Rybalchenko and Santos-Sacchi, 2003).

Because hearing sensitivity and frequency selectivity in mammals span the kiloHertz range, any mechanism designed to augment hearing must function at these rates. Indeed, OHC motility has been demonstrated, *in vitro*, to extend well into the tens of kiloHertz range. Nevertheless, because the mechanical response is voltage dependent, it will be affected by the RC time constant of the OHC. In this scenario, at high frequencies, transmembrane ac receptor potentials, which presumably drive the mechanical response *in vivo*, will be attenuated greatly. Consequently, a

current debate focuses on the relative contributions of lateral membrane activity and stereocilia activity, each of which is capable of force production. Active mechanical responses of the stereocilia bundle may be driven by calcium influx through calcium-sensitive, mechanically activated stereocilia channels, and thus may not be limited by the membrane filter. Of course, identification of the important role of chloride in the function of prestin *in vivo* and its mechanically activated flux through the lateral plasma membrane may underlie a similar voltage independence. In this way the OHCs of the mammalian inner ear may have overcome the limiting effects of the membrane filter at high-frequency acoustic stimulation.

To summarize, OHCs, probably through a mechanical feedback scheme, are required to boost BM motion and enhance frequency selectivity, a process termed the “cochlear amplifier.” In the absence of OHCs or with a deletion of the gene for Prestin (Liberman *et al.*, 2002), hearing sensitivity and frequency selectivity are likewise impaired. OHCs are unique because they function as both receptors and effectors, transducing mechanical stimuli via hair bundle displacement and changing length and other mechanical properties in response to the generated receptor potentials. These mechanical events, via an energetic boost to BM motion, provide an enhanced stimulus to the inner hair cells, which are the cells that provide synapses to the overwhelming majority of auditory nerve afferents.

### Cochlear Endolymph Increases the Sensitivity of Hearing

An increase in the sensitivity of hair cells is made possible by the unique composition of the inner ear fluids. Within the inner ear, fluids are contained in three compartments known as *scalae*: *scala tympani*, *scala media*, and *scala vestibuli* (Fig. 26.2B). These *scalae* extend in parallel along the length of the cochlea from the base to the apex. *Scala tympani* and *scala vestibuli* contain perilymph, which is high in  $\text{Na}^+$  and low in  $\text{K}^+$ , similar to other extracellular fluids. *Scala media* contains endolymph, a specialized fluid with a low concentration of  $\text{Na}^+$  and a high concentration of  $\text{K}^+$  (about 160 mM). The endolymph is also unusual because it has a positive electrical potential (about 90 mV), observable even in the absence of sound. The endolymph is generated by a highly vascularized tissue in the lateral edge of the cochlea, the *stria vascularis* (Fig. 26.2B).

The organ of Corti, which contains the hair cells, is located at the junction between endolymph and perilymph (Fig. 26.2B). Stereocilia are surrounded by endolymph, whereas the remainder of the hair cell

(basolateral membrane) is surrounded by perilymph. The endolymph increases the sensitivity of the hair cells because it increases the transduction current, a  $\text{K}^+$  current that flows from the endolymph into the hair cells (Fig. 26.2B). The endolymph increases this current because (1) the high concentration of  $\text{K}^+$  in endolymph forms a concentration gradient that favors  $\text{K}^+$  flow into the cells and (2) the positive potential of the endolymph forms a large electrical gradient that also favors  $\text{K}^+$  flow into the hair cells. Once the chemical and electrical properties of the endolymph are established and sound stimulates the cochlea,  $\text{K}^+$  flows into the hair cells with little energy expenditure by the hair cells, as  $\text{K}^+$  is flowing down its electrochemical gradient. Thus, they do not require a high blood flow that might bring noise to the organ of Corti, interfering with sound reception. In fact, there are only a few blood vessels near the organ of Corti.

### Sensorineural Hearing Loss Often Results from Damage to Hair Cells

Sensorineural hearing loss results from damage to hair cells or, less commonly, from damage to afferent nerve fibers (reviewed by Schuknecht, 1993). Hair cells can be destroyed or their hair bundles damaged by intense sound such as those generated by guns, jet engines, or even earphones operated at high sound levels. Hair cell loss is permanent in the mammalian cochlea, but in the bird cochlea, hair cells are regenerated from nearby supporting cells (Corwin and Cotanche, 1988). Damage from intense sounds can be minimized by (1) decreasing the duration of the sound exposure and (2) decreasing the level of the sound at the tympanic membrane (by wearing protectors such as earguards and earplugs). Hair cells can also be destroyed by chemical agents like aminoglycoside antibiotics (e.g., streptomycin, kanamycin). These agents block the transduction channels directly, but their mechanism of hair cell destruction is independent. In individuals with sensorineural hearing loss, some hearing can be restored with a cochlear implant (Box 26.2).

### Summary

Current research on the cochlea is centered on the mechanisms of outer hair cell motility and how this motility contributes to basilar membrane motion. The mechanisms of how sound causes active stereocilia motion remain to be worked out. Substantial interest focuses on the processes and factors involved in hair cell regeneration with the eventual hope that approaches like stem cell implants might encourage restoration of

## BOX 26.2

## COCHLEAR IMPLANTS

The cochlear implant is one of the most successful prostheses used to stimulate the nervous system (Niparko *et al.*, 2000). The cochlear implant can provide partial restoration of hearing for individuals with sensorineural hearing loss. In sensorineural hearing loss, there is usually a partial or complete loss of the sensory cells (hair cells) in the inner ear (cochlea). Hair cells normally transduce the mechanical energy of sound into the electrical energy of receptor potentials. They synapse on primary auditory nerve fibers, which send information to the brain. Hair cells can be damaged irreversibly by intense sound, ototoxic drugs, or the aging process. Once lost, hair cells are not regenerated in mammals. Often, however, individuals with hair cell loss retain a significant complement of auditory nerve fibers. It is these fibers that are stimulated by the cochlear implant.

The cochlear implant consists of a microphone to detect sound, an electronic “processor” that transforms the sound waveform into a code of electrical stimuli, and an array of stimulating electrodes in the cochlea. The electrode array (Fig. 26.10) is inserted through or near the round window into scala tympani where it lies close to the peripheral axons of primary auditory neurons. Usually, the implant consists of about a dozen electrodes that begin in the base and are spaced apically along the cochlear spiral. Those electrodes in the most basal regions are positioned to stimulate nerve fibers that originally responded to high frequencies and those in more apical regions are positioned to stimulate fibers that originally responded to lower frequencies.

In some individuals that have received implants, comprehension of speech is possible, even when there are no other cues such as lip reading. These individuals can carry on a normal conversation, even via telephone. In other individuals, however, full speech comprehension is not restored but the implant, together with lip-reading ability, assists with spoken conversation. It also provides for the detection of important sounds such as the ring of a telephone and the approach of a vehicle. Variability in the success of the implant from patient to patient probably depends on the number of surviving primary auditory neurons, the exact orientation of the electrodes with respect to the neurons, and the coding scheme of the processor that is used. The individual’s motivation and the assistance received from clinicians are also likely to be important factors. Finally, individuals who have become deaf after the acquisition of spoken language reacquire language ability more easily than prelingually deafened individuals, almost certainly because of differences in the central nervous system. Cochlear implant research is focused on making improved designs for the processor and electrodes so that in the future implant users may be able to more fully comprehend speech.

function in the mammalian cochlea. The improvement of cochlear implants is also a very active area of clinical research.

## THE AUDITORY NERVE

Hair cells receive their primary afferent innervation from neurons of the spiral ganglion, located in the central core, or modiolus, of the cochlea (Figs. 26.2, 26.10). These bipolar auditory neurons send peripheral axons to the hair cells and central axons into the brain by way of the auditory nerve, a subdivision of the eighth cranial nerve. Two types of afferent neurons

separately innervate the inner and outer hair cells (Fig. 26.11). The first type (the type I neuron) sends processes to contact inner hair cells, almost always contacting a single hair cell, whereas the second type (the type II neuron) sends processes to contact from 5 to 100 outer hair cells. Fibers from type I neurons are relatively large in diameter and myelinated; thus their information reaches the brain quickly, within a few tenths of a millisecond. Fibers from type II neurons are thin and unmyelinated and transmit information much more slowly. Both types of afferent fibers project centrally into the cochlear nucleus in the brain stem. Interestingly, type I neurons total about 95% of the afferent population (about 30,000 in humans), whereas type II neurons total only about 5%. Thus, outer hair cells,

**FIGURE 26.10** Drawing of the human cochlea showing cochlear implant electrodes. The electrode array is inserted through the round window of the cochlea into the fluid-filled space called scala tympani. It stimulates peripheral axons of the primary auditory neurons, which send messages via the auditory nerve into the brain. In the normal cochlea, frequency is mapped along the cochlear spiral, with the lowest frequencies at the apex of the cochlea (at the top of the figure). The different electrodes of the cochlear implant are designed to stimulate different groups of nerve fibers that originally responded to different frequencies, although because of spatial constraints the implant is not inserted all the way to the cochlear apex. From Loeb (1985).

which number over three-quarters of the receptor cell population, are innervated by only a small minority of the afferent neurons. This innervation plan strongly suggests that the functional role for inner hair cells and type I neurons is to serve as the main channel for sound-evoked information flow into the brain.

### Responses Are Sharply Tuned to Frequency

Type I auditory nerve fibers respond to sound and transmit these responses to the brain via discrete action potentials (reviewed by Ruggero, 1992; Geisler, 1998). The brain must extract information from these spikes and process this information to eventually form a percept of the stimulus. The information available to the brain via the auditory nerve consists of which nerve fibers are responding and the rate and time

pattern of the spikes in each fiber. The response area for a nerve fiber usually is plotted as a graph of sound pressure level vs. frequency with the line showing the threshold contour; such a graph is known as a tuning curve (Fig. 26.12). The lowest point on the tuning curve is at the characteristic frequency (CF). This is the frequency that evokes a response at the lowest sound pressure level; at CF, auditory nerve fibers can respond to sound levels as low as 0dB in the most sensitive range of hearing. At low sound levels, the tuning curve is impressively narrow, indicating that the fiber responds only to a narrow band of frequencies near CF. This sharply tuned “tip” region (Fig. 26.12) is likely generated by the active motility of the outer hair cells. At high sound levels, the tuning curve becomes much wider, especially for frequencies below CF. This response to a broad range of frequencies likely reflects

**FIGURE 26.11** Innervation patterns of afferent and efferent neurons in the organ of Corti. Afferent innervation is provided by ganglion cells of the spiral ganglion in the cochlea, which have central axons that form the auditory nerve. There are two types of afferent neurons: (1) type I neurons, which synapse with inner hair cells, and (2) type II neurons, which synapse with outer hair cells. Efferent innervation is provided by a subgroup of neurons in the superior olivary complex that send axons to the cochlea and are hence called olivocochlear (OC) neurons. There are two types of OC neurons: (1) lateral OC neurons, which innervate type I dendrites near inner hair cells, and (2) medial OC neurons, which innervate type II dendrites near outer hair cells. Lateral OC neurons are distributed mainly ipsilaterally to the innervated cochlea, whereas medial OC neurons are distributed bilaterally to the innervated cochlea, with approximately two-thirds from the contralateral side (not illustrated) and one-third from the ipsilateral side of the brain. From Warr *et al.* (1986).

**Figure 26.12** Tuning curves of two type I auditory nerve fibers. These curves plot the sound pressure level necessary to cause a response as a function of sound frequency. Within the tuning curve, the fiber responds to sound, whereas outside the tuning curve, there is only spontaneous firing (insets at right). The lowest point on the tuning curve corresponds to the characteristic frequency (CF); it is the point of maximal sensitivity. The sharply tuned region near the CF is called the tuning curve tip. The sharp tuning and high sensitivity of this region are generated by the mechanical properties of the outer hair cells. Tuning curves from two fibers are shown, one from a high SR (spontaneous rate) fiber and another from a low SR fiber. As is typical, the high SR fiber has the highest sensitivity. From Kiang (1984).

the passive mechanical characteristics of basilar membrane motion with little contribution from outer hair cells.

The relationship between CF and its point of innervation in a type I fiber has been studied by single unit labeling (Lieberman, 1982). The distance to the point of innervation along the length of the cochlea is logarith-

mically related to fiber CF. Fibers with the lowest CFs innervate the apex of the cochlea, and fibers with progressively higher CFs innervate progressively more basal positions, as expected from the pattern of basilar membrane vibration. This precise mapping of frequency to position is known as tonotopic mapping. It is preserved as the auditory nerve projects centrally

into the cochlear nucleus and for much of the central pathway. This observation strongly suggests that frequency is coded via a place code, with neurons at different places coding for different frequencies.

### Phase Locking of Responses and Codes for Sound Frequency

Responses of auditory nerve fibers can show time-locked discharges at particular phases within the cycle of the sound waveform, a property known as phase locking (Fig. 26.13). Although locked to a particular phase, there is generally not a spike for every waveform peak. Phase locking in nerve fibers results from the phasic release of neurotransmitter as dictated by the ac receptor potential (Fig. 26.6). Phase locking and the ac receptor potential decrease for frequencies above 1 kHz. At low sound frequencies, phase locking is an important temporal code for sound frequency and the sensation of pitch. At high frequencies where phase locking is diminished, the only code for sound frequency is the place code.

**Figure 26.13** (A) Preferential firing of an auditory nerve fiber at a certain phase of the sound waveform. This pattern is called “phase locked,” although the firing is not on every cycle of the waveform. Stimulus frequency was 0.3 kHz. (B) Histograms that quantify the time of firing plotted within one cycle of the sound waveform for many repeated cycles of the stimulus. Response of the fiber is phase locked at the moderate and high SPLs shown, even on this very fast time scale (time for one period was about 0.9 ms, given the stimulus frequency of 1.1 kHz). (A) From Evans (1975). (B) From Rose *et al.* (1971).

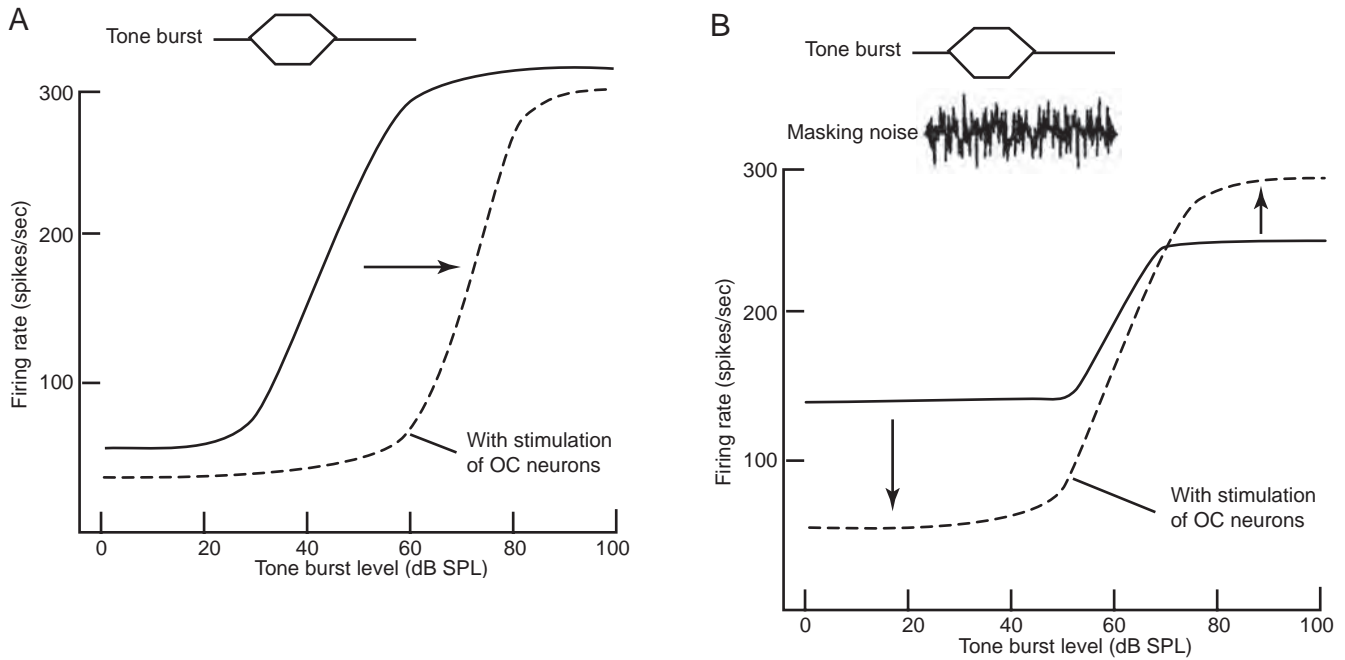

### Neural Response Is a Function of Sound Level and Spontaneous Activity

The response of a single auditory nerve fiber increases with sound level until a point at which the rate of the fiber no longer increases and is saturated (Fig. 26.14A, solid line). The dynamic range over which the rate of most fibers increases is generally between 20 and 30 dB, with some fibers showing somewhat greater dynamic ranges. How then can the auditory nerve signal the large range in level of audible sound from 0 to 100 dB? First, it is likely that as the level of a tone increases, more and more fibers that are tuned to other CFs begin to respond, because tuning curves become broader at higher sound levels (Fig. 26.12). Second, auditory nerve fibers vary in their sensitivity to sound, and as sound level is increased, the less sensitive fibers begin to respond. Sensitivity of fibers at a given CF varies by as much as 70 dB. The sensitivity of response is correlated with the rate of spontaneous firing, which is the rate of firing when there is no stimulus or when the stimulus is outside the tuning curve (Fig. 26.12). Spontaneous rates (SRs) vary from one fiber to another over the range of 0 to 100 spikes/s.

Although there may be a continuum of SR, three main groups of fibers have been defined (low SR: <0.5 spikes/s; medium SR: 0.5 to 17.5 spikes/s; high SR: >17.5 spikes/s), and these groups predict many physiological and anatomical characteristics of auditory nerve fibers. The high SR fibers have higher sensitivities than medium and low SR fibers (Fig. 26.12). Low and medium SR fibers give off the largest number of terminals in the cochlear nucleus of the brain stem and preferentially innervate certain regions, such as the peripheral cap of small cells, suggesting that information carried by the different SR groups may be kept somewhat separate in the brain stem. Low SR fibers may be less sensitive, but they likely play important roles in detecting changes in sounds at high sound levels. Low SR fibers can signal changes at high sound levels because their low sensitivity causes them to respond mostly at higher sound levels and because they have less tendency to saturate, as their response often grows more slowly with sound level.

### Masking Involves Adaptation and Suppression

The auditory nerve response to one stimulus may be masked, or hidden, by the presence of other stimuli. Masking involves properties of auditory nerve response such as adaptation and two-tone suppression, and possibly refractory properties. In adaptation, firing to a tone burst is high initially and then lessens, or adapts,

**Figure 26.14** Rate level function for an auditory nerve fiber in response to tone bursts without (solid lines) and with (dashed lines) electrical stimulation of olivocochlear (OC) neurons. (A) With tone bursts alone, the discharge rate rises with sound level until it reaches a maximum and no longer increases (saturation). Stimulation of the OC neurons shifts the function to the right toward higher tone burst levels (arrow). This shift adjusts the dynamic range of the fiber so that it can signal changes in the tone burst level even for high sound levels; this is likely to be an important function of OC neurons. (B) When the tone bursts are accompanied by continuous masking noise (insets at top), the function in response to tone bursts is changed (solid curve). At low levels of tone bursts, the fiber has a significant firing rate because it is responding mainly to the noise. Even at high levels of tone bursts, the fiber is still responding to the noise in between tone bursts, which causes adaptation, and the fiber responds less to the tone burst than with tone bursts alone. In this case, stimulation of OC neurons (dashed line) decreases the response to the noise, thus decreasing the rate of the fiber at low levels of tone bursts (left arrow). Because the fiber is responding less to the noise, it is less adapted and has a greater response at high levels of the tone burst (right arrow). The fiber now has a greater ability to signal changes in level of the tone burst; this effect has been called “antimasking” and is likely to be another important function of the OC system. Adapted from Winslow and Sachs (1987).

to a steady state over time (Fig. 26.15). Adaptation probably takes place at the hair cell/nerve fiber synapse, as there is little adaptation in receptor potentials of hair cells for these short times (Fig. 26.6). Because of adaptation to one stimulus, the fiber is less likely to respond to a second stimulus; that is, the first stimulus masks the second stimulus. Masking by continuous noise changes the responses to tone bursts greatly. With tone bursts alone (Fig. 26.14A, solid line), there is a moderate dynamic range and a large difference in firing rate from low to high tone burst levels. With tone bursts in masking noise (Fig. 26.14B, solid line), there is a substantial rate at low tone burst levels because the fiber is now responding to the masking noise. At high tone burst levels, the rate is decreased because the fiber is adapted by the noise and is less likely to respond to the tone burst. Thus, with masking noise, there is much less difference in the rate of the fiber as a function of tone burst level as well as a lower dynamic range: these effects decrease the ability of the fiber to signal changes in the tone burst level.

**Figure 26.15** Poststimulus time (PST) histogram from an auditory nerve fiber in response to a tone burst (outline indicated below). A PST histogram is constructed by repeatedly presenting a stimulus while counting the number of action potentials that fall into bins of time during and after the stimulus. The histogram can be thought of as the probability of firing as a function of time. This function has an initial peak and then a decrease in firing (adaptation) during the burst. After the burst ends, spontaneous firing is lessened but then returns gradually.

An additional type of masking, referred to as suppressive masking, involves a phenomenon called two-tone suppression. In two-tone suppression, one tone lowers the response to a second tone even though the first tone does not excite the auditory nerve fiber. Two-tone suppression is present in the motion of the basilar membrane. It may help control the amount of gain provided by the cochlear amplifier, because as stimuli composed of several frequencies increase in sound level, two-tone suppression decreases the response of the nerve fiber so that it does not saturate. Whether there is adaptive masking or suppressive masking depends on the frequencies and levels of signals relative to the response area of the fiber. Masking is important in the auditory system because many auditory processes, such as speech comprehension, are affected greatly by maskers and because background or masking signals are common in many everyday situations.

### Descending Systems to the Hair Cells and Nerve Fibers

The auditory periphery and other hair cell organs receive an efferent innervation from the brainstem (Fig. 26.11). The cochlear efferent neurons have cell bodies in the superior olivary complex and project to the cochlea and hence are called olivocochlear (OC) neurons (reviewed by Warr, 1992; Guinan, 1996). There are two groups of OC neurons—medial and lateral (Fig. 26.11)—named according to the positions of their cell bodies in the superior olive. These olivocochlear fibers separately innervate the two types of hair cells. Medial OC neurons innervate outer hair cells, whereas lateral OC neurons innervate the inner hair cell region by synapsing on dendrites of type I auditory nerve fibers. Little is known about the lateral OC neurons, as their very thin axons are difficult to study. Medial OC neurons can be activated experimentally by electrical stimulation, which causes them to release the neurotransmitter acetylcholine. At the outer hair cell, acetylcholine acts on a nicotinic receptor that allows  $\text{Ca}^{2+}$  influx, which then opens  $\text{Ca}^{2+}$ -activated  $\text{K}^{+}$  channels, allowing  $\text{K}^{+}$  efflux that hyperpolarizes the cell. The hyperpolarization and accompanying decrease in input resistance of the cell probably reduces the electromotility of the outer hair cell, decreases basilar membrane motion, and reduces the responses of inner hair cells and auditory nerve fibers. These decreases shift responses of auditory nerve fibers to higher sound levels (Fig. 26.14A, dashed line). This shift means that sound levels that previously saturated the discharge rates are now within the increasing portion of the rate level curve of the fiber, so the fiber can now signal

**Figure 26.16** Simplified schematic of the pathways of the ascending auditory system of a generalized mammal. The pathway begins at the lower left with the cochlea and ends at top right with the auditory cortex. The large band crossing the midline indicates that the bulk of the pathway is crossed by the level of the inferior colliculus. Some ipsilateral pathways and frequent commissural pathways explain the responses of some units at higher centers to ipsilateral sound. AC, auditory cortex; AN, auditory nerve; AR, auditory radiations; AS, acoustic striae; BIC, brachium of the inferior colliculus; C, cochlea; CIC, commissure of the inferior colliculus; CN, cochlear nucleus; DNLL, dorsal nucleus of the lateral lemniscus; ES, ectosylvian sulcus; IC, inferior colliculus; INLL, inferior nucleus of the lateral lemniscus; LSO, lateral superior olive; MGB, medial geniculate body; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olive; OW, oval window; RW, round window; S, stapes; SOC, superior olivary complex; SS, suprasylvian sulcus; VNLL, ventral nucleus of the lateral lemniscus. From Kiang and Peake (1988).

changes in sound level even at higher sound levels. Thus, one function of medial OC neurons may be to control the gain of the cochlear amplifier to prevent saturation of responses.

Medial OC neurons may also reduce the effects of masking noise on the responses of auditory nerve fibers. Decreases in responses by maskers can occur by adaptation and suppression. The effect of OC stimulation on masked responses to tone bursts can be to *enhance* the response (Fig. 26.14B, dashed line). Responses at low tone burst levels are decreased

because the response of the fiber to the noise is decreased (left arrow on Fig. 26.14B); responses at high tone burst levels are increased because there is less noise-induced adaptation and a greater response to the tone bursts (right arrow on Fig. 26.14B). The fiber now has a greater ability to signal changes in level of the tone burst; this effect has been called antimasking, and may be an important function of the OC system. An additional function of medial OC neurons may be to protect hair cells in the cochlea from damage due to intense sounds via their large synaptic endings on outer hair cells.

### Summary

Although the function of type I auditory fibers is fairly well understood, we do not yet know how afferent fibers of the outer hair cells, the type II auditory nerve fibers, function in the hearing process. Future experiments will provide insight into the roles played by different spontaneous rate groups of type I auditory nerve fibers. More work is needed to identify the mechanisms used to prevent the degradation of signals by masking noise. These mechanisms could potentially be applied clinically in the design of hearing aids and cochlear implants.

## CENTRAL NERVOUS SYSTEM

### Auditory Pathways Are Tonotopically Organized

The auditory nerve terminates centrally in the cochlear nucleus, which in turn projects to the other auditory nuclei of the brain stem: the superior olivary complex, nuclei of the lateral lemniscus, and inferior colliculus (Fig. 26.16). These multiple brain stem nuclei are important for determination of the location of a sound source (see discussion later). The external location of a sound source is not represented directly along the receptor organ of the auditory system in contrast to other systems such as the somatosensory system, where position of a stimulus is mapped by sensory endings along the body surface. Instead, the cochlea maps frequency. Thus, directional information must then be determined by neural processing that compares interaural differences in responses; this processing is accomplished mainly in the brain stem. Above the brain stem, auditory information proceeds to the thalamus and cortex, analogous to other sensory systems. At these highest stages of the auditory pathway are the medial geniculate body of the thalamus and the auditory fields of cerebral cortex (Fig. 26.16). In addition to the ascending pathways shown in Figure 26.16, descending systems link “higher” to “lower” centers in the auditory pathway. The functions of these descending systems have not been well explored, except for the olivocochlear perhaps system (see earlier discussion).

An important characteristic of most central auditory nuclei is tonotopic organization, the mapping of neural CF onto position (reviewed by Webster *et al.*, 1992; Popper and Fay, 1992; Ehret and Romand, 1997). This tonotopy is established by the basilar membrane and is relayed into the central nervous system by the auditory nerve. Such inputs result in isofrequency laminae, sheets of tissue in which neurons have the same CF. These observations support a place code for sound frequency in much of the auditory central nervous system. This is especially true in higher nuclei because these neurons have a decreased ability to phase lock to the sound waveform, and thus a temporal code does not seem to be as robust. In most auditory nuclei there are not large overrepresentations of certain frequencies, although, as noted later, a given nucleus may be more devoted to low frequencies (e.g., medial superior olive) or to high frequencies (e.g., lateral superior olive). An important exception is the case of echolocating bats that use a constant frequency in their echolocating pulse; in these species, there is an overrepresentation of one of the constant frequencies. This overrepresentation begins in the cochlea and is preserved in the cortex (e.g., Fig. 26.23C). In these bats much cortical area is devoted to the constant frequency, analogous to the large somatosensory cortical areas devoted to important areas such as the hands and face.

Under certain conditions, tonotopic mappings have been shown to be capable of plastic changes (Robertson and Irvine, 1989; reviewed by Buonomano and Merzenich, 1998). After peripheral hearing loss, tonotopic mapping of the auditory cortex is altered such that a region that originally processed frequencies within the hearing loss begins to respond to adjacent frequencies. For instance, when the cochlea is damaged so that it no longer responds to high frequencies, the high frequency portion of the cortex does not stay unresponsive, but over time becomes responsive to middle frequencies where hearing is still normal. Plasticity is of interest to humans because of a common condition called presbycusis, which is hearing loss with advanced age. Presbycusis generally begins with a loss at high frequencies and spreads to lower frequencies with advancing age. Although presbycusis is likely caused by peripheral changes, it may result in plastic changes in the central pathways that change the way sound is processed in the brain.

## Units Are Classified by Their Responses to Sound

### Classification by PST Histograms

The cochlear nucleus is the auditory center that is understood best at the cellular level (reviewed by Rhode and Greenberg, 1992). Cochlear nucleus neurons have been well classified both anatomically and physiologically, and structure–function correlations can be made between these classifications. Physiologically, excitation of cochlear nucleus neurons arises from their auditory nerve inputs. Single-unit recordings from cochlear nucleus neurons reveal that the auditory nerve spike pattern is changed to many new patterns. The patterns may be used to classify units on the basis of the shape of the poststimulus time (PST) histogram, which plots the spike pattern of the unit as a function of time for short-duration tone bursts. Unit types are

called “pauser,” “onset,” “primary-like with notch,” “chopper,” and “primary-like” (Fig. 26.17). A correspondence has been established between these unit types and anatomical cell types of the cochlear nucleus. The correspondence was first suggested by the regional distributions of unit and cell types; for example, there is a region of the cochlear nucleus in which one finds mostly “octopus” cells and from which mostly onset units are recorded. Direct correspondence has been made by single-unit labeling, in which a single unit is first classified physiologically according to PST type and subsequently injected with a neural tracer (e.g., horseradish peroxidase) that fills the neuron and its processes. The anatomical cell type can then be determined from postexperiment histology. These types of experiments are difficult and low yielding, but they firmly establish the structure–function correspondences, at least for neurons large enough to record and

**Figure 26.17** Schematic of the main anatomical cell types of the cochlear nucleus and their corresponding poststimulus time (PST) histograms. (Left) An auditory nerve fiber is shown with its typical response, a primary-like PST histogram (shown in Fig. 26.15). (Center) The auditory nerve fiber divides to innervate the main cochlear nucleus cell types. (Right) PST histograms corresponding to these cell types are shown. In their PST histograms, pauser units fire an initial spike and then have a distinct pause before a slow resumption of activity. Onset units fire mainly at the tone burst onset. Primary-like units get their name from the similarity of their PSTs to those of primary auditory nerve fibers, but the primary-like with notch type additionally has a brief notch following the initial spike. Chopper units have regular interspike intervals that result in regular peaks in the PST. Most of these patterns are very different from the primary-like PST and irregular interspike intervals of the auditory nerve fibers. For histograms, the sound stimulus is typically a 25-ms tone burst with frequency at the CF of the neuron and sound level at 30 dB above threshold. From Kiang (1975).

label *in vivo*. For instance, a major cell type in the ventral subdivision of the cochlear nucleus, “spherical bushy” cells, corresponds to a major unit type, the “primary-like” units (Fig. 26.17).

Use of PST histograms is helpful not only in classifying units, but also in revealing functional properties of the neurons. Let us consider the example of primary-like units. The primary-like pattern reveals that the spherical bushy cell faithfully has preserved the temporal properties of the auditory nerve fiber response and implies that these units receive endbulbs from nerve fibers (see Box 26.3). In contrast, other types of cochlear nucleus neurons alter the spike patterns of the auditory nerve fibers and presumably have distinct functions. For instance, onset units respond mainly at the onset of a short tone burst (Fig. 26.17). One subclass of onset units can increase its response over a large range of SPL and might be involved in signaling sound level. Relative to mammals, tests of such hypotheses are easier in birds, where there is much more regional segregation of neurons by anatomical and physiological type in the cochlear nucleus. In birds, bushy cells are segregated in one region (nucleus magnocellularis), whereas other cell types, such as multipolar cells, are confined to a second region (nucleus angularis). The bushy cells in nucleus magnocellularis have excellent phase locking, but a poor dynamic range of response when sound level is increased. Multipolar neurons in nucleus angularis have complementary properties: poor phase locking, but excellent dynamic ranges. Overall, these results suggest that in the auditory system of diverse animal species there are separate neural pathways for time coding vs. sound level coding as well as for other types of coding. Thus, the cochlear nucleus is the level where parallel pathways in the auditory system begin.

#### *Classification by Response Map*

Another important way to classify neurons in the cochlear nucleus, as well as throughout the auditory nervous system, is by the response map of a neuron (Fig. 26.19). Response maps are plotted on graphs of sound level versus frequency; like tuning curves, these maps show areas of excitation but they additionally show areas of inhibition. They are especially valuable where inhibitory influences play a role in shaping responses, such as in the dorsal subdivision of the cochlear nucleus, the inferior colliculus, and at higher stages of the auditory system. In the dorsal cochlear nucleus, five response types have been defined (Fig. 26.19). Type I neurons have excitatory tuning curves similar to those of the auditory nerve (Fig. 26.12) and have no inhibitory areas.

Other response types have progressively larger inhibitory areas; for example, type IV neurons have only a small excitatory area near CF and a narrow, knife-sharp excitatory area above CF, with the rest of their area dominated by inhibition. This inhibition is generated by inhibitory circuits within the dorsal cochlear nucleus, in part from type II neurons. Type IV neurons correspond to the main projection neurons of the dorsal cochlear nucleus, the pyramidal neurons, whereas type II neurons are likely to be inhibitory interneurons. One hypothesis for the functional role of type IV neurons is that their sharp borders between excitatory and inhibitory areas serve to detect the spectral notches that result from the acoustic characteristics of the external ear, especially the pinna. These notches could be used for sound localization, as their frequencies depend on sound source location. The notches also depend on position of the pinna; in fact, type IV neurons receive input from brain stem somatosensory nuclei that may inform the type IV neurons about the position of the animal’s moveable pinna. Animals that lack a moveable pinna, such as humans and cetaceans (whales and porpoises), have a dorsal cochlear nucleus that differs greatly from that of other mammals by being unlayered and possibly lacking in several cell types (granule and cartwheel cells).

#### *Classification by Laterality of Response: The Response to the Contralateral versus Ipsilateral Ear*

A final important way to classify neurons is by their laterality of response, which is defined as whether the neuron responds to the contralateral or ipsilateral ear and whether the response is excitatory or inhibitory (reviewed by Irvine, 1986). Many neurons in central auditory nuclei above the cochlear nucleus are binaural and can be influenced by sound presented to either ear. A predominant pattern, however, is for the neuron to be excited by sound in the contralateral ear (the side opposite to where the neuron is located). The influence of the ipsilateral ear can be excitatory, inhibitory, or mixed. The contralateral response results from the fact that many central auditory pathways cross to the opposite side of the brain (Fig. 26.16). There are also uncrossed pathways; these pathways generate the response to the ipsilateral ear. Despite an influence of the ipsilateral ear, lesion studies indicate the functional importance of excitation from the contralateral ear. For instance, damage to the inferior colliculus or auditory cortex on one side decreases the ability to localize sounds on the opposite side. Thus, as in other sensory and in motor systems, one side of the brain is concerned primarily with function on the opposite side of the body.

## BOX 26.3

## GIANT SYNAPTIC TERMINALS: ENDBULBS AND CALYCES

The largest synaptic terminals in the brain are contained in the central auditory pathway. There are two types of these giant synaptic terminals: (1) endbulbs of Held, which are found in the ventral cochlear nucleus (Fig. 26.18A); and (2) calyceal endings, which are found in the medial nucleus of the trapezoid body. Calyces are so large that it is possible to use patch electrodes to record and clamp the presynaptic terminal while simultaneously doing the same with their postsynaptic target in *in vitro* preparations (Forsythe, 1994). This type of study has given insight into presynaptic and postsynaptic regulation of transmitter release at this glutamatergic synapse.

Endbulbs and calyces enable secure transmission of information to their postsynaptic neurons. Endbulbs of Held are formed by primary auditory nerve fibers; each nerve fiber forms one or sometimes two endbulbs. The endbulbs contact and completely encircle their postsynaptic target, the spherical bushy cells of the cochlear nucleus (Fig. 26.18A). The endbulb probably forms hundreds of synapses directly onto the soma of the spherical bushy cell. In single-unit recordings near bushy cells, a metal microelectrode records a complex waveform that differs from recordings in other regions of the brain (Fig. 26.18B). The waveform consists of a prepotential followed about 0.5 ms later by a spike. The prepotential is likely from the presynaptic endbulb and the spike is from the postsynaptic bushy cell. The delay between the two events is the synaptic delay. This unusual synapse has several important properties. First, the prepotential is almost always followed by a spike, indicating that the discharge

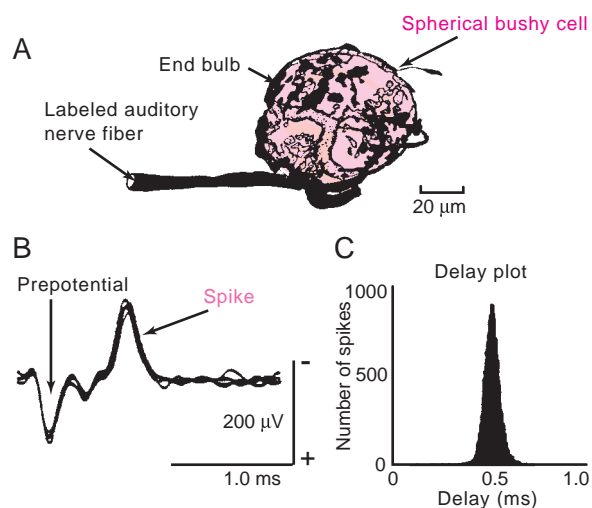

in the endbulb is securely followed by a discharge in the bushy cell. Second, the delay between the prepotential and the spike is almost always the same, indicating that the synapse has a low jitter, or variability in time (Fig. 26.18C).

The large influence of the endbulb would, for most neurons, last many milliseconds so that two closely spaced presynaptic spikes would produce only one post-synaptic spike or a second spike that was delayed, thus smearing in time the pattern of input spikes. However, the bushy cell membrane potential recovers quickly because its membrane contains specialized  $K^+$  channels that allow the cell to repolarize after firing an impulse so it is “reset” and ready to fire again (Manis and Marx, 1991). The overall effect of endbulb–bushy cell specializations are to replicate the spike pattern of the auditory nerve fiber, producing a PST histogram and phase-locking pattern like that of an auditory nerve fiber. These characteristics are important because the end bulb–bushy cell synapse is the only central synapse in the pathway to the medial superior olivary nucleus, a nucleus where timing information from the two ears is compared in order to localize sound sources (Fig. 26.20A).

From Rouiller *et al.* (1986). (B) Superimposed waveforms recorded by an extracellular metal electrode in the anteroventral cochlear nucleus. The endbulb is such a large synaptic ending that it generates a prepotential, which is followed after a synaptic delay by the spike from the bushy cell. At this synapse, prepotentials are usually accompanied by spikes, demonstrating the reliability of the synapse. From Pfeiffer (1966). (C) Histogram of the delay time between prepotential and spike. This represents the synaptic delay between endbulb and bushy cell. The delay of this synapse has an exceptionally low jitter in time. From Molnar and Pfeiffer (1968).

**Figure 26.19** Unit classification by “response map.” Shown are response areas for the five response types (types I–V) typically found in the cochlear nucleus. Response types are distinguished by the positions of their response areas: excitatory (green shading) and inhibitory (pink shading). Question marks show variable or uncertain areas. Type I neurons have excitatory response areas similar to the tuning curves of auditory nerve fibers. Type II neurons have similar excitatory areas and are inferred to have inhibitory flanking areas because they have little response to broadband signals like noise. Type III neurons have similar excitatory areas and definite inhibitory areas on either side. Type IV neurons have a small excitatory area at low levels (near the characteristic frequency), as well as a knife-sharp excitatory area at higher frequencies. Inhibition dominates much of the remainder of their response area. Type V neurons are similar to type IV neurons but lack a low-level excitatory area. From Young (1984).

## The Auditory Brain Stem Uses Binaural Cues to Determine Sound Location

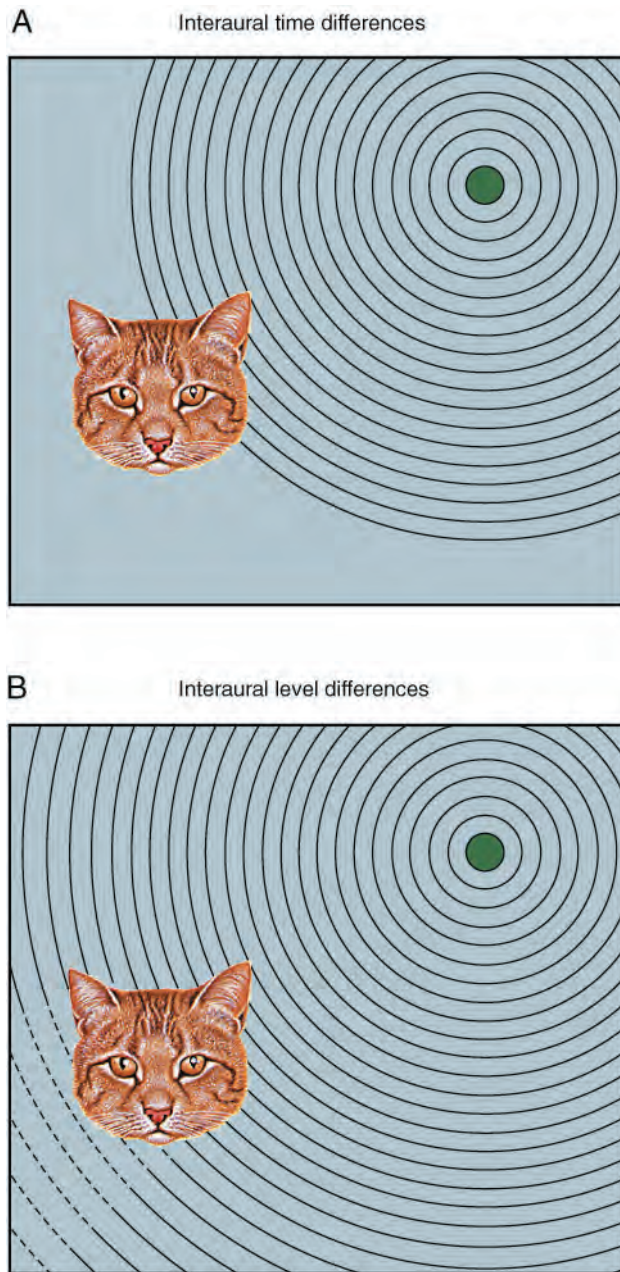

An important function of the auditory system is to determine the location of sound sources in space. Binaural sound localization occurs when cues from both ears are used to locate sounds (reviewed by Wightman and Kistler, 1993). This is the predominant type of localization for determining the azimuthal position of a sound source. Binaural localization uses two cues: interaural time differences (ITDs) and interaural level differences (ILDs) (Fig. 26.20). ITDs result because sound reaches the ear closest to the source sooner than the ear farther from the source (Fig. 26.20A). ITDs are a good cue for localization because they depend greatly on the azimuth of the source. For ongoing sounds, such as pure tones, they can be translated into phase differences in the sound waveforms at the two ears. These phase differences are useful at low frequencies, but become ambiguous for frequencies above about 1.5 kHz (for a human-sized head), because by the time sound reaches the ear away from the source, the waveform has repeated by a cycle or more. Auditory neurons can phase lock to the sound waveform, as noted earlier. The decline in phase locking for frequencies above 1 to 3 kHz is a second reason that phase differences are less important for localizing sounds at high frequencies.

Interaural level differences (ILDs) result when the head forms a “sound shadow,” reducing the level of sound at the ear away from the source (Fig. 26.20B). ILDs vary greatly with sound-source azimuth, but due to the directional characteristics of sound, ILDs are significantly large only at high frequencies and are much smaller at low frequencies. Thus, for sound localization at low frequencies (<1 kHz), ITDs are the major cues, but for localization at high frequencies

(>3 kHz), ILDs are the major cues. For human performance using pure tones, the accuracy of azimuthal localization is good at low frequencies and at high frequencies, but somewhat less accurate at middle frequencies, perhaps because the cues are more ambiguous in this range. In psychophysical experiments in humans under optimal conditions, the minimum discriminable angle for localization of a sound source approaches one degree of azimuth. The physical cues corresponding to this angle are about 10  $\mu$ s in ITD or 1 dB in ILD. When experiments are conducted with headphones to manipulate the ITDs and ILDs, such interaural differences are indeed discriminable in human subjects.

### *Mechanisms of Interaural Time Sensitivity*

Two neural circuits that provide sensitivity to ITD or ILD are within the superior olivary complex (Fig. 26.21; Irvine, 1986; Yin and Chan, 1990). The neural mechanisms that generate sensitivity to ITDs are impressive given the small sizes of the differences. For instance, the central nervous system must be able to detect ITDs of 10  $\mu$ s by comparing spikes coming in from the neural channels of the two sides that differ in time by 10  $\mu$ s. However, 10  $\mu$ s is less than the rise time of neural spikes, making the incoming spikes almost identical. The neural circuit that is sensitive to ITDs in the mammal is the medial superior olive (MSO) and its inputs (Fig. 26.21A); a similar circuit is present in birds in nucleus laminaris. The MSO inputs are from primary-like units (spherical bushy cells) of left and right cochlear nuclei. These inputs preserve the phase-locking and timing characteristics of the auditory nerve because of the low jitter in the endbulb/bushy cell synapse (see Box 26.3). For a low frequency sound with

**Figure 26.20** The two cues for binaural localization of sound. A sound source is shown as a solid dot to the right of the animal's head and sound waves are shown as concentric lines. (A) Interaural time differences result from the longer time it takes sound to travel from the source to the ear away from the source. (B) Interaural level differences result from the head forming a "sound shadow," reducing the level of sound at the ear away from the source.

an ITD, phase-locked spikes from one side will have a time difference relative to the other side. Phase-locked spikes will repeat this time difference many times during the many waveforms of a continuous sound.

Neural delay lines that "make up" for this time difference are formed by axons for both contralateral and

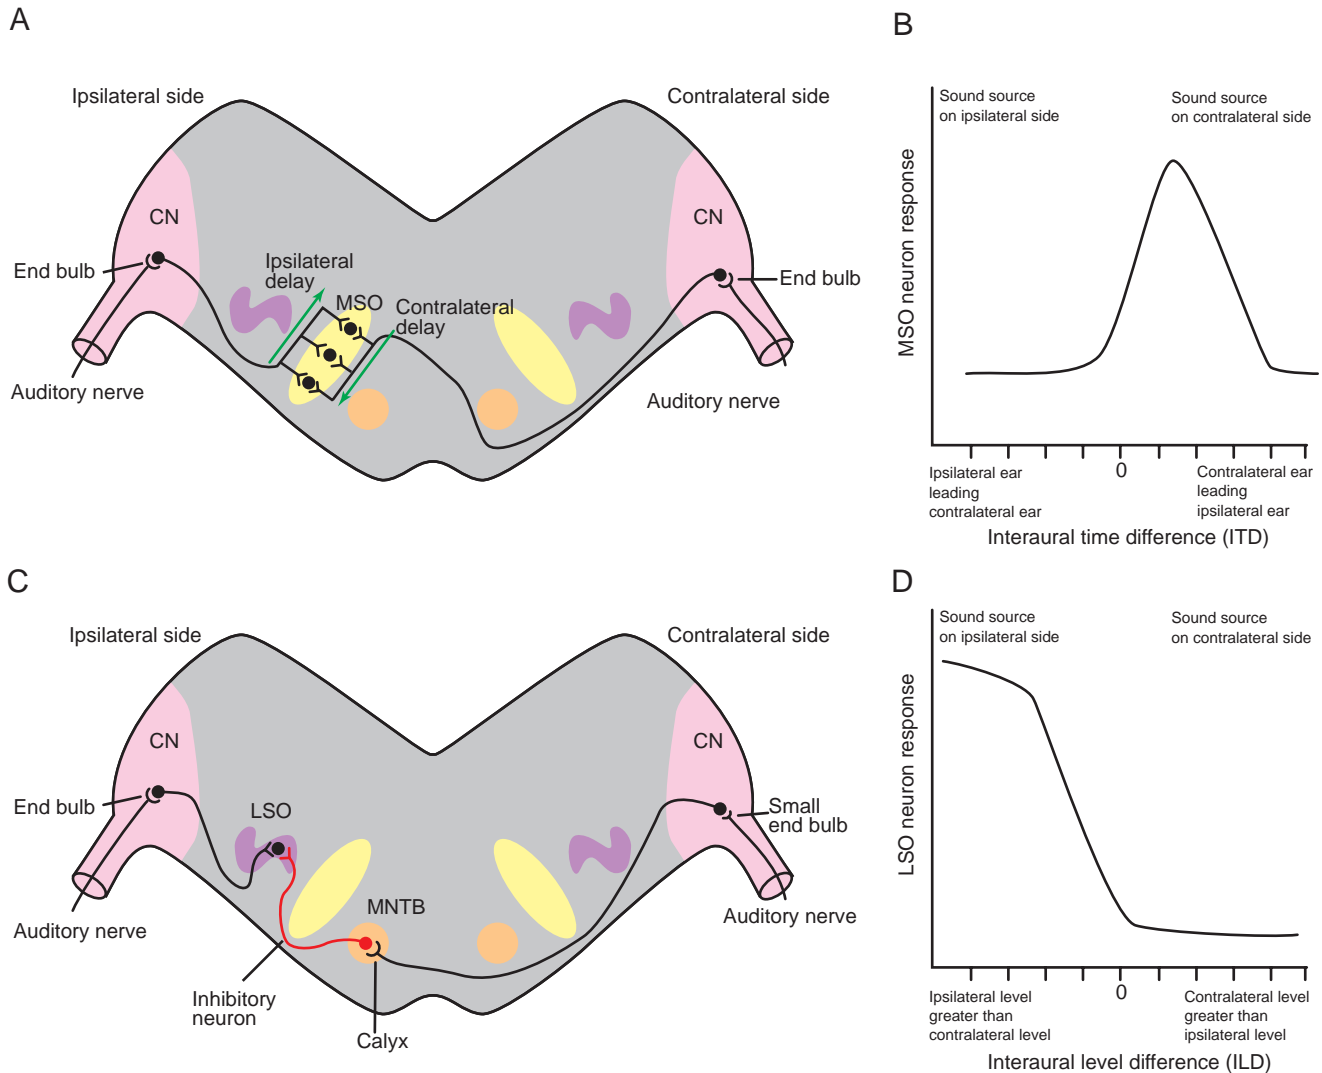

ipsilateral inputs, in the model originally proposed by Lloyd Jeffress (Fig. 26.21A). An axon forms a delay line simply because it takes time for an impulse to travel along the axon. Within the MSO, neurons respond best when they receive coincident input from the two sides; thus a neuron in the middle of the drawing of the MSO in Figure 26.21A would respond best if the delays were about equal. A neuron at the bottom of the drawing has a long contralateral axonal delay that makes up for stimuli coming in later from the ipsilateral side. Thus, this neuron would respond best if the sound to the contralateral ear were leading, which occurs for a sound source located on the contralateral side (Fig. 26.21B). Medial superior olive neurons thus are tuned to a particular ITD and respond less to other ITDs.

The Jeffress model recently has been challenged: new data in small mammals demonstrates that the best delays are outside the physiological range for the size of the animal's head and the neural inhibition in the MSO is not explained in the Jeffress model (Brand *et al.*, 2002). As mentioned earlier, ITDs are most important for sound localization at low frequencies and the MSO has a tonotopic organization that is composed predominantly of neurons with low characteristic frequencies.

#### *Mechanisms of Interaural Level Sensitivity*

A second neural circuit in the brain stem, within the lateral superior olive (LSO), generates responses that are sensitive to ILDs (Fig. 26.21C). Input to the LSO from the ipsilateral side is excitatory by way of spherical bushy cells of the cochlear nucleus. Input from the contralateral side is inhibitory. This input originates from globular bushy cells of the cochlear nucleus and synapses by way of giant calyceal endings on neurons in the medial nucleus of the trapezoid body (MNTB; Fig. 26.21C). Many of the neurons in the medial nucleus of the trapezoid body are inhibitory and use the neurotransmitter glycine, which is a common inhibitory transmitter throughout the auditory brain stem. These inhibitory neurons then project to the LSO. Because of these inputs, LSO neurons compare the difference in levels of the sound at the two ears: they are excited when sound in the ipsilateral ear is of higher level, but are inhibited when sound in the contralateral ear is of higher level (Fig. 26.21D).

When the sound is of equal level in the two ears, the strong contralateral inhibition usually dominates and there is little response. These neurons are thus excited by sound sources located on the ipsilateral side of the head. As the lateral superior olive projects centrally, this ipsilateral-side response is transformed to a contralateral-side response by crossing to the inferior colliculus on the opposite side. (There is also an uncrossed

**Figure 26.21** Innervation schematics and responses of two circuits in the lower brain stem that are important in binaural sound localization. Neuronal cell bodies are shown as dots, and fiber pathways are shown as lines; positions of large synaptic terminals (endbulbs and calyces) are indicated. (A) Circuit of the medial superior olive (MSO), which is sensitive to interaural time differences (ITD). Input to the cochlear nucleus (CN) from the auditory nerve terminates at the large endbulbs of Held that synapse onto spherical bushy cells (see Fig. 26.18). Bushy cells project bilaterally such that a single MSO receives input from both sides. Bushy cell inputs form delay lines such that ITD is mapped along the MSO. Data suggest that the delay line is oriented rostrocaudally and that only contralateral inputs are delayed. (B) Response of an MSO neuron as a function of ITD. Neurons within the MSO respond when spikes from their two inputs arrive at the same time. The response plotted is of a neuron in the lower part of the MSO drawn in part A; there is a large response when the ipsilateral input lags so that early contralateral input has time to proceed down the axonal delay line to reach the neuron at the same time as the lagging ipsilateral input. This type of lagging ipsilateral input would be produced by a sound source located on the contralateral side, as would be the case for a MSO on the left side of the animal shown in Fig. 26.20. (C) Circuit of the lateral superior olive (LSO), which is sensitive to interaural level differences (ILD). Excitatory input arises from the ipsilateral CN. Inhibitory input (red line) from the contralateral side is through the medial nucleus of the trapezoid body (MNTB), a nucleus of inhibitory neurons. The large synaptic ending in the MNTB is called a calyx (similar to the endbulb pictured in Fig. 26.18). (D) Response of an LSO neuron as a function of ILD. There is a large response when sound is of higher level on the ipsilateral side and no response when sound is of higher level on the contralateral side. Thus, a response is produced by a sound source located on the ipsilateral side.

projection, but it is inhibitory.) As mentioned earlier, ILDs are most important for sound localization at high frequencies and the LSO has a tonotopic organization that is composed predominantly of neurons with high characteristic frequencies.

### Inferior Colliculus

Ascending input from lower brain stem centers converges at the inferior colliculus, which is an obligatory synaptic station for almost all ascending neurons. The inferior colliculus consists of several subdivisions, the

best studied of which is the large, laminated, central nucleus. In the central nucleus, direct input from the cochlear nucleus interacts with binaurally responsive input from the MSO and LSO. Terminals from the MSO and LSO may have limited spatial overlap, however, as the central nucleus is organized tonotopically. Low CF input (including that from the MSO) projects to the dorsolateral part of the colliculus and high CF input (including that from the LSO) projects to the ventromedial part. Many low CF collicular neurons are sensitive to ITDs, like their MSO inputs, whereas many high CF collicular neurons are sensitive to ILDs, like their LSO inputs. Interestingly, large lesions of the superior olivary complex do not completely disrupt ILD sensitivity in the colliculus; this is evidence that ILD sensitivity is created anew at levels above the LSO. ILD sensitivity may be created in part by the dorsal nucleus of the lateral lemniscus, a nucleus within the lateral lemniscus that sends a large inhibitory projection to the colliculus. ILD sensitivity may also be created anew by inhibitory mechanisms within the colliculus. Additional circuits for the generation of ITD sensitivity have not been identified, thus the colliculus appears to be sensitive to ITD because of its inputs from the MSO.

An important question is whether the colliculus uses its inputs to form a “space map”—a mapping of sound source location to position within the brain. Such a mapping has not been reported in the mammalian inferior colliculus, but a mapping exists in the deep layers of the superior colliculus, where it is in register with a mapping of the visual field. These deep layers of the superior colliculus have sensorimotor functions concerning orientation movements of the head, eyes, and pinnae. Another auditory space map has been observed in the barn owl, which hunts for prey in darkness using acoustic cues (reviewed by Cohen and Knudsen, 1999, see Chapter 22). In the owl, the mapping has been observed within a nucleus homologous to the external nucleus of the inferior colliculus (nucleus mesencephalicus lateralis dorsalis). Here, spatial receptive fields of neurons are narrow in both azimuth and elevation. These receptive fields are arranged such that there is a mapping of sound source location within the brain. This mapping demonstrates that space maps do exist, but they do not appear to be a common feature of the auditory system of nonspecialized mammals.

### The Medial Geniculate and Auditory Cortex Are the Highest Stages of the Auditory Pathway

The medial geniculate and auditory cortex contain subdivisions that have clear tonotopic organization,

as well as subdivisions with less obvious tonotopy (reviewed by Clarey *et al.*, 1992; de Ribaupierre, 1996). For instance, in the cortex of the cat, there are four fields that have clear tonotopic mappings (fields AI, A, P, VP), but other fields that do not (Fig. 26.22). The tonotopic axis of field AI runs from high frequencies rostrally to low frequencies caudally; other adjacent fields (such as A) have mirror-image tonotopy (Fig. 26.22B). The major ascending pathway that connects tonotopic areas at the highest levels of the pathway begins in the central nucleus of the inferior colliculus,

**Figure 26.22** Auditory cortical fields in the temporal cortex of the cat. (A) Lateral view. (B) Lateral view that is “unfolded” to show the part of the fields that normally are hidden within the sulci (orange shading), as well as the high- and low-frequency limits of the tonotopic fields. The four tonotopic fields are the anterior (A), primary (AI), posterior (P), and ventroposterior (VP). Positions of the lowest and highest CFs in these fields are indicated in B. Note that at the boundaries of the tonotopic fields, the direction of tonotopy is reversed so that adjacent fields have “mirror-image” tonotopy. Other cortical fields have less rigidly organized tonotopy or little tonotopy. These fields are secondary (AII), ventral (V), temporal (T), and dorsoposterior (DP). Also indicated are suprasylvian sulcus (sss) and anterior and posterior ectosylvian sulci (aes, pes). From Imig and Reale (1980).

forms synapses in the laminated ventral division of the geniculate, and then continues to most of the tonotopic cortical fields. Other parallel pathways exist. A parallel pathway connecting less tonotopic areas begins in the dorsal cortex of the colliculus, forms synapses in the dorsal division of the medial geniculate, and projects mainly to cortical field AII. Finally, a polysensory pathway begins in the external and dorsal nuclei of the colliculus and projects via the medial division of the geniculate to almost all the auditory cortical fields.

In general, the physiology of tonotopic areas has been explored better than that of other areas. Units from the tonotopic areas, such as the ventral division of the geniculate and cortical field AI, tend to have short latencies and sharply tuned tuning curves. Neurons in areas with less obvious tonotopy tend to have longer latencies, broader tuning curves and responses that can habituate or stop responding after multiple presentations of the stimulus, especially in anesthetized preparations. In humans, the primary auditory cortex is located on Heschl's gyrus, which is on the superior surface of the temporal lobe (Fig. 26.16). Sound-evoked activation is seen in this region with positron emission tomography (PET) and functional magnetic resonance imaging (fMRI).

The medial geniculate exerts its influence on ascending information, but it does so with extensive influence from the cortex. The medial geniculate receives a large number of projections from the auditory cortex: it probably receives more input from auditory cortex than from lower centers. One large projection is from the tonotopic cortical fields AI and A to the tonotopic ventral division of the medial geniculate. Apparently, however, the geniculate mediates some functions that do not require the cortex. For example, fear conditioning is a behavior that can be established by pairing a sound with a painful electric shock in rats. After conditioning is established, conditioned responses such as an increase in blood pressure can be elicited by sound alone. Work by Joseph LeDoux has shown that lesions of the auditory pathway up to and including the geniculate have a large effect on such conditioning; however, lesions of the auditory cortex do not produce large alterations. Pathways directly from the geniculate to the amygdala mediate such conditioned responses. Cortical neuron responses are also changed by conditioning; for example, the pairing of an acoustic stimulus with a noxious stimulus greatly alters the response of cortical neurons. Such observations indicate that responses at these high levels of the auditory pathway are context dependent.

### *Cortical Columns*

A fundamental feature of cortical organization is the cortical column, which is oriented normal to the cortical surface and runs across all six of the cortical layers. In the cortex, neurons within a column tend to have similar response characteristics. For instance, in the auditory cortex, neurons within a given column generally have similar CFs. Neurons also tend to have similar types of responses to binaural sounds; these binaural interaction characteristics are tested in preparations in which each ear is stimulated with a separate sound source. Usually one ear, the main ear, excites a cortical neuron; most often this ear is the contralateral ear. The effect of the opposite ear can be either to excite by itself or to facilitate the main ear response of the neuron (summation interaction), or to inhibit by itself or to suppress the main ear response (suppression interaction). Typically, either summation interactions or suppression interactions are found for neurons within a column. For the high-CF part of AI, summation and suppression columns show some organization, although not nearly as ideal as a checkerboard pattern with CF on one axis and summation/suppression interaction on the perpendicular axis.

The binaural interaction classification is useful, but oversimplified, as some neurons can show both summation and suppression, depending on factors such as sound level. However, one finding that supports summation/suppression columns as an organizational plan is the pattern of projections from a column in one hemisphere to the opposite cortical hemisphere. Neurons within a summation column tend to have large projections to the opposite hemisphere. Suppression columns tend to have few projections (with the exception of less common columns in which the contralateral ear is inhibitory and the ipsilateral ear is excitatory). These findings support binaural interaction characteristics as an important property of cortical columns.

### *Cortical Field AI and Sound Localization*

Physiological studies suggest a role for cortical field AI in sound localization. In AI, many neurons are sensitive to interaural time and level differences, much as for neurons at lower stages of the pathway. When tested with a sound source in space, the response of many neurons depends on the azimuth of the source. As expected from the fact that auditory pathways are predominantly crossed, a large number of cortical neurons respond to sound sources centered on the contralateral side. The receptive fields for many neurons occupy much of the azimuth on the contralat-

eral side and some have even wider fields that encompass both sides (omnidirectional fields). Other neurons, however, have receptive fields that are very narrow. Units within a given column tend to have receptive fields that are similar, probably because of the similar binaural interaction characteristics within a column. It is easy to imagine that neurons with summation characteristics would tend to have receptive fields that would be large and encompass both contralateral and ipsilateral sides because of their bilateral excitatory input. Units with suppression characteristics, however, would tend to have narrower fields located mainly on one side because they receive inhibitory input from the other side. Finally, the auditory cortex has not yet been shown to have an organized space map of a sound's position in external space onto a dimension within the cortex.

Behavioral studies also indicate a strong role of AI in sound localization (Jenkins and Merzenich, 1984). Cats with lesions of AI on one side have a deficit for localizing sounds on the contralateral side. Lesions of the posterior auditory field (a tonotopic field just caudal to the primary auditory field) and an area near the anterior ectosylvian sulcus, but not other fields, also produce deficits (Malhotra and Lomber, 2006). Furthermore, the deficit is frequency specific: if the lesion is in areas of AI tuned to certain frequencies, the deficit is observed only for those frequencies. The deficit is most pronounced when the task is for a subject to localize and move toward the sound source and is less obvious when the task is simply to lateralize the sound; that is, to press a bar on the right or left side corresponding to the side of the sound source. This finding suggests that the simpler lateralization task is processed at a subcortical location, but the more difficult task of forming an image of a sound source's position in space and moving toward that position is processed at the cortex.

### *Coding of Complex Signals in the Cortex*

Animals emit a variety of vocal signals. These signals make possible a wide range of behaviors, including communication and even echolocation in bats (Box 26.4). Are there specific "call detectors" in the auditory cortices of these animals? This area is relatively unexplored; however, available evidence suggests that this type of detector may exist only rarely and that the response to vocalizations is probably represented by spatially dispersed, synchronized assemblies of cortical neurons rather than by individual neurons. However, cortical neurons do show selectivity to complex sounds such as noise bands and species-specific calls over what would be predicted from their

pure tone frequency selectivity (Rauschecker *et al.*, 1995). For instance, a neuron that responds well to a particular type of call does not usually respond as well to the call played backward in time even though it has an identical frequency content. Similar results in response to speech stimuli have been found in recordings of units from auditory areas in the superior temporal gyrus of human patients undergoing surgery for epilepsy.

A number of studies using lesions of the auditory cortex indicate a strong role of the cortex in processing complex acoustic signals. After bilateral lesions of the auditory cortex, experimental animals cannot discriminate between different temporal patterns of sounds, such as a sequence in which the sound frequency pattern is a repeated "low-high-low" and a sequence in which the pattern is a repeated "high-low-high." In primates, lesions of the cortex impair discrimination of species-specific vocalizations. This impairment is more pronounced after lesion of the left cortex, indicating lateralization of processing of these vocalizations at the cortical level. Human speech is an especially complex acoustical signal; its intelligibility and production can be decreased greatly by a stroke that creates a lesion of the cortex in humans. Although there is great variability in the extent and effect of such lesions, language processing is most interrupted by lesions of perisylvian cortex regions, especially in Wernicke's area and Broca's area (Chapter 51). Wernicke's area is especially close to auditory cortex and can be considered an auditory association area. Lesions lateralized in the left hemisphere in right-handed individuals are most disruptive of speech comprehension and production. The lateralization of language processing in one hemisphere is a unique finding of asymmetry in brain function, very different from the apparent symmetry of subcortical nuclei and primary auditory cortical fields.

Imaging studies (PET, fMRI) in normal subjects suggest acoustic stimuli such as noise and modulated tones activate primary auditory cortical fields, but do not activate surrounding areas. These surrounding areas, including Wernicke's and Broca's areas, can be activated by speech stimuli. Furthermore, the activation by speech stimuli usually is lateralized to the left hemisphere of right-handed individuals. Taken together, the lesion and imaging studies suggest a hierarchical pattern of cortical activation with simple stimuli being processed in the primary cortical fields and more complex stimuli, such as speech, processed in association areas that are lateralized in one hemisphere. Further imaging studies will be very useful in showing more specifically the functions of the auditory areas in the cortex.

## BOX 26.4

## BAT ECHOLOCAATION

Bats offer unique opportunities for researchers studying the auditory system. Echolocating bats emit high-frequency pulses of sound and use the return echoes to locate and capture their flying insect prey. These pulses are above the upper frequency limit of human hearing. They were discovered in the 1940s by Donald Griffin, who was then an undergraduate student at Harvard University. The echolocation performance of the bat is impressive: bats are adept enough to find a mosquito above a golf course at night. Indeed, Griffin demonstrated that bats can avoid wires as thin as 0.3mm diameter while flying in a darkened room.

There are more than 800 species of echolocating bats, all within the suborder Microchiroptera. One of the best-studied bats is the mustached bat, *Pteronotus parnellii*. It emits echolocating pulses that have an initial part of constant frequency, followed by a part of decreasing frequency (frequency modulated). This bat is thus called a CF-FM bat (Fig. 26.23B). Some other species of bats emit only the FM portion and are called FM bats. Bats use differences between the emitted pulse and the returned echo to locate targets. Relative to the pulse, the returned echo is delayed because of the sound's round-trip travel time from the bat to the target. The delay between the pulse and echo can thus be used as a measure of target range.

The echo can also be changed in frequency, or Doppler-shifted, because the bat is moving relative to the reflecting surface. Bats that are moving toward a reflecting surface will have an echo that is Doppler-shifted toward higher frequency. Most background surfaces will be Doppler shifted about the same. However, targets that are moving differently from the background will generate different Doppler shifts. For instance, a moth with moving wings will reflect an echo with a moving Doppler shift that is quite different from the stationary background. Such dif-

ferences are presumably used by the CF-FM bat to locate moving targets. Insects are not always passive in the face of such predatory behavior. For instance, some moths have good ultrasonic hearing and take evasive flight maneuvers when exposed to a bat's pulse.

Research on the auditory system of bats has been greatly aided by knowledge of the "relevant" stimulus, since much of the time the bat hears an emitted pulse followed a short time later by an echo. Pioneering work by Suga (1990) has demonstrated that the auditory cortex of the mustached bat contains many specialized areas (Fig. 26.23C). One large area (DSCF area) is devoted to processing the Doppler-shifted echo for the strongest harmonic of the pulse, near 60kHz. These frequencies also have large representations throughout the bat's auditory system beginning at the cochlea. Within the DSCF area, there is a mapping of neuronal best level as well as characteristic frequency. In other cortical regions, there are neurons whose response properties cause them to detect various features of the pulse and echo. For instance, neurons in the FM-FM region respond preferentially to two FM pulses separated by a specific delay. The best delays for these neurons range from 0.4 to 18ms, which would correspond to target ranges of 7 to 310cm. Furthermore, these best delays are mapped along cortical distance. Work on the bat cortex has resulted in specific hypotheses about the function of most of their auditory cortical fields. Our state of knowledge of the cortical fields in other animals is by contrast much more primitive.

### Summary

Much about the central auditory pathways remains to be explored. Although these pathways are mapped tonotopically, whether there are other mappings in orthogonal dimensions is unknown. Much current research is focused on the plasticity of central auditory responses with auditory experience and after hearing loss and whether this plasticity is generally present at

the many subcortical auditory centers. The fact that there are descending systems at many levels of the pathways is known, but research is necessary to show how these systems alter the processing of auditory information. Finally, the medial geniculate and auditory cortex are likely to play a role in sound localization, but the specifics of this role and their functions in many of the other hearing processes remain to be discovered.

**Figure 26.23** (A) Close-up view of an echolocating bat, *Megaderma lyra*. Like many echolocating bats, this bat has an enlarged nose leaf that probably focuses the echolocating pulse ahead. Also like many echolocating bats, this bat has enlarged external ears that make the bat more sensitive to echoes coming from ahead. From Griffin (1958). (B) Schematic of emitted pulse and returned echo of the mustached bat, *Pteronotus parnellii*. The emitted pulse consists of four harmonics ( $H_1$ – $H_4$ ), the strongest of which is  $H_2$  at about 60 kHz. Each harmonic has an initial part of constant frequency (CF) and a later part of changing frequency (frequency modulation, FM). The echoes are returned after a travel time that causes a delay relative to the pulse. Additionally, if the target is moving relative to the bat, the echo is returned with a Doppler shift (DS) in frequency. (C) Dorsolateral view of the auditory cortex of the mustached bat showing several of the areas specialized for processing the echolocation signals. The primary auditory cortex, AI, is delineated by a red line and its isofrequency contours are indicated in kHz. It contains a region called the Doppler-shifted CF region (DSCF), which is a greatly expanded region devoted to the most prominent component of the Doppler-shifted echo (60 to 63 kHz). Other shaded regions contain neurons that are combination sensitive and respond to combinations of the pulse and echo, often at certain delays. Neurons that respond to pulse/echo CF portions are in the CF/CF region. Those that respond to pulse/echo FM portions are in the FM/FM region. From Fitzpatrick *et al.* (1993).

# Vision

---

---

## OVERVIEW

---

Vision is the most studied and perhaps the best understood topic in sensory neuroscience. This chapter is concerned primarily with vision in mammals and focuses on the pathway in the visual system that has to do with perception: from the retina to the lateral geniculate nucleus of the thalamus (LGN) and on to the multiple areas of visual cortex. Other regions of the brain that receive visual input (such as the superior colliculus) are dealt with briefly in this chapter and more extensively in the chapter on eye movements (Chapter 33).

Studying vision provides the opportunity to explore the brain at many different levels, from the physical and biochemical mechanisms of phototransduction to the boundary between psychology and physiology (Chapters 51 and 52). At each of these levels, the visual system has evolved to solve a number of difficult problems. In terms of the physical stimulus, vision operates over extremely wide ranges of illumination. The visual system detects single photons in the dark but can also see clearly in bright sunlight, when the retina is bombarded with over  $10^{14}$  photons per second. At a much higher level of complexity, ensembles of neurons in the cerebral cortex are able to solve extremely difficult problems, such as extracting the three-dimensional motion of an object from two-dimensional retinal images.

At every moment, the visual system is confronted with the vast amount of information present in visual scenes. The complex circuitry of the retina has evolved so that much of this information is extensively processed and relayed to the rest of the central nervous system, both efficiently and with great fidelity. Vision, however, has not evolved to treat all of this informa-

tion equally; instead, it appears to be best suited to extract the sort of information that may be useful to animals, including humans, in a natural environment. Vision allows animals to navigate in the world; to judge the speed and distance of objects; and to identify food, members of other species, and familiar or unfamiliar members of the same species.

In many animals, primates in particular, more of the brain is devoted to vision than to any other sensory function. This is perhaps because of the extreme complexity of the task required of vision: to classify and to interpret the wide range of visual stimuli in the physical world. At the highest levels of processing, the cerebral cortex extracts from the world the diverse qualities experienced as visual perception: from motion, color, texture, and depth to the grouping of objects, defined by the combination of simple features.

### The Receptive Field Is the Fundamental Concept in Visual Physiology

The strategies that the brain uses to solve the problems of vision can be understood at a very intuitive level. The most useful concept to aid this intuition is that of the *receptive field*, which is the cornerstone of visual physiology. As defined by H. K. Hartline in 1938 (Ratliff, 1974, p. 167), a visual receptive field is the "region of the retina which must be illuminated in order to obtain a response in any given fiber." In this case, "fiber" refers to the axon of a retinal neuron, but any visual neuron, from a photoreceptor to a visual cortical neuron, has a receptive field. The definition was later extended to include not only the region of the retina that excited a neuron, but also the specific properties of the stimulus that evoked the strongest

response. Visual neurons can respond preferentially to the turning on or turning off of a light stimulus—termed *on-and-off* responses—or to more complex features, such as color or the direction of motion. Any of these preferences can be expressed as attributes of the receptive field.

### Sensory Systems Detect Contrast or Change

In the 1930s and 1940s, Hartline developed the concept of the receptive field with studies of the axons of individual neurons that project from the lateral eye of the horseshoe crab (*Limulus*) and from the frog's eye (Ratliff, 1974). The lateral eye of the *Limulus* is a compound eye made up of about 300 *ommatidia* arranged in a roughly hexagonal array. Each ommatidium contains optical elements, photoreceptors, and a single neuron whose axon joins the optic nerve. Hartline found that when an isolated ommatidium was illuminated, the firing rate of its axon increased. More surprisingly, the firing of the same axon was decreased by a light stimulus in any adjacent ommatidium. This form of antagonistic behavior, known as *lateral inhibition*, serves to enhance responses to edges while reducing responses to constant surfaces. Without it, visual neurons would be just as sensitive to a featureless stimulus, such as a clean white wall, as to stimuli defined by edges, such as a white square on a black wall. Similar spatially antagonistic visual responses were found in mammals, as first demonstrated by Kuffler (1953) in the retina of the cat (Box 27.1).

Lateral inhibition represents the classic example of a general principle: most neurons in sensory systems are best adapted for detecting changes in the external environment. This principle can be explained in behavioral terms. As a rule, it is change that has the greatest significance for an animal, for example, the edge of an extended object or a static object beginning to move. This principle can also be explained in terms of information processing. Given a world that is filled with constants—with uniform objects, with objects that move only rarely—it is most efficient to respond only to changes.

Several types of visual responses can be discussed in terms of the detection of change, or of *contrast*—defined as the fractional difference in luminance between two stimuli. There are several forms of contrast. The first is spatial contrast, the detection of which is enhanced by neurons in the retina that have lateral inhibition (center-surround organization; Box 27.1). Next, there is temporal contrast, or change over time. Starting in the retina, visual neurons are affected very little by slow changes in illumination, but are extremely sensitive to more rapid changes. Finally, there is

motion, which is distinguished by characteristic changes in a stimulus over both space and time. Many neurons in the visual system are excited selectively by objects that have a certain rate or direction of motion. In summary, contrast sensitivity can take on at least three forms: sensitivity to spatial variations in a stimulus (spatial contrast), sensitivity to changes over time (temporal contrast), and sensitivity to changes in both space and time (motion; Box 27.4).

### Receptive Fields Encode Increasingly High-Order Features of the Visual World

From the photoreceptors to the multiple visual cortical areas, the visual system is hierarchical. One level provides input to the next in a feedforward progression, although lateral interactions and feedback are almost always present as well. As a general rule, receptive fields at successive stages of processing (from photoreceptors, bipolar cells, ganglion cells, and geniculate neurons, through neurons in multiple visual cortical areas) encode increasingly high-level features of the visual stimulus. The outer segment of a photoreceptor, which contains the visual pigment, is influenced only by a small point in visual space. It is therefore almost entirely insensitive to the spatial structure of a stimulus. At the opposite extreme, neurons in the inferior parietal region of visual cortex seem to respond best when the animal is viewing a specific face (Chapter 46).

These two extremes of visual responses illustrate the visual system's dual task: to maintain generality—the ability to respond to any stimulus—while being able to represent specific, environmentally important classes of stimuli. High-level neurons classify visual stimuli by integrating information that is present in the earlier stages of processing, but also by ignoring information that is independent of that classification. For instance, motion-sensitive neurons in area MT of the cerebral cortex (see later) are exquisitely sensitive to the direction and rate of motion of an object, but very poor at distinguishing the object's color or its position. This lack of localization is quite common in high-level neurons: receptive fields become larger as the features they represent become increasingly complex. Thus, for instance, neurons that respond to faces typically have receptive fields that cover most of visual space. For these cells, large receptive fields have a distinct advantage: the preferred stimulus can be identified no matter where it is located on the retina.

### Summary

The mammalian visual system is a complex, hierarchical system that can be studied from a number of

## BOX 27.1

KUFFLER'S STUDY OF CENTER-SURROUND RETINAL  
GANGLION CELLS

The classic experiments that Kuffler (1953) performed on retinal ganglion cells have formed the foundations for much of the subsequent physiological analysis of the mammalian visual system. Even beyond the study of vision, they represent a model for understanding the neurobiology of sensory systems. These experiments were performed *in vivo* in anesthetized cats. The first step in this sort of experiment is the careful placement of a fine micro-electrode close to a single neuron so that action potentials can be recorded extracellularly. An oscilloscope trace of the firing pattern of this neuron is important, but the sound of action potentials on an audio monitor is even more critical. This immediate feedback allows the researcher to search for visual stimuli that excite or inhibit the neuron. Kuffler's first finding was that there were two categories of ganglion cells, as Hartline had seen in the retina of the frog. The cells were either *on*, i.e., excited by light increment, or *off*, i.e., excited by light decrement.

One of Kuffler's most important contributions was the careful mapping of lateral interactions in the retina, or what he termed the *center-surround* structure of the receptive field. When an *on* ganglion cell was being studied, a small light spot placed in the center of its receptive field would cause an immediate increase in firing rate of the cell (Fig. 27.3B, top). The center of the receptive field of an *on* ganglion cell was defined as all positions where the small spot evoked an *on* excitatory response. When the same spot was placed just beyond the center, in the region termed the *surround*, the neuron decreased its firing rate

(Fig. 27.3B, bottom). Kuffler mapped the spatial extent of the regions that evoked excitation or inhibition simply by listening to the responses to spots flashed at many different locations. Alternatively, Kuffler studied receptive fields by searching for an optimal stimulus—one that increased the firing of a ganglion cell most effectively. The strongest stimulus for an *on* center cell was a spot of light that filled the receptive field center entirely (Fig. 27.3C). Similarly, the most effective inhibitory stimulus was a bright annulus shown to the surround alone. Following such strong inhibition, the cell had an excitatory response when the stimulus was turned off (Fig. 27.3D). Finally, Kuffler studied interactions between receptive field sub-regions. A large bright stimulus that covered both center and surround was found to evoke a much weaker response than a smaller spot confined to the center; the surround inhibition weakened or altogether eliminated the central excitation (Fig. 27.3E).

Kuffler's early experiments, along with those of Hartline, established the technical and conceptual foundations for the field of visual physiology. Almost all subsequent work in this field can be seen as falling into the three broad categories of experiments, exemplified by Kuffler's 1953 study: (1) the mapping of responses with isolated, suboptimal stimuli, (2) the search for an optimal stimulus, and (3) the study of interactions between responses evoked by two or more stimuli.

R. Clay Reid

different viewpoints. This chapter concentrates on the physiology of visual neurons, which is based on the study of receptive fields. Originally, receptive fields were defined as the area of the retina that could evoke responses in a visual neuron. The concept has evolved to include the stimulus attributes that lead to a neural response, such as color, motion, or even the complex features of a specific physical object. Within the hierarchy of the visual system—from retina to the multiple areas of the visual cortex—neurons are selective for increasingly complex or high-order features.

## THE EYE AND THE RETINA

### The Optics of the Eye Project an Inverted Visual Image on the Retina

The study of vision begins with the eye (Fig. 27.1), whose refractive properties are determined by the curvature of the cornea and the lens behind it. These optical elements act to focus an inverted image on the retina, where the first stages of neural visual processing take place. The curvature of the cornea is fixed, but the curvature of the lens is adjusted by smooth muscles that

FIGURE 27.1 Schematic diagram of the human eye.

flatten the lens when they relax, thus bringing more distant objects into focus. The amount of light that reaches the retina is controlled by the iris, whose aperture is the pupil. The iris, which is situated between the cornea and the lens in the *anterior chamber* of the eye, contracts at high light levels and expands in the dark.

### The Retina Is a Three-layered Structure with Five Types of Neurons

The anatomy of the retina has an almost crystalline beauty, a beauty that is enhanced by the clear relationships between form and function (Dowling, 1997). It is composed of five principal layers: three layers of cell bodies separated by two layers of neural processes, dendrites and axons (Fig. 27.2). The vertebrate retina is oriented within the eye so that light must travel through the entire thickness of the neuropil to reach the photoreceptors. Of the three cell layers, the first is farthest from the center of the eye and thus is called the *outer nuclear layer*. It contains the cell bodies of the photoreceptors, the rods and cones. The next cell layer is the *inner nuclear layer*, which contains the cell bodies of the interneurons of the retina, both excitatory and inhibitory. These include horizontal cells, bipolar cells, and amacrine cells. Finally, the *ganglion cell layer* is home to the retinal neurons whose axons form the

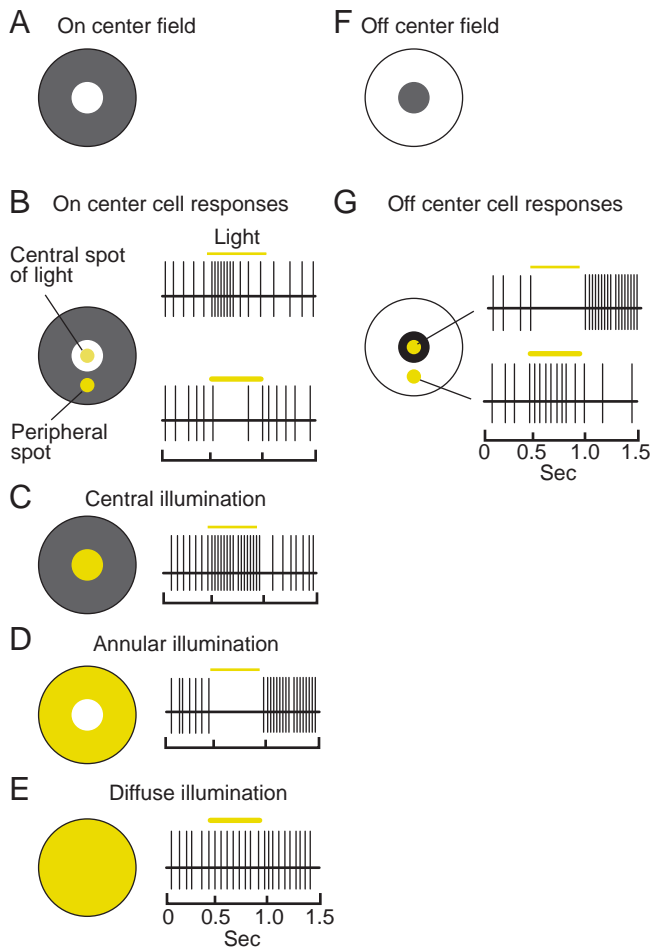

FIGURE 27.2 Summary diagram of the cell types and connections in the primate retina. R, rod; C, cone; H, horizontal cell; FMB, flat midget bipolar; IMB, invaginating midget bipolar; IDB, invaginating diffuse bipolar; RB, rod bipolar; A, amacrine cell; P, parasol cell (also confusingly called an M cell because of its thalamic targets; see text for details); MG, midget ganglion cell (also confusingly called a P cell). Adapted from Dowling (1997).

optic nerve, the sole pathway from the retina to the rest of the central nervous system. Interposed between the cell body layers are two layers of cell processes: *inner* and *outer plexiform layers*. The two plexiform layers are the sites of all interactions between the neurons of the retina.

The retina is one of the few circuits in the nervous system simple enough that cell types and connections can be learned without great effort. This is made even easier since the role of each of the five cell types can be placed within a simple functional scheme. The two main attributes of the output of the retina—the point-to-point representation of the visual image and the spatially antagonistic center-surround interactions in the receptive field (Box 27.1)—can be understood in terms of the anatomy. The direct pathway, photoreceptor → bipolar cell → ganglion cell, is the substrate for the center of the receptive field of the ganglion cell

**FIGURE 27.3** Visual responses of *on*-center (white) and *off*-center (dark gray) retinal ganglion cells. Visual stimuli are indicated in yellow, and the responses to these stimuli are shown to the right. See text for details.

and thus for its spatial resolution. Lateral interactions in the retina, most notably the center-surround antagonism, or lateral inhibition, are mediated by horizontal cells and amacrine cells.

### Photoreceptors Are Hyperpolarized by Light

The two major types of photoreceptors in the vertebrate eye are the rods and cones (Fig. 27.2). Both types of photoreceptor have an outer segment that contains the molecular machinery for phototransduction, an inner segment that contains densely packed mitochondria, a cell body that contains the nucleus and other important organelles, and a terminal process that releases neurotransmitter. Although rods and cones were once viewed as the only cells in the vertebrate eye to transduce light energy into an electrical response, recent work shows that phototransduction also takes place in melanopsin-containing ganglion cells that

likely convey nonspatial information about light levels to regions of the brain involved with circadian rhythms.

Rods and cones work together to allow the visual system to operate over a wide range of luminance conditions. Under scotopic conditions when luminance levels are very low (e.g., starlight), only the rods are active. As luminance levels increase to mesopic conditions (e.g., moonlight), both the rods and cones contribute to vision. As luminance levels increase further yet, to scotopic condition (e.g., sunlight), rod responses saturate and only the cones contribute to vision. Because the center of our retina (the fovea) contains very few, if any rods, we have a foveal blind spot under very dim conditions. Consequently, a dim star will disappear when we move our eyes to look at it directly.

Phototransduction occurs when photons of light are absorbed by photopigments located in the outer segments of photoreceptors. Photopigments have an organic, light-absorbing component (11-*cis* retinal) and a protein component (opsin). The opsin determines the wavelength specificity of the photopigment and has the ability to interact with G proteins. Rods contain a single photopigment, rhodopsin, whereas cones contain one of three cone opsins (the relationship between these opsins and color vision is discussed later). Once a photon is absorbed, a cascade of events occurs that ultimately affects the membrane potential of the photoreceptor. This cascade begins with the activation of the G protein (transducin) that then activates a phosphodiesterase that hydrolyzes cGMP and reduces the intracellular concentration of cGMP. Because the outer membrane of a photoreceptor contains many cGMP-gated cation channels, a decrease in the intracellular concentration of cGMP will cause the photoreceptor to hyperpolarize. In this way, light increments lead to hyperpolarization and a reduction in neurotransmitter release, whereas light decrements lead to depolarization and an increase in transmitter release. Importantly, photoreceptors do not produce action potentials, but rather have graded potentials that are modulated around a mean level.

### Bipolar Cells Can Be Hyperpolarized or Depolarized by Light

Similar to photoreceptors, bipolar cells generate graded potentials rather than action potentials. Bipolar cells are divided into two broad classes, termed *on* and *off* bipolars, that respond to light stimuli with depolarization and hyperpolarization, respectively. *On* bipolars are also known as *invaginating bipolars*, and *off* bipolars are known as *flat bipolars* because of the shape

of the synaptic contacts they receive from photoreceptors (Fig. 27.2). Because all photoreceptors use glutamate as their neurotransmitter, these opposite responses require that *on*-and-*off* bipolar cells respond to the same neurotransmitter in opposite ways (Wu, 1994). Glutamate, typically an excitatory transmitter, is inhibitory for *on* bipolars. It acts by closing a cGMP-gated sodium channel, similar to that seen in photoreceptors. The depolarization of *on* bipolars by light results not from excitation, but from the removal of inhibition, which occurs when photoreceptors are hyperpolarized by light. *Off* bipolars are excited by glutamate via more typical kainate receptors (named for the pharmacological agent that selectively activates them; Chapter 9). When these cells are inhibited by light, the inhibition is in fact due to the removal of tonic excitation, which again occurs when the photoreceptors are hyperpolarized.

The functional importance of the *on* and the *off* pathways can best be understood in terms of contrast. From the bipolar cells onward (i.e., once *on*-and-*off* pathways have been established), visual neurons respond best to spatial and temporal contrast rather than to absolute light levels. Objects in the world are visible by the light they reflect; their borders are discerned usually because of different degrees of reflectance, which leads to contrast (changes in illumination, except for shadows, tend to be much more gradual). Because the visual system is adapted for seeing objects that can be either brighter or darker than their backgrounds, it is not too surprising that it is equally sensitive to positive and negative contrast steps.

Most ganglion cells, the output cells of the retina, receive their main excitatory input from bipolar cells. Thus these ganglion cells also have either *on* or *off* responses in the center of their receptive fields, according to which class of bipolar cells provide their input (Box 27.1). Other ganglion cells, known as *on-off* cells, respond to both light onset and to light offset. These latter cells receive input from both classes of bipolar cells. Many of these cells respond preferentially to stimuli moving in a particular direction of motion (Box 27.4).

### Horizontal and Amacrine Cells Mediate Lateral Interactions in the Retina

There is a complex three-way synaptic relationship among the terminals of the photoreceptors, the processes of horizontal cells, and the dendrites of bipolar cells (Fig. 27.2). Horizontal cells are inhibitory (GABAergic) and, as the name implies, they contact photoreceptors over a much larger horizontal extent of

retina than bipolar cells. Thus, because they are the only neurons that sample over a sufficiently large area in the outer plexiform layer, horizontal cells are thought to be responsible for the antagonistic surround seen in the receptive fields of bipolar cells.

The second family of lateral interneurons in the retina, the amacrine cells (literally, cells with no axons), is a diverse class of cells that exhibits a wide range of morphologies. As is true of horizontal cells, all processing takes place on the dendrites of amacrine cells (in the inner plexiform layer), which contain both pre- and postsynaptic elements (Fig. 27.2). Most amacrine cells use GABA, glycine, or both acetylcholine and GABA as neurotransmitters, but it is thought that virtually every transmitter found in the brain is used by some amacrine cell. The functions of most of these diverse subclasses remain poorly understood. In addition to a possible role in the creation of the antagonistic surround, it has been proposed that some amacrine cells are responsible for the nonlinear responses in Y cells of the cat (Box 27.2) or for the direction selectivity seen in the rabbit retina (Box 27.4).

### Retinal Ganglion Cells Provide the Output of the Retina

Visual information leaves the eye via the optic nerve, which is composed of the axons of all the different classes of ganglion cells. The optic nerve begins at the *optic disc* (Fig. 27.1). Because there are no photoreceptors at the optic disc, this circular region constitutes a blind spot in the retina. The routing of ganglion cell axons to different parts of the brain provides a number of interesting problems for developmental neurobiology (Chapters 19 and 23). The routing of axons is both macroscopic—different types of ganglion cells project to different regions of the brain—and microscopic: within any given target region, axons are sorted out in a precise manner. In each of two principal targets of retinal axons, the superior colliculus and lateral geniculate nucleus of the thalamus (LGN), a topographical map of visual space is created in which spatial relations are maintained between neighboring neurons.

This chapter is concerned primarily with the classes of retinal ganglion cells that project to LGN neurons, which in turn project to the primary visual (striate) cortex. Although cells in the LGN are more than mere relays of information from the retina, their receptive fields are quite similar to those of their ganglion cell inputs. The following discussion of retinal receptive fields, therefore, can serve equally well to describe receptive fields in the LGN.

## BOX 27.2

## QUANTITATIVE METHODS IN THE STUDY OF VISUAL NEURONS CLASSIFICATION OF RETINAL GANGLION CELLS

Although neuroscientists have learned a tremendous amount about the visual system using the tools developed by Kuffler, researchers have been following a parallel line of studies of the visual system by asking different sorts of questions with the aid of more quantitative methods. In Kuffler's experiments and, most notably, many of Hubel and Wiesel's (see later), easily produced stimuli (such as spots, edges, and bars) were used to stimulate visual neurons. Action potentials were detected primarily with an oscilloscope and audio monitor. In the more quantitative studies of visual physiology, stimuli are shown primarily on video monitors and data are recorded with computers. The quantitative study of visual physiology constitutes a large field, which stems from the work of Hartline, Ratliff, Campbell, Barlow, and others (see Ratliff, 1974). Analysis of the receptive fields of retinal ganglion cells in the cat performed by Enroth-Cugell and Robson (1966) represents an early and influential example of this line of research.

Stimuli used by Enroth-Cugell and Robson, and in many studies that followed theirs, consisted of *gratings*: light and dark bands whose luminance varied in a sinusoidal fashion across a screen. Gratings were not designed to be the most effective stimuli for visual neurons. The broad goal of this sort of experiment is to study not just what makes neurons respond best, but to study how they would respond to *any* stimulus and to probe what mechanisms they use to produce these responses. The analytical framework that goes along with these experiments is called *systems theory*, the study of input-output (or stimulus-response) systems. *Linear systems*, those that simply add up all their inputs to produce an output, constitute an important part of this theory.

Enroth-Cugell and Robson used a simple test of linearity in their study of retinal ganglion cells in the cat.

A grating was presented at different positions (called phases), and the responses to its introduction and removal were recorded. Two questions were addressed for each cell studied: (1) If a certain phase (whose bars were arranged white, black, and white; as in Fig. 27.4, 0°) excited the cell, did the opposite grating (black, white, and black; Fig. 27.4, 180°) inhibit it? (2) More importantly, were there null positions for the grating that evoked no response, as excitation and inhibition were perfectly balanced (Fig. 27.4, 90° and 270°)?

One class of ganglion cells, called *X cells*, passed these tests for linear spatial summation (Fig. 27.4, left). A second class of cells, *Y cells*, behaved differently. Like *X cells*, these cells also had a center-surround receptive field when mapped with spots and annuli. When studied with two opposite gratings, however, the responses evoked were not equal and opposite. Instead, the introduction and removal of the gratings at all positions resulted in two peaks of excitation, and no null position could be found (Fig. 27.4, right).

The use of systems theory and quantitative techniques in the study of the visual system has had a number of notable successes. It has helped in the classification of different families of visual neurons, such as *X* and *Y* cells. Further, it has been used to elucidate some of the mechanisms responsible for the responses of visual neurons (such as directionally selective cells, see Box 27.4). Perhaps most importantly, along with a large body psychophysical experiments that employ the same stimuli, it has helped create a common framework in which the responses of neurons can be related to perception.

R. Clay Reid

### Parallel Pathways Are Composed of Distinct Classes of Retinal Ganglion Cells in the Cat

Kuffler found that retinal ganglion cells in the cat have a stereotyped center-surround organization. Similar cells (both *on* and *off*) were found at every position across the entire retina. Researchers later discovered, however, that there are in fact several different

functional classes of ganglion cells, each with distinct response properties. Although different cell classes have been found in different species, in none is the retina composed of a single mosaic of identical cells. The fact that there are multiple types of output from the retina has had a profound effect on the study of visual processing in the brain. The degree to which these *parallel pathways* (Livingstone and Hubel, 1984;

**FIGURE 27.4** Visual responses of X and Y cells to contrast-reversing sine-wave gratings at different spatial phases (different positions, indicated schematically in the middle column). Visual responses, in spikes per second, are shown as poststimulus time histograms synchronized to the repetitive stimulus. Upward deflection of the lowest trace indicates introduction of the grating pattern (contrast on), and downward deflection indicates removal of the pattern (contrast off, but no change in mean luminance). Adapted from Enroth-Cugell and Robson (1966).

Merigan and Maunsell, 1994; Sincich and Horton, 2005) are combined or kept separate has been a major theme in the study of central visual pathways, particularly the visual cortex.

The idea that there are parallel sensory pathways into the brain is not new. At the beginning of the nineteenth century, both Bell and Müller argued for what Müller termed the “specific energy of nerves.” This term is a precursor of the idea that axon sensory neurons are “labeled lines,” each of which conveys distinct signals to the brain. A surprisingly modern version of this idea was given in 1860 by Helmholtz in the *Handbook of Physiological Optics* (2000), in which he expressed Thomas Young’s theory of color vision (1807) in the following manner: “The eye is provided with three distinct sets of nervous fibers. Stimulation of the first excites the sensation of red, stimulation of the second the sensation of green, and stimulation of the third the sensation of violet.”

In one of the earlier studies using a quantitative approach to receptive field mapping (Box 27.2), Enroth-Cugell and Robson (1966) found that cat retinal ganglion cells could be classified into two categories: X and Y (more categories have been found subsequently).

This classification was based on a simple criterion: did ganglion cells simply add together all their excitatory and inhibitory inputs (linear summation) or were the interactions between inputs more complicated (non-linear summation)? The linear/nonlinear distinction between X and Y cells (Box 27.2) may seem fairly abstract, but these cells turned out to be different in a number of other ways. Most notably, Y cell receptive fields are, on average, three times larger than those of neighboring X cells. X cells are therefore far more numerous, because many more X cell receptive fields are needed to effectively tile, or cover, the retina. One view is that the large, nonlinear receptive fields of Y cells make them well suited to detect change, at the cost of their ability to signal the exact location or nature of the stimulus; similarly, X cells are better at localizing more specific stimulus features, but less sensitive in detecting change.

### Primate Ganglion Cells Project to Three Subdivisions of the Lateral Geniculate Nucleus: Parvocellular, Magnocellular, and Koniocellular

Primates have a number of different classes of retinal ganglion cells, each with distinct cellular morphology, projection patterns, and visual response properties. This discussion focuses on ganglion cells that project to the lateral geniculate nucleus (LGN). There are many differences among primate species (nocturnal versus diurnal, Old World versus New World); this section concentrates on the macaque; a diurnal, Old World primate. The macaque visual system has been studied extensively with anatomical, physiological, and behavioral methods. Most importantly, macaque vision is very similar to human vision.

The most numerous class of ganglion cells in the macaque retina are sometimes referred to as *P cells*, so-called because they project to the dorsal-most layers of the LGN, the *parvocellular layers* (small cells; Fig. 27.9). *M cells*, which project to the two ventral layers of the LGN, the *magnocellular layers* (large cells), constitute a second class of retinal neurons. P and M cells have distinct morphologies (Fig. 27.2). P cells (also known as P/3 or, in the central retina, midget ganglion cells) have very small dendritic fields. M cells (also known as *Pa* or parasol cells) have much larger dendritic fields. Finally, members of a third class of retinal cells project to the *intercalated layers* between principal parvocellular and magnocellular layers. These intercalated layers are also termed *koniocellular* (dust-like, or tiny cells). There are roughly 1,000,000 P cells in the

## BOX 27.3

INHERITED AND ACQUIRED DEFECTS OF COLOR VISION:  
RETINAL AND CORTICAL MECHANISMS

Inherited defects of color vision have been studied for over 200 years, originally with psychophysical methods but more recently with the tools of molecular genetics. Normal color vision is *trichromatic* (literally, three-colored) because there are three different classes of cone photoreceptors. In the most common form of color vision defect, there are three pigments, but one of them is abnormal, or anomalous. More severe defects are found in *dichromats*, who lack a single cone type entirely. The current terminology for the three types of dichromacy was proposed by von Kries in 1897: *protanopia* (literally, the first type of blindness, or “red-blindness”), *deutanopia* (second type, or “green-blindness”), and *tritanopia* (third type, or “blue-blindness”). Whereas dichromats are unable to make certain color distinctions, only the very rare *monochromats*—people with one cone type or only rods—are truly color blind.

The genetics of red-green defects have long been known to be X-linked: they are inherited from the mother and are fairly common in men, but they are uncommon in women. Roughly 2% of European white males are protanopes or deutanopes and, depending on the population, between 2 and 6% are trichromats with a single anomalous pigment (either protanomalous or, more commonly, deutanomalous). In contrast, only 0.4% of women in similar populations have red-green defects. Tritanopia, found equally in men and women, is significantly rarer. It is inherited as an autosomal-dominant trait thought to occur at low frequencies, estimated variously between 1 in 500 and 1 in over 10,000.

Because of the overlap in cone pigments, inherited color vision defects are not as simple as terms such as “red blindness” might suggest. In broad terms, protanopes and deutanopes are unable to make specific discriminations along the red-green axis. Depending on the defect, they are unable to distinguish certain reds and greens from gray or from each other. Tritanopes are unable to discriminate between colors with and without a short wavelength component, such as between gray and certain shades of violet or yellow.

In the 1980s, Nathans, Hogness, and colleagues cloned and sequenced the three cone pigment genes and related

them to color defects in humans. The cloning strategy was based on the pigments predicted close homology to rhodopsin (Fig. 27.7B). As expected from the genetics of protanopia and deutanopia, two very similar genes for L and M pigments were found on the X chromosome. The third gene, which codes for the S pigment, was found on chromosome 7. In subsequent work by this group and others, molecular genetics of the inherited color defects, including anomalous trichromacy, have been studied in great detail.

Although the inherited color deficiencies are fairly simple and well understood, acquired defects in color vision—found in a number of ocular, neurological, and systemic diseases—are far more varied. One such syndrome, *cerebral achromatopsia*, was described in the neurological literature in the 1880s. In rare patients with certain cortical lesions, the discrimination of colors and the naming of colors were severely impaired. In the majority of cases, there were other associated deficits—either an area of complete blindness (a scotoma) or an inability to recognize faces (prosopagnosia)—but in some cases, vision was otherwise quite normal. From the location of the lesions, some neurologists early on inferred the existence of a region of cortex required for color vision, near the inferior border of the primary visual cortex.

The literature of cerebral achromatopsia, quite developed in the late nineteenth century, fell into eclipse for the first half of the twentieth century when highly specific functional divisions of the cortex were questioned. With the discovery in the 1970s of multiple visual areas in primate cerebral cortex (Felleman and Van Essen, 1993), however, the existence of a cortical region devoted to color in humans seemed less far-fetched. With recent advances in noninvasive brain imaging there is little doubt that such regions exist in humans, although their homology to brain regions in nonhuman primates remains controversial.

## BOX 27.4

## THREE TYPES OF SELECTIVITY FOR MOTION

Motion is one of the most important aspects of the visual world. It is a powerful cue for navigating in the world, for segregating figures from their background, and for predicting the trajectory of objects. It is not surprising, therefore, that sensitivity to motion is a highly developed feature of the mammalian visual system. At the lowest level, a class of neurons in the retina respond best to stimuli moving in a specific direction (Barlow *et al.*, 1964). These neurons give *on-off* responses to flashed lights (denoted  $\pm$  in Fig. 27.16A), but are best excited by the motion of an object anywhere in their receptive fields. They can signal that motion in a particular range of directions is present, but because their receptive fields are relatively large and have both *on-and-off* responses, they cannot resolve the details of an object. Directionally selective retinal neurons do not project to the LGN so directional neurons found in the visual cortex (Hubel and Wiesel, 1962) create their selectivity independently and with a different mechanism.

Unlike directionally selective ganglion cells, which signal that motion is present somewhere within a large region, directionally selective simple cells in the visual cortex maintain detailed spatial information as well. A moving stimulus, such as a light bar moving to the left (Fig. 27.16B, left), is described by its trajectory in space over time. If the trajectory is plotted in space versus time, the slope represents the direction and velocity of the object. For instance, a bar moving to the right traces an oblique trajectory (up and to the left) in such a space-time plot (Fig. 27.16B, middle). When represented in a similar plot, the receptive fields of directionally selective simple cells can show a similar orientation (Fig. 27.16B, right). This plot is exactly analogous to Kuffler's maps of ganglion cell receptive fields. It represents the responses of the cell to a bright or dark bar at different positions, but it includes the time course of the responses as well. The *on* responses of this receptive field (the responses to a bright bar) are indicated with solid contour lines and are shown in white for added emphasis; *off* flanks (the responses to dark bars) are indicated with dotted contour lines.

For directionally selective simple cells, the timing of the response is directly related to the position of the stimulus. In the illustration, the cell is sensitive to a bright bar at a range of positions, but the timing of the peak response changes with position. These responses to flashed bars explain the responses to moving stimuli. Just as *on-center/off-surround* ganglion cells respond best to a bright spot on a dark background (Fig. 27.3C), a directionally selective simple cell responds best to a bar moving in a specific direction. A moving bar is the stimulus that best matches the template formed by its receptive field. In this manner, simple cell receptive fields can be strongly direction selective, but their responses preserve precise information about the position and structure of the stimulus.

A third kind of directionally selective cell is found in cortical area MT of the macaque. Receptive fields of individual neurons in MT integrate motion information over large regions of visual space. By comparison, receptive fields in the retina, LGN, and V1 can be thought of as viewing the world through much smaller apertures. If the goal of vision is to extract the properties of objects, rather than isolated features, then the existence of small receptive fields can lead to what is known as the *aperture problem*. As illustrated in Figure 27.16C, two objects moving in different directions can appear to have the same direction of motion when viewed through an aperture. In a dual study of perception in humans and of MT neurons in macaques, Movshon and colleagues (1985) analyzed the responses to complex stimuli whose components moved in different directions (such as the edges of the square in the bottom half of Fig. 27.16C), but which were perceived as coherent patterns moving in an intermediate "pattern direction." Unlike neurons in V1, many neurons in MT responded to the pattern direction rather than to the components. This would imply that these MT neurons combine their inputs in a complex manner to achieve a selectivity for the motion of extended objects rather than primitive features.

R. Clay Reid

retina and parvocellular neurons in the LGN; there are 100,000M and magnocellular neurons. Although the intercalated layers appear quite sparse and thin in standard histological sections (Fig. 27.9), there are as many intercalated cells as there are magnocellular

cells. Due to their size and location, intercalated cells have been difficult to study and little is known about them in the macaque. Therefore the following section discusses only the functional properties of P and M pathways.

## P and M Pathways Have Different Response Properties

As noted earlier, the receptive field properties of the LGN relay cells match closely those of their retinal afferents, but the two parallel pathways, P  $\rightarrow$  parvocellular and M  $\rightarrow$  magnocellular, are quite different. Five main characteristics distinguish the responses of P cells and M cells (Figs. 27.5 and 27.6):

1. P cell receptive fields are smaller than M cell receptive fields at the same retinal position.
2. M cell axons conduct impulses faster than P cell axons.
3. The responses of P cells to a prolonged visual stimulus, particularly a color stimulus, can be very sustained, whereas M cells tend to respond more transiently.
4. Most P cells are sensitive to the color of a stimulus; M cells are not (Figs. 27.5A–27.5C).
5. M cells are much more sensitive than P cells to low-contrast, black-and-white stimuli (Fig. 27.5D).

These last two differences, which have strong implications for the functional role of these pathways, are discussed next.

## Color-Selective Responses in the P Pathway Are Derived from Antagonistic Inputs from L and M Cones

Color vision depends on the distinct sensitivities of the three classes of cone photoreceptors to different wavelengths of light (the rods are active only under low light levels and are not involved in color vision). Although fine distinctions can be made between different wavelengths, it is important to emphasize that each of the light-sensitive pigments in the three cone classes is sensitive to a broad range of wavelengths. The spectral sensitivities of these pigments overlap considerably (Fig. 27.6A). Consequently, the names sometimes used for these pigments—red, green, and blue sensitive—are inaccurate. For instance, the “red” pigment is most sensitive to light whose wavelength is 564 nm, or yellow, although it is more sensitive than the other pigments to red light. A more accurate terminology, one that identifies the relative sensitivities of the three cone absorption spectra, usually is employed: long, middle, and short wavelength sensitive (or L, M, and S).

Because green light will excite both long and middle wavelength cones, the color green can be distinguished only by the fact that it excites middle wavelength cones more strongly than it excites long wavelength cones. This distinction can be made by neurons that are sensi-

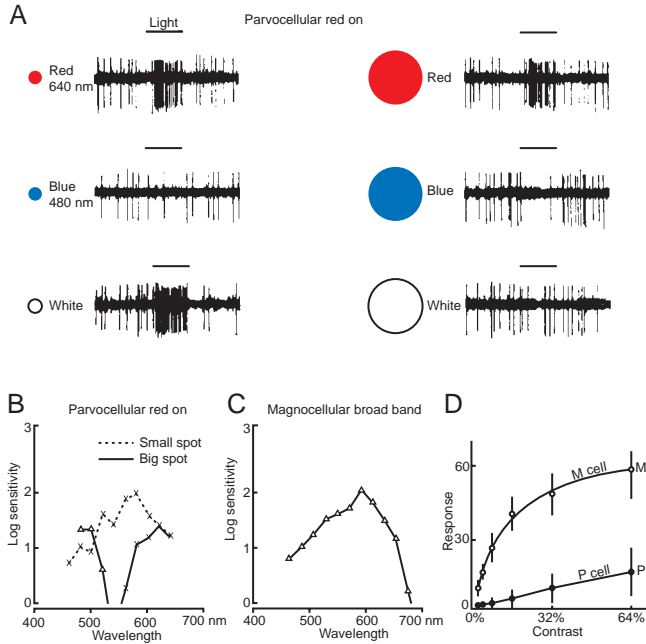

tive to the difference between the signals from two cone classes, or neurons that are *color opponent*. In the retina and LGN, there are two categories of color-opponent cells: red-green and blue-yellow (yellow is made of the sum of long and middle wavelength cone signals; Dacey, 2000). These are sometimes also termed red-minus-green cells and blue-minus-yellow cells. The most numerous color-opponent neurons in the primate retina are red-green opponent P cells. These cells receive antagonistic input from long and middle wavelength-sensitive (L and M) cones.

Near the fovea, the center of the retina, a P cell receives input from only one bipolar cell. This *midget bipolar* in turn receives input from a single cone (Fig. 27.2). This arrangement ensures not only that the center of the ganglion cell’s receptive field is as small as possible, but also that the center receives input from only one cone type: L or M. Classically, the antagonistic surround of these P cells (or their counterparts in the LGN) has been thought to be dominated by the other main cone class, M or L, respectively (Wiesel and Hubel, 1966). Although the exact nature of the surround in red-green P cells has been somewhat controversial in recent years (Dacey, 2000), this classical view is shown in Fig. 27.6B.

There are four different types of red-green opponent P cells in the retina (Fig. 27.6B), and hence parvocellular neurons in the LGN. *L-on* center and *M-off* center cells are excited by red and inhibited by green (and some blues; see Fig. 27.5A). *M-on* and *L-off* cells are excited by green and inhibited by red. As Wiesel and Hubel showed (1966), parvocellular neurons in the LGN are sensitive to small bright spots presented in their receptive field centers, but they are most selective for the color of the stimulus when larger stimuli are used (see Figs. 27.5A and 27.5B). This is because only larger stimuli are effective in stimulating simultaneously the color-opponent center and surround. Because they absorb a broad range of wavelengths (Fig. 27.6), single cones are not very color selective. Parvocellular neurons are most color selective when the stimulus evokes antagonistic influences from two cone classes: one found in the center and the other found only in the surround.

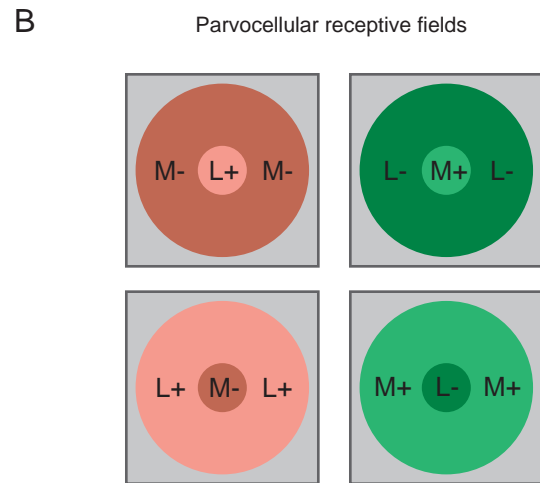

## M Cells Are Highly Sensitive to Contrast

Because of their marked color sensitivity and small receptive fields, P cells have long been thought to be involved with the ability to make color discriminations and to see the finest details. When tested with black-and-white stimuli, however, P cells responded to low contrast very poorly compared to M cells. In a study that used the quantitative methodology similar

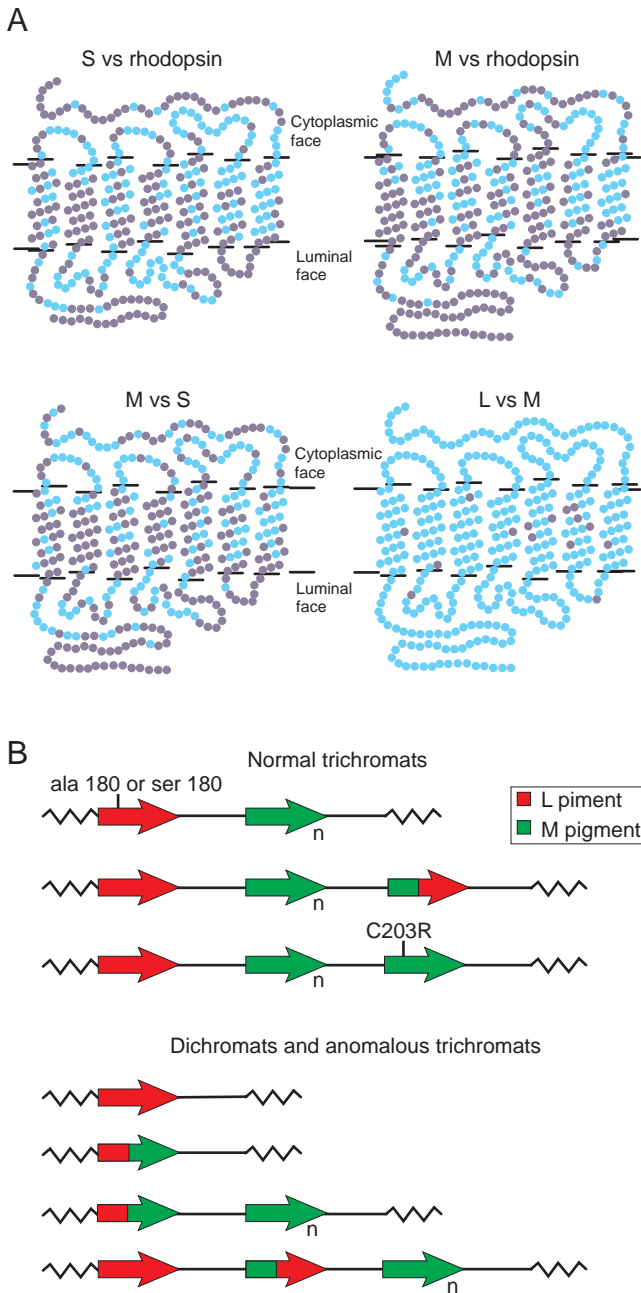

**FIGURE 27.5** Visual responses of magnocellular and parvocellular neurons in the macaque. (A) Responses of a color-opponent (red-on/green-off) parvocellular neuron to small and large stimuli. For small spots, roughly the size of the receptive field center, the neuron was excited by both red and white and was weakly inhibited by blue. The responses to large spots were more selective. Red was excitatory, blue was strongly inhibitory, and white stimuli were ineffective. (B) Responses of the same red-on/green-off parvocellular neuron to different wavelengths of light. For small spots, the neuron was excited (X) for a broad range of wavelengths. For big spots, it was excited above 550nm, from yellow to red, and inhibited (D) below 550nm, from blue to green. (C) Responses of a magnocellular neuron to different wavelengths of light presented in the receptive field center. The neuron had off (D) responses at all wavelengths, i.e., no wavelength specificity was found. (D) Average contrast response functions of P (•) and M (o) cells measured in spikes per second. P cells respond poorly to low contrasts and do not saturate at high contrasts. M cells respond better to low contrasts, but saturate by 20–30%. A–C: From Wiesel and Hubel (1966). D: From Kaplan and Shapley (1986).

to Enroth-Cugell and Robson’s (Box 27.2), Kaplan and Shapley (1986) measured the responses of P and M cells to sine-wave gratings of various contrasts (Fig. 27.5D). Perceptually, stimuli can be detected that have less than 1% contrast (i.e., 1% luminance deviation from the mean). Kaplan and Shapley (1986) found that M cells often responded well to contrasts of under 5% and that they gave their strongest responses at contrasts as low as 20%. P cells tended to respond poorly to contrasts below 10%, a stimulus that is quite salient,

**FIGURE 27.6** Aspects of color vision. (A) Absorption spectra of the three cone photoreceptors in humans: long, middle, and short wavelength sensitive (L, M, and S). L and M cones in particular are sensitive to overlapping ranges of wavelengths. (B) Receptive field of the four types of red-green parvocellular cells in the macaque (labeled L+ and M+ or L- and M- according to their on-or-off centers, respectively). Classically, these small receptive fields have been described as receiving antagonistic input from L cones in their centers and M cones in their surrounds, or vice versa. When probed with color stimuli, L-on center and M-off center cells are excited by red and inhibited by green (and some blues: see Fig. 27.5A). M-on and L-off cells are excited by green and inhibited by red. When probed with small white spots, L-on and M-on cells are excited when the stimulus is turned on; L-off and M-off cells are excited when the stimulus is turned off. (C) Receptive fields of the two main types of magnocellular cells. These larger receptive fields receive mixed L and M input to both center and surround. There are two types: on center (M+ L+) and off center (L- M-).

**FIGURE 27.7** Molecular biology of photopigment genes. (A) Transmembrane model of cone photopigments. Homologies between the different photopigments are shown, with differences between proteins highlighted. The amino acid sequences of M and S cone pigments and rhodopsin are all approximately 40% identical (and 75% homologous), whereas L and M pigments are 96% identical (99% homologous). (B) Structure of the portion of the X chromosome coding for L and M pigments. Normally, there is one L pigment gene and several M pigment genes. Because not all these genes are expressed, different variants can result in normal color vision (top). Many different patterns of recombination and deletion can be associated with a defect in red-green vision: either dichromacy or anomalous trichromacy (bottom). A: From Nathans *et al.* (1986). B: From Nathans (1994).

and rarely reached their strongest responses below 64%. From this, Kaplan and Shapley concluded that the ability to see low contrasts is due primarily to the M cell system.

The relatively poor sensitivity of P cells to low-contrast stimuli is not well understood, but it may be partially the result of two factors: receptive-field centers receive input from a very small region of the retina, and the inputs from different cone classes are subtracted from each other, rather than added together. Whatever the reason, the poor performance of the P pathway in detecting low contrast implies an important role for M cells in the detection of the form of objects (which is robust at low contrasts), in addition to their role in the motion pathway (discussed later).

### Summary

The retina, part of the central nervous system, is a self-contained neuronal circuit whose anatomy and physiology have been studied in great detail. There are five types of cells in the retina. Photoreceptors, bipolar cells, and ganglion cells constitute the direct, feed-forward pathway. Horizontal cells and amacrine cells subserve lateral interactions within the retina. Photoreceptors are all hyperpolarized by light, but bipolar cells can be either hyperpolarized (*off* cells) or depolarized by light (*on* cells). There is a great variety of retinal ganglion cells, but most have an antagonistic center-surround organization. In the primate, the two best studied classes of ganglion cells are P cells and M cells, which project to the parvocellular and magnocellular layers of the LGN, respectively. P cells have small receptive fields, are sensitive to the color of a stimulus, and are relatively insensitive to low contrasts. M cells have larger receptive fields, are insensitive to color, and are very sensitive to low contrasts.

## THE RETINOGENICULOCORTICAL PATHWAY

### Visual Information Is Relayed to the Cortex via the Lateral Geniculate Nucleus

In mammals with forward-facing eyes, such as most carnivores and the primates, retinal axons are routed so that visual information from the same points in space coming from the two eyes can be combined. From both eyes, ganglion cells whose receptive fields are in one half of the visual field project to the opposite cerebral hemisphere (Fig. 27.8). This cross-routing occurs at the optic chiasm (from the Greek letter *chi*,

**FIGURE 27.8** The retino-geniculo-cortical pathway in the human. Optic nerve axons from the nasal retina cross at the optic chiasm and join axons from the temporal retina of the other eye. Together, these contralateral and ipsilateral axons make up the optic tract, which projects to the LGN. Each of the six layers of the LGN receives input from only one eye. Axons from the LGN make up the optic radiations, which project to the striate cortex. Adapted from Polyak (1941).

$\chi$ ). Here, axons from the medial (nasal, or nearer the nose) half of one retina cross over to join the axons from the lateral (temporal, or nearer the temples) half of the other retina. In other words, the temporal retina projects to the *ipsilateral* (same-side) hemisphere and the nasal retina projects to the *contralateral* (opposite-side) hemisphere. Unlike somatic sensation, which is entirely crossed (Chapter 25), only half of the retinal axons cross. Like somatic sensation, however, the crossing of retinal axons results in each half of the external visual field being represented in the opposite cerebral hemisphere.

### The LGN Is a Layered Structure That Receives Segregated Input from the Two Eyes

As they leave the optic chiasm, retinal axons from the two eyes travel together in the optic tract, which terminates in the LGN (Fig. 27.8). The LGN is composed of layers, each of which receives input from only one eye, although the number varies between species. In the macaque, the six principal layers contain most of the relay cells to primary visual cortex (Fig. 27.9).

**FIGURE 27.9** The six-layered LGN of the macaque monkey. The top four parvocellular layers (6, 5, 4, and 3) receive input from the ipsilateral and contralateral eye in the order of contra, ipsi, contra, and ipsi. The bottom two magnocellular layers (2 and 1) receive ipsi and contra input, respectively. In between these principal layers are intercalated or koniocellular layers. The arrow from layer 6 to 1 indicates organization of the precisely aligned retinotopic maps of the six layers. The receptive fields of neurons found along this line are located at the same position in visual space. From Hubel and Wiesel (1977).

The four parvocellular layers are found dorsally. They receive P cell input from the contralateral and ipsilateral eye in the order of contra, ipsi, contra, and ipsi. The magnocellular layers are found more ventrally. They receive M cell input in the order of ipsi and contra. Interposed between these principal layers are the intercalated layers, populated by konio-cellular neurons.

In the cat, the LGN has only two principal layers, called A and A1, which receive input from the contralateral and ipsilateral retinas, respectively. The neurons are again quite similar to either the retinal X cells or the Y cells that innervate them.

### The Primary Visual Cortex in the Cat Is an Example of a Functional Hierarchy

Cat primary visual cortex (area 17) is perhaps the best understood neocortical area in any species. The first studies of Hubel and Wiesel (1962) form the foundation of this understanding. Hubel and Wiesel found cells whose responses differed dramatically from those in the retina and thalamus. Many of these cells could be excited by stimuli presented to either eye. The

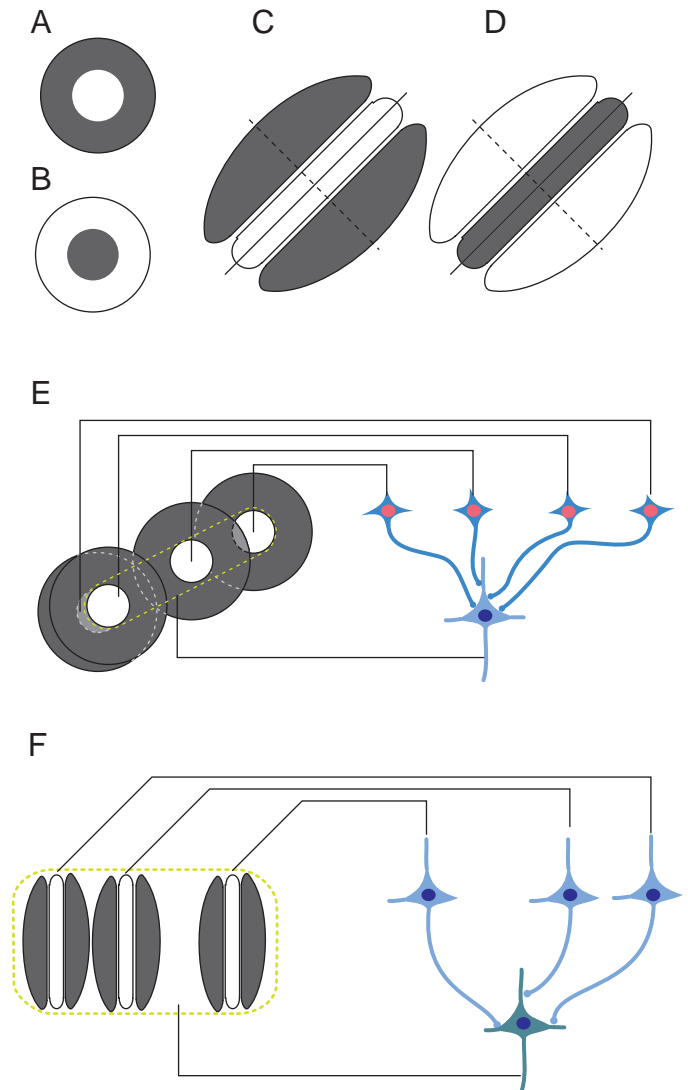

primary visual cortex thus represents the first level of the visual system at which binocular interactions could form a substrate for depth perception. Most strikingly, Hubel and Wiesel found that the vast majority of cortical cells respond best to elongated stimuli at a specific orientation and give no response at the orthogonal orientation. This is in sharp contrast to cells in the retina and LGN, which are not selective for orientation.

Hubel and Wiesel described two broad classes of neurons in area 17: *simple cells* and *complex cells*. The receptive fields of simple cells were segmented into oriented *on-and-off* subregions (Figs. 27.10C and 27.10D) and were therefore most sensitive to similarly oriented stimuli. In these receptive field subregions, responses were evoked by turning a light stimulus *on* or *off*, but not by both. Given these well-defined *on-and-off* subregions in simple cells, Hubel and Wiesel suggested a straightforward hierarchical model to explain orientation selectivity: neurons in the lateral geniculate nucleus whose receptive fields are arranged in a row could all converge to excite a specific simple cell (Fig. 27.10E). Although this model has generated much controversy over the ensuing years, many of its elements have been demonstrated directly (Reid and Alonso, 1995; Ferster *et al.*, 1996).

The second class of cortical neurons, complex cells, also responded best to oriented stimuli, but their receptive fields were not elongated along a preferred orientation, nor were they divided into distinct *on-and-off* subregions. It would therefore be difficult to imagine how the responses of these neurons could be constructed directly from the center/surround receptive fields in the thalamus. Given the properties of simple cells, Hubel and Wiesel proposed a hierarchical scheme. Complex cells receive their orientation selectivity from convergent input from simple cells whose receptive fields have the same orientation preference, but have slightly different spatial locations (Fig. 27.10F).

This original model is hierarchical or serial; information flows from one level to the next in a well-defined series. In contrast to this hierarchical model of cortical processing, it also has been proposed that each region of the cerebral cortex is made up of several different streams of information that are all processed in parallel. As with most dichotomies, elements of both hierarchical and parallel processing have been found in the visual cortex of all mammals studied. For simplicity, an outline of the organization of visual cortex in the cat is discussed here in terms of a hierarchical model. Parallel processing will be illustrated with the example of a primate visual cortex.

The hierarchical scheme has received support from several correlations between anatomy and physiology

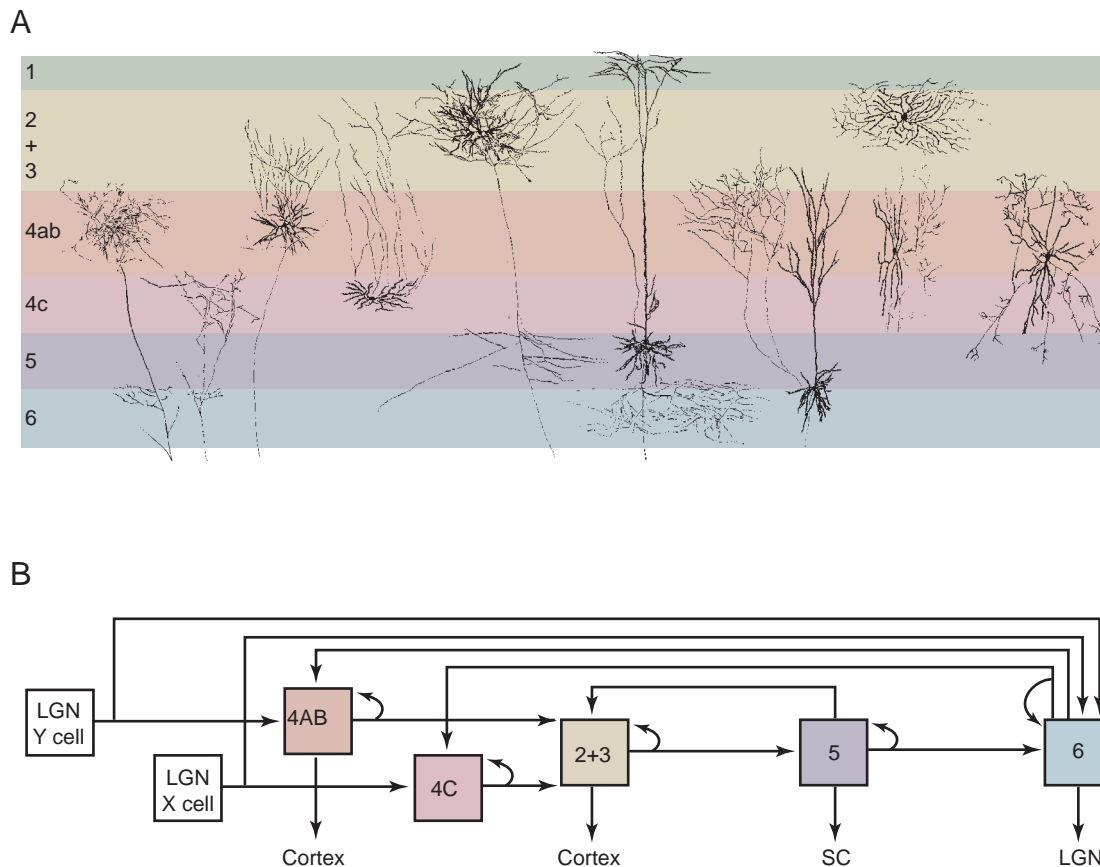

**FIGURE 27.10** Hubel and Wiesel's original models of visual cortical hierarchy. (A and B) Receptive field maps of center-surround receptive fields in LGN. White: *on* responses; dark gray: *off* responses. (C and D) Receptive field maps of simple cells. (E) Model of convergent input from LGN neurons onto the cortical simple cell. (F) Model of convergent input from simple cells onto complex cells. Adapted from Hubel and Wiesel (1962).

of area 17. In broad terms, simple cells are more common in the layers of cortex that receive direct input from the thalamus (layer 4 and, to a lesser extent, layer 6). Complex cells are found more frequently in layers that are more distant from the thalamic input in layers 2 + 3, which receive input primarily from layer 4, and in layer 5, which receives most of its input from layers 2 + 3 (Gilbert and Wiesel, 1985; Fig. 27.11).

In terms of their probable function in perception, the receptive fields of complex cells furnish an early example of what was meant in the introduction by a higher order representation. Complex cells convey

**FIGURE 27.11** Circuitry of cat cortical area 17. (A) Morphology of individual cells stained with horseradish peroxidase. Thick lines: dendrites; thin lines: axons. (B) Schematic diagram of connections. Most thalamic (LGN) input is concentrated in layer 4 and, to a lesser degree, in layer 6. Y cells tend to project more superficially in layer 4 than X cells (note that sublayers 4ab and 4c are not strictly analogous to 4A, 4B, and 4C in the macaque). There is a fairly strict hierarchical pathway from layers 4  $\rightarrow$  2 + 3  $\rightarrow$  5  $\rightarrow$  6 with feedback connections from 5  $\rightarrow$  2 + 3 and 6  $\rightarrow$  4. There are also many lateral connections between neurons within the same layer. Adapted from Gilbert and Wiesel (1985).

information about orientation to later stages of processing, but that information has been combined and generalized. A simple cell responds to an oriented stimulus of a specific configuration and a specific location; in particular, it has separate *on-and-off* subregions. A complex cell also responds to stimuli at one orientation, but the receptive field is not segregated into *on-and-off* subregions. Instead, it can respond to a light or dark stimulus of the correct orientation, independent of the exact location of the stimulus within the receptive field. This sort of generalization is a recurrent theme in the cortical processing of visual information.

### Several Parallel Streams Are Found in the Macaque Primary Visual Cortex

In the macaque primary visual cortex (V1, or striate cortex), a hierarchical organization is certainly present, but it is also clearly composed of several parallel

streams. As discussed earlier, at least three types of inputs to visual cortex (parvocellular, magnocellular, and koniocellular) are first segregated within the LGN. Each class of neurons projects to a specific subdivision of primary visual cortex. Most thalamic afferents terminate in layer 4C, which is split into two divisions. 4C $\alpha$  receives its input from magnocellular neurons and 4C/3 from parvocellular neurons. Intercalated, or koniocellular, geniculate neurons project to layers 2 + 3, specifically to regions known as “blobs” (discussed later) that stain densely for the enzyme cytochrome oxidase (Livingstone and Hubel, 1984)

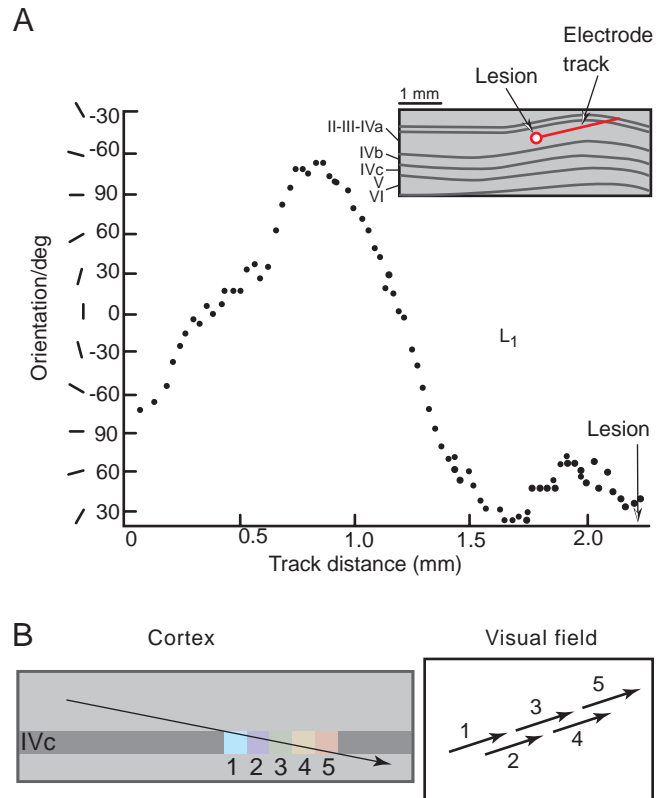

Thus visual information from functionally and anatomically distinct M and P retinal neurons are kept separate through the LGN and at least up to the cortical neurons that receive direct thalamic input. The degree to which these pathways—as well as the more poorly understood koniocellular pathway—are kept separate within visual cortex remains an area of active research (Fig. 27.15).

## Functional Architecture Can Be Seen in the Columnar Structure of the Visual Cortex

So far, the physiology of the visual cortex has been considered in terms of individual neurons and their response properties. Another major contribution of Hubel and Wiesel was their demonstration that cells with similar receptive field properties tend to be found near each other in the cortex. Further, they found that physiological response properties, such as orientation selectivity, are organized in an orderly fashion across the cortical surface. They termed the relationship between anatomy and physiology the *functional architecture* of visual cortex.

Hubel and Wiesel's key observation in this arena was that when an electrode is advanced through the cortex perpendicular to its surface, all neurons encountered have similar response properties. If a cell near the surface has a specific orientation and is dominated by input from one eye, then cells below it share these preferences. This finding is consistent with the idea, proposed by Lorente de Nó, that the fundamental unit in cortical architecture is a vertically oriented *column* of neurons. Hubel and Wiesel proposed that a cortical column is both a physiological and an anatomical unit, as had Mountcastle in his study of somatosensory cortex (Chapter 26). A second observation was that the property of orientation preference varies smoothly over the cortical surface. If an electrode takes a tangential path through the cortex through many different columns, the orientation preference generally changes in a steady clockwise or counterclockwise progression, although occasionally there are discontinuous jumps (Fig. 27.12A).

In addition to orientation, at least two other parameters are mapped smoothly across the cortical surface. Cells in the visual cortex receive inputs from the two eyes in varying proportion, a property that Hubel and Wiesel termed *ocular dominance*. In tangential microelectrode penetrations, cells are found that are dominated first by input from one eye and then the other. This provides evidence for *ocular dominance columns*, which have subsequently been demonstrated anatomically as well as physiologically. Second, prior to Hubel and Wiesel's work, a precise map of visual space across the surface of the cortex had been demonstrated. For any cortical column, receptive fields are all located at roughly the same position on the retina. Nearby columns represent nearby points in visual space in a precise and orderly arrangement. The position of a stimulus on the retina is termed its *retinotopy*; thus a region of the brain (such as the superior colliculus, LGN, or the visual cortex) that maintains the relations between adjacent retinal regions is said to have a *retinotopic map*.

**FIGURE 27.12** Two aspects of the functional architecture of the macaque primary visual cortex. (A) Graph of the preferred orientation of neurons encountered in a long microelectrode penetration through layers 2 + 3 (inset). There was a steady, slow progression of preferred orientations, although there were a few positions where the orientations changed more abruptly. (B) Schematic diagram of an electrode penetration through layer 4C (left) and the retinotopic positions of receptive fields (right). Numbers (1–5) indicate regions dominated by input from alternating eyes. At the border between ocular dominance columns (e.g., instance between 1 and 2), the location of receptive fields jumps back to a point represented near the middle of the previous ocular dominance column. There is a complete representation of visual space in columns dominated by each eye (1,3,5 or 2,4) and these representations are spatially interleaved. Adapted from Hubel and Wiesel (1977).

Given the existence of multiple functional maps, the obvious question is: How do these maps relate to each other? This question has been answered most definitively for the relationship between retinotopy and ocular dominance. Layer 4 in the primate is ideal for studying this question, as the receptive fields are quite small and the borders between ocular dominance columns are well defined. By making long, tangential penetrations through layer 4 of the striate cortex, Hubel and Wiesel found a precise interdigitating map from each eye. When eye dominance shifts, the receptive field location shifts to a point corresponding to the middle of the previous ocular dominance column (Fig. 27.12B). Thus there is a 50% overlap in the spatial

locations represented by adjacent ocular dominance columns. In this manner, a complete representation of space is attained for both eyes while ensuring that cells that respond to overlapping points in visual space are always nearby within the cortex.

### Ocular Dominance and Orientation Columns Can Be Revealed with Optical Imaging

The technique of optical imaging has proven extremely useful in the study of the functional architecture of the visual cortex. Optical imaging allows direct visualization of the relative activity of small cortical ensembles rather than relying on inferences made from single-unit studies (Blasdel and Salama, 1986; Grinvald *et al.*, 1986). The technique uses dyes that change their optical properties with neural activity. Even if no dyes are used, brain activity can be mapped with an intrinsic signal, caused primarily by changes in blood flow and blood oxygenation.

A typical optical imaging experiment works as follows (Fig. 27.13A). First, a series of digitized images is taken of a region of visual cortex (Fig. 27.13B) while the animal is presented with visual stimuli through the left eye. Next, a similar series is captured during right eye stimulation. When the right eye images are subtracted digitally from the left eye images, a striking picture is created that reveals the functional architecture of ocular dominance (Fig. 27.13C). Previously, anatomical methods had been used to produce maps of ocular dominance, and these maps appear similar to those found with optical imaging, but an important feature of optical imaging is that multiple images can be obtained from the same region of the cortex. For instance, in addition to ocular dominance, maps of the preferred orientation can also be made. A useful way to present these data is in terms of a color code, in which each color represents a different preferred orientation (Fig. 27.13D). The orientation columns revealed by optical imaging were consistent with earlier microelectrode studies (compare Fig. 27.13E with Fig. 27.12A), but the images for the first time gave a detailed picture of the layout of orientation across the cortical surface. Details of these orientation maps—and their relationships with ocular dominance—were entirely new and had not been demonstrated with previous techniques.

### Cytochrome Oxidase Staining Reveals Blobs and Stripes in Cortical Areas V1 and V2

In the primate, there is a fourth feature of the functional architecture of visual cortex in addition to retinotopy, orientation, and ocular dominance columns.

When stained for the enzyme cytochrome oxidase (a metabolic enzyme whose presence indicates high activity), histological sections of V1 revealed a regular pattern of patches, or blobs (Fig. 27.14). In layers 2 + 3, these blobs were reported to contain neurons whose receptive fields are color selective, poorly oriented, and monocular (Livingstone and Hubel, 1984).

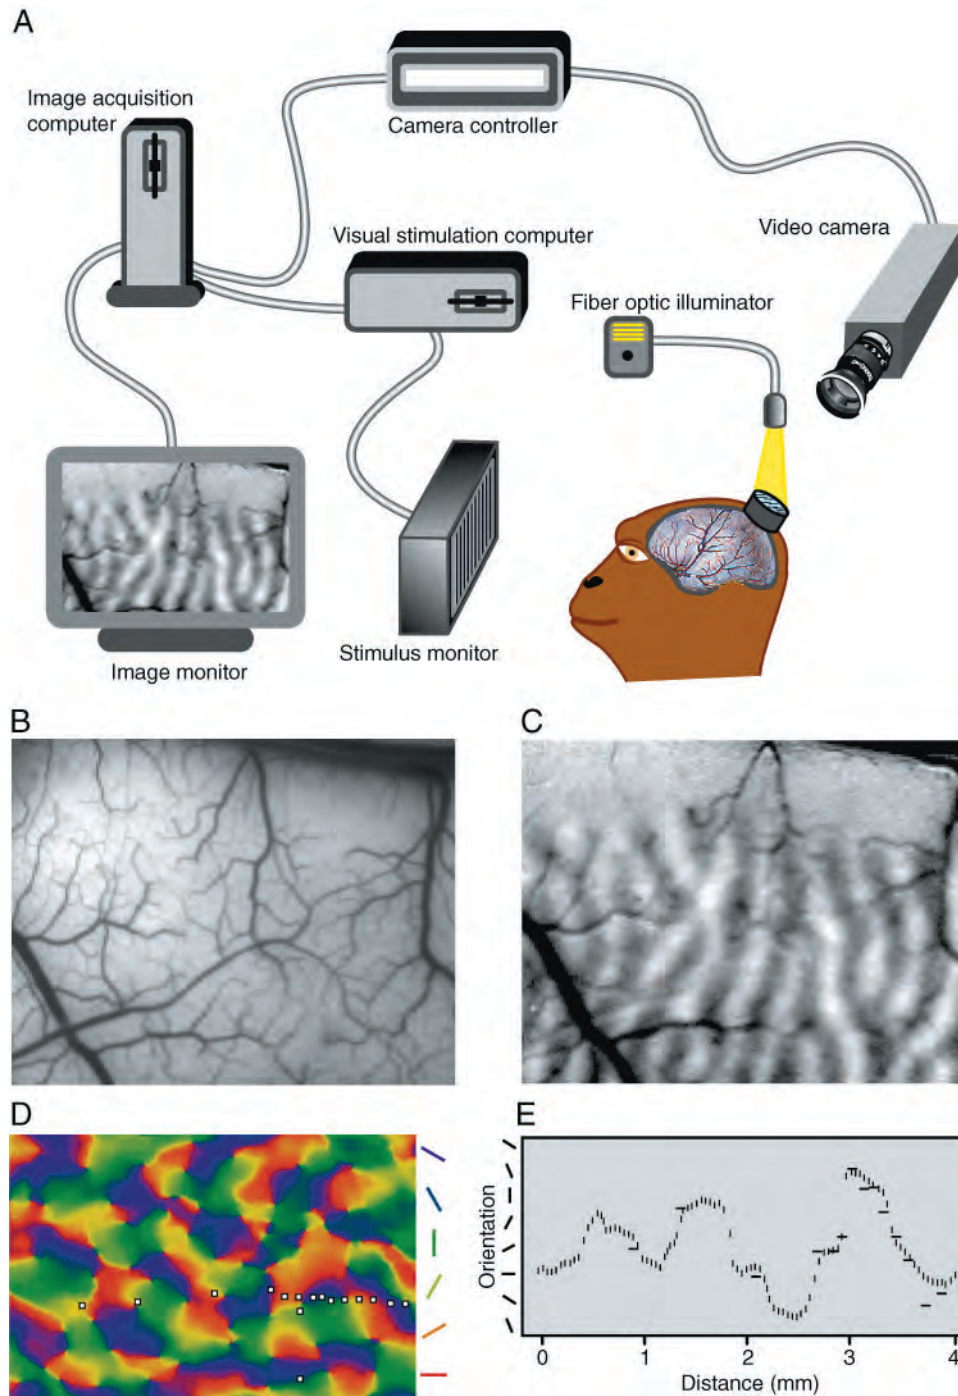

In V2, the second visual area in the cerebral cortex (see later), cytochrome oxidase staining reveals regions of high and low activity arranged in parallel stripes (thick, thin, and pale stripes; Fig. 27.14, along the top). The anatomical connections between V1 and V2 are strongly constrained by the subdivisions revealed by cytochrome oxidase staining. In an early view, V1 neurons in the blobs projected to the thin stripes of V2, neurons in the interblobs projected to the pale stripes, and neurons in layer 4B projected to the thick stripes (Livingstone and Hubel, 1984). More recently, this organizational scheme has been revised and simplified such that V1 neurons in blob (or patch) columns, including underlying regions of layer 4B, project to the thin stripes of V2, whereas neurons in the interblob (interpatch) columns, again including underlying regions of layer 4B, project to both the pale stripes and thick stripes (Sincich and Horton, 2005).

One of the reasons it is important to understand the anatomical relationship between V1 and V2 is that neurons in the thick, thin and pale stripes of V2 give rise to projections that appear selective for either the dorsal or ventral streams of visual processing in extrastriate cortex (described later), whereby neurons in the thick stripes provide input to the dorsal stream and neurons in the thin and pale stripes provide input to the ventral stream.

### Many Extrastriate Visual Areas Perform Different Functions

In early studies of the cytoarchitecture of cerebral cortex, the visual cortex was divided into three areas according to Brodmann's classification: areas 17, 18, and 19. These divisions were based on differences in cell cytoarchitecture, or differences in the size, morphology, and distributions of cells within the six cortical laminae. Area 17 is primary visual cortex, or striate cortex, so named because of a heavily myelinated sublamina within layer 4 ( $4C\alpha$ ), prominently visible as a stripe in transverse section. Areas 18 and 19 were known simply as the visual association cortex. An assumption behind these designations was that areas defined by anatomical criteria would ultimately prove to be functionally specialized.

The demonstration of multiple visual cortical areas has been one of the important discoveries of the past

**FIGURE 27.13** Optical imaging of functional architecture in the primate visual cortex. (A) Schematic diagram of the experimental setup for optical imaging. Digitized images of a region of visual cortex (as in B) are taken with a CCD camera while the anesthetized, paralyzed animal is viewing a visual stimulus. These images are stored on a second computer for further analysis. (B) Individual image (9 by 6 mm) of a region of V1 and a portion of V2 taken with a special filter so that blood vessels stand out. (C) Ocular dominance map. Images of the brain during right-eye stimulation were subtracted digitally from images taken during left-eye stimulation. (D) Orientation map. Images of the brain were taken during stimulation at 12 different angles. The orientation of stimuli that produced the strongest signal at each pixel is color coded, as indicated to the right. The key at the right gives the correspondence between color and the optimal orientation. (E) Comparison of the preferred orientation of single neurons with the optical image. At each of the locations indicated by squares in D, single neurons were recorded with microelectrodes. The preferred orientations of the neurons (dashes) were compared with the preferred orientations measured in the optical image, sampled along the line connecting the recording sites (dots). A: Adapted From Grinvald *et al.* (1988). B and C: Adapted from Ts'o *et al.* (1990). D and E: Adapted from Blasdel and Salama (1986).

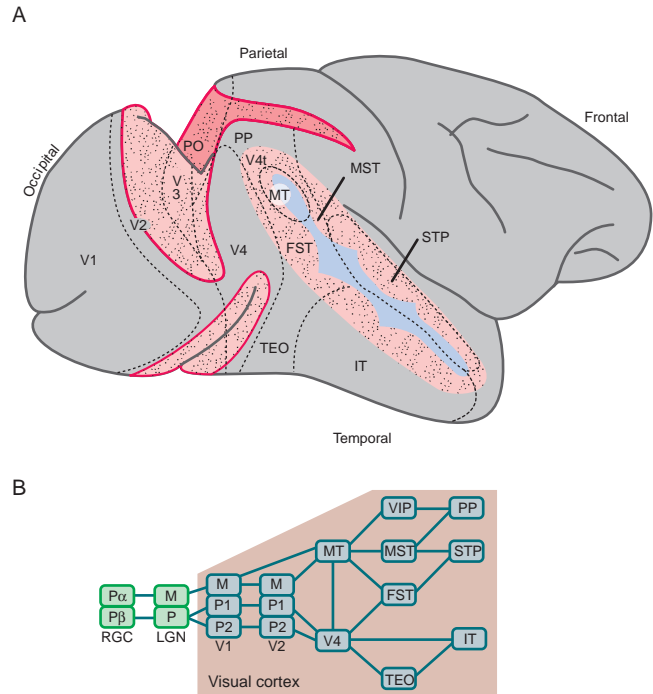

**FIGURE 27.14** Macaque visual cortex stained for the metabolic enzyme, cytochrome oxidase. A tangential section through layers 2 + 3 of V1 (below) and V2 (above) is shown. In V1, blobs are seen in a regular array with a spacing of 400  $\mu$ m. In V2, there are cytochrome oxidase-rich stripes with much coarser spacing. The distinction between thick and thin stripes (see text) is seen less readily in the macaque than in the owl monkey. Scale bar: 1 mm. From Livingstone and Hubel (1984).

quarter century in the field of sensory neurobiology. A vast expanse of cerebral cortex—greater than 50% of the total in many primate species—is involved primarily or exclusively in the processing of visual information. The extrastriate cortex now includes areas 18 and 19, as well as large regions of the temporal and parietal lobes (see Fig. 27.15 for a diagram of the four main regions of cerebral cortex: occipital, parietal, temporal, and frontal). It is composed of some 30 subdivisions that can be distinguished by their physiology, cytoarchitecture, histochemistry, and/or connections with other areas (Felleman and Van Essen, 1991). Each of these extrastriate visual areas is thought to make unique functional contributions to visual perception and visually guided behavior.

As a testament to the increasing complexity of the field, the naming of visual areas (Fig. 27.15) has progressed from the use of simple labels—V1 through V4—to the use of more complex terms specifying anatomical location of each new area, such as MT (medial temporal, or V5), MST (medial superior temporal), or IT (inferotemporal, itself made up of several distinct areas).

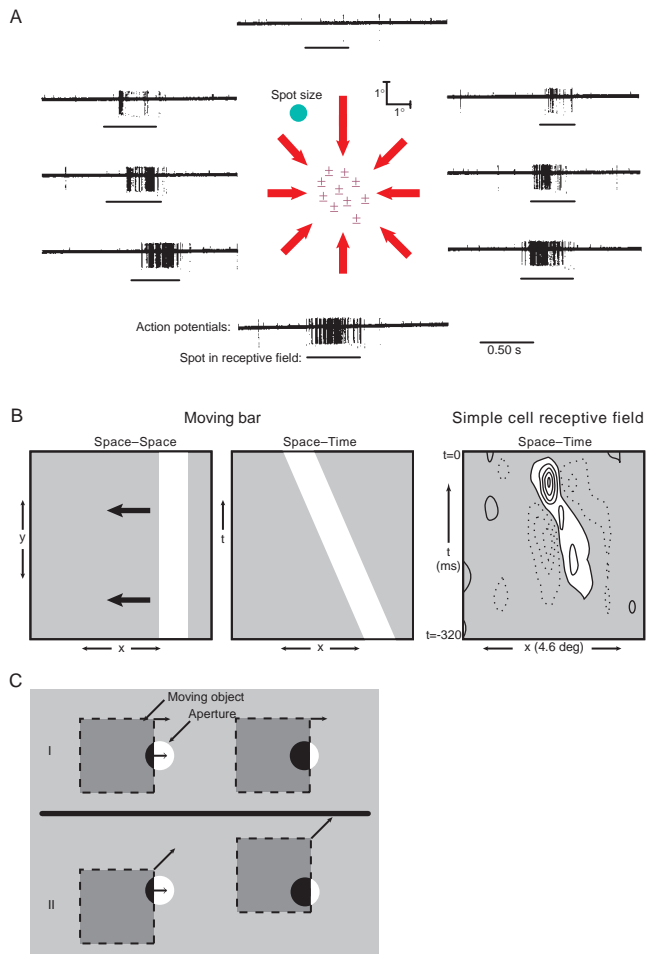

The dual themes of parallel and hierarchical processing are central to the understanding of the extrastriate cortex. Figure 27.15 is a vastly simplified version of a wiring diagram between visual areas (Felleman and Van Essen, 1991). Several criteria have been used to define new visual cortical areas. First, extrastriate regions have retinotopic maps of the visual world that

**FIGURE 27.15** Extrastriate cortical regions. (A) Lateral view of the macaque brain, with the sulci partially opened to expose the areas within them. Shown are the rough outlines of the main visual areas, which take up all of the occipital cortex and much of the parietal and temporal cortex. (B) Partial diagram of the connections between visual areas. Emphasis is placed on the hierarchical organization of the connections and on the partially segregated P parvocellular and M magnocellular pathways. Adapted from Albright (1993).

can be demonstrated by physiological recordings. Second, a clear hierarchy between many cortical areas can be demonstrated anatomically. There is a stereotyped pattern of projections from one visual area to the next. Where strong connections between two areas exist, these connections tend to be bidirectional. The feedforward and feedback connections are distinguished by the layers that send and receive the connections. In such a manner, a clear hierarchy can be traced, for instance, along the pathway V1  $\rightarrow$  V2  $\rightarrow$  V3  $\rightarrow$  MT  $\rightarrow$  MST (with several shortcuts, such as V1  $\rightarrow$  MT).

Physiological studies of cortical areas revealed profound differences between them, and a series of studies by Ungerleider and Mishkin (1982) uncovered a higher order dichotomy between two types of processing in the extrastriate cortex. Using behavioral analyses of animals with anatomically defined cortical lesions, Ungerleider and Mishkin found a strong dissociation between the types of deficits exhibited by animals with lesions in either their parietal cortex or their temporal cortex (Fig. 27.15). Animals with temporal lesions were often much worse at recognizing objects visually, although lower level visual function, such as acuity,

**FIGURE 27.16** Three types of direction selectivity. (A) Receptive field map of a directionally selective ganglion cell in the rabbit ( $\pm$  indicates where neuron responded in an *on-off* manner). Surrounding it are individual responses to stimuli moving in eight different directions. The smooth traces below each train of action potentials correspond to the position of the stimulus as it moves in the indicated direction. Horizontal bars indicate when the spot was in the receptive field. (B) Direction selectivity in cortical simple cells of the cat. A bar moving to the left (shown in a space-time plot in the middle panel) matches the template formed by a directionally selective simple receptive field (shown in a space-time plot at right). The vertical time axis in the right-hand panel corresponds to the stimulus location 0 to 320 ms *before* the neuron fired. Bright regions in the receptive field correspond to the best location for a bright stimulus at each delay between stimulus and response. (C) The ambiguous motion of an extended object when viewed through a small aperture—known as the aperture problem—is partially resolved by some neurons in macaque cortical area MT. The squares in I and II (each shown at two successive time points) are moving in different directions, but they appear identical when viewed through a small aperture. A: Adapted from Barlow *et al.* (1964). B: Far right adapted from McLean *et al.* (1994).

was not appreciably lessened. Parietal lesions led to little or no deficit in object recognition, but visuospatial tasks, such as visually guided behavior, were impaired profoundly. From these studies and the growing body of physiological evidence, two distinct streams were postulated: a *temporal* or *ventral stream* devoted to object recognition and a *parietal* or *dorsal stream* devoted to action or spatial tasks. Ungerleider and Mishkin termed these the “what” and “where” pathways.

The ventral stream,  $V1 \rightarrow V2 \rightarrow V3 \rightarrow V4 \rightarrow IT \dots$ , is discussed in Chapter 55. This chapter considers only the dorsal stream,  $V1 \rightarrow V2 \rightarrow MT \rightarrow MST \dots$ . The dorsal stream is dominated by magnocellular cells and the ventral stream by parvocellular cells, although the segregation is far from strict (Merigan and Maunsell, 1994).

### In the Parietal Cortex, Neurons Are Selective for Higher Order Motion Cues

MT, or V5, is perhaps the best understood of the extrastriate visual areas. It has held particular interest ever since it was discovered in 1971 (Allman and Kaas, 1971; Dubner and Zeki, 1971), primarily because it was the first area found that was strongly dominated by one visual function. Fully 95% of the neurons in MT are highly selective for the direction of motion of a stimulus (Dubner and Zeki, 1971). In V1, a significant fraction of neurons are selective for the direction of motion, but the optimal speed may vary depending on the spatial structure of the object that is moving. In MT, speed tuning is less dependent on other stimulus attributes. Receptive fields of individual neurons in MT integrate motion information over large regions of visual space and are qualitatively less selective than neurons in the primary visual cortex. This generalization of motion signals can be achieved in a simple manner, such as by adding together inputs over space or, in a complex manner, by combining two component motions in different directions into a single coherent motion (Box 27.4). Of even greater interest, neurons in MT (and, to a greater extent, those in MST) appear to be sensitive to more complex aspects of visual motion, such as the motion of extended objects rather than isolated features (Albright, 1993).

The range of stimuli that a given MT neuron can respond to is impressively broad—the attributes, or form cues, that define a figure can be luminance, texture, or relative motion—but the preferred direction and speed are always the same for that neuron (Albright, 1993). This is an extreme example of what were termed high-order responses in the introduction to this chapter. Neurons at lower levels in the visual

system are sensitive to isolated and specific features in visual scenes. Higher visual areas respond to very specific attributes, but these attributes are increasingly remote from the physical stimulus. Instead, they represent increasingly complex concepts, such as the motion of an extended object or the identity of a face.

## Summary

The lateral geniculate nucleus of the thalamus is a layered structure that receives segregated input from the two eyes and projects to the primary visual cortex (V1). Geniculate neurons have center-surround receptive fields that are similar to those of their retinal inputs. In contrast, most neurons in the primary visual cortex are sensitive to the orientation of a stimulus. In mammalian species, there are elements of both hierarchical and parallel processing in the primary visual cortex. This section has emphasized that the visual cortical circuit in the cat can be seen as a functional hierarchy that transforms geniculate input into simple and then complex receptive fields. In the macaque monkey the focus has been on the parallel pathways that are kept relatively separate in the striate and extrastriate cortex.

The visual cortex has an orderly functional architecture. Neurons within a cortical column have similar receptive field attributes, such as orientation selectivity, ocular dominance, and receptive field location. Each of these receptive field attributes varies smoothly over the cortical surface. The organization of ocular dominance columns and orientation columns across the cortical surface can be visualized with optical imaging.

Finally, in the macaque monkey, there are more than 30 extrastriate visual cortical regions, each of which performs different functions. These extrastriate regions can be divided into two pathways: the ventral stream, devoted to form recognition, and the dorsal stream, devoted to action or to spatial tasks. Areas in each stream form a functional and anatomical hierarchy. Neurons in successive visual areas respond to increasingly high-order or abstract features of the visual world.

MOTOR SYSTEMS

This page intentionally left blank

## Fundamentals of Motor Systems

“All mankind can do is to move things . . . whether whispering a syllable or felling a forest.”—Sherrington

This brief quote is a reminder of the basic fact that all interactions with the surrounding world are through the actions of the motor system. When a human baby is born it is a sweet but very immature survival machine, with a limited behavioral repertoire. It is able to breathe and has searching and sucking reflexes so that it can be fed from the mother's breast. It can swallow, vomit and process food, and cry to call for attention if something is wrong. A baby also has a variety of protective reflexes that mediate coughing, sneezing, and touch avoidance. These different patterns of motor behavior are thus available at birth and are due to innate motor programs (Fig. 28.1).

During roughly the first 15 years of life the motor system continues to develop through maturation of neuronal circuitry and by learning through different motor activities. Playing represents an important element both in children and in young mammals such as kittens and pups. During the first year of life the human infant matures progressively. It can balance its head at 2–3 months, is able to sit at around 6–7 months, and stand with support at approximately 9–12 months. The coordination of different types of posture, such as standing, is a complex motor task to master, with hundreds of different muscles taking part in a coordinated fashion. Sensory information contributes importantly, in particular from the vestibular apparatus, eyes, muscle, and skin receptors located at the soles of the feet. This development represents to a large degree a maturation process following a given sequence, but with individual variability among different children. When the postural system has evolved to a sufficient

degree, a child is able to start walking, which requires that the body posture be maintained while the points of support are changing by the alternating movements of the two legs. In common language the child is said to “learn” to walk, but in reality a progressive maturation of the nervous system is taking place. Identical twins start to walk essentially at the same time, even if one has been subjected to training and the other has not. At this point the motor pattern is still very immature. Proper walking coordination followed by running appears later, and the basic motor pattern actually continues to develop until puberty. The fine details of the motor pattern are adapted to the surrounding world, but also to modification by will. The basic motor coordination underlying reaching and the fine control of hands and fingers undergo a similar characteristic maturation process over many years.

The newborn human infant is comparatively immature, but other mammals, such as horses and deer, represent another extreme. The gnu, an African buffalo-like antelope, needs to run away in order to survive attacks of predators such as lions. The young calf of the gnu can stand and run directly after birth and has been reported to be able to gallop ahead 10 minutes after delivery, tracking the running mother (Fig. 28.2). Clearly the neural networks underlying locomotion, equilibrium control, and steering must be sufficiently mature and available at birth, needing minimal calibration. This is astounding. A similar range of maturity is present in birds. To get out of the egg, a chick makes coordinated hatching movements to open up the eggshell to subsequently lift off the top of the egg and to stand up to walk away on two legs following the mother hen and start picking at food grains. Most birds are more immature when hatching, but after a

**FIGURE 28.1** Motor development of the infant and young child. The pattern of maturation of the motor system follows a characteristic evolution. Two months after birth a child can lift its head, at 4 months it sits with support, and subsequently it is able to stand with support; later it crawls, stands without support, and finally walks independently. The approximate time at which a child is able to perform these different motor tasks is indicated above each figure. The variability in the maturation process is substantial. Modified from M. M. Shirley.

**FIGURE 28.2** Some animals are comparatively mature when they are born. Ten minutes after the calf of the gnu, a buffalo-like antelope, is born it is able to track its mother in a gallop. This means that the postural and locomotor systems are sufficiently mature to allow the young calf to generate these complex patterns of motor coordination at birth. There is thus little time to calibrate the motor system after birth and obviously no time for learning. Courtesy of Erik Tallmark.

few weeks they leave the nest flying rather successfully, for the first time in their life, and thus without any previous experience.

In addition to the basic motor skills such as standing, walking, and chewing, humans also develop skilled motor coordination, allowing delicate hand and finger movements to be used in handwriting or playing an instrument or utilizing the air flow and shape of the oral cavity to produce sound as in speech or singing. The neural substrates allowing learning and execution of these complex motor sequences are expressed genetically and characteristic of our species. What is learned, however, such as which language one speaks or the type of letters one writes, is obviously a function of the cultural environment.

## BASIC COMPONENTS OF THE MOTOR SYSTEM

### Motoneurons and Motor Units

The motoneurons that control different muscles are located in different motor nuclei along the spinal cord and in the brain stem. Each motoneuron sends its axon to one muscle and innervates a limited number of muscle fibers. A motoneuron with its muscle fibers is referred to as a motor unit. The muscle fibers of each motor unit have similar contractile properties and metabolic profile. The muscle fibers in different muscles are composed of three main types specialized for different demands, such as a continuous effort as in long-distance running (slow motor units) or fast explosive movements, such as lifting a heavy object (fast motor units (two subtypes)).

Motoneurons are activated by interneurons of different motor programs or reflex centers and by descending tracts from the forebrain and the brain stem. Thus motoneurons supplying different muscles can be activated with great precision by these different sources that together determine the degree of activation, as well as the exact timing of the motoneurons of a given muscle.

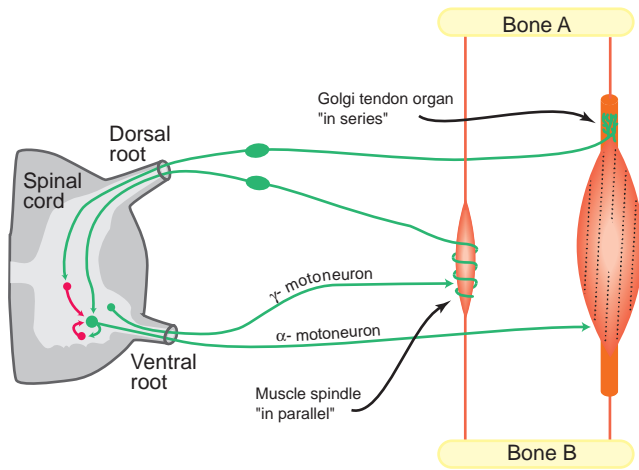

#### *Sensory Receptors Are Important in Movement Control*

Signals from sensory receptors are used by the motor system in a number of ways.

1. Sensory signals can trigger behaviorally meaningful motor acts such as withdrawal, coughing, or swallowing reflexes.
2. Sensory receptors may contribute to the control of an ongoing motor pattern and influence the

switch from one phase of movement to another. For instance, in the case of breathing, sensory signals from lung volume receptors control when inspiration is terminated. In walking, sensory signals related to hip position and load on the limb help regulate the duration of the support and swing phases of the step cycle and correct for perturbations.

3. Sensory signals may also be more specific and influence only the level of activity of one muscle or a group of close synergists. Muscle receptors play a particularly important role in this context. They are of two types: (1) Golgi tendon organs that sense the degree of contraction in a muscle (located in series with the muscle fibers at their insertion into the tendon) and (2) muscle spindles that signal the length of a muscle (located in parallel to the muscle fibers), as well as the speed of changes in length. Moreover, the sensitivity of muscle spindles can be regulated actively through a separate set of small motoneurons, referred to as  $\gamma$ -motoneurons (in contrast to the larger  $\alpha$ -motoneurons that control muscle contraction). These two muscle receptors have fast conducting afferent axons that provide rapid feedback to the spinal cord and take part in the autoregulation of the motor output to a given muscle. Fast muscle spindle afferents provide direct monosynaptic excitation to the  $\alpha$ -motoneurons that control the muscle in which the muscle spindle is located. Thus, lengthening a muscle will lead to excitation of its motoneurons, counteracting the lengthening. This stretch reflex thus involves negative feedback. This reflex arc also provides the basis of the muscle contraction elicited by a brief tendon tap, which is used as a clinical test to investigate whether responsiveness of the motoneuronal pool is normal (the tendon reflex) (Fig. 28.3).
4. Sensory signals from a number of different receptor systems help detect and counteract any disturbance of body posture during standing or maintenance of another body position. Skin and muscle receptors and receptors signaling joint position, as well as vestibular receptors and vision, contribute to different aspects of the dynamic and static control of body position.
5. When an object is held by the fingers, skin receptors at the contact points at the fingertips play an important role. If the object tends to slip, the skin receptors become activated and signal rapidly to the nervous system that there is a need for extra muscle force.
6. A great variety of sensory signals provide information about the position of different parts

**FIGURE 28.3** Feedback from muscle receptors to motoneurons: the stretch reflex. In a muscle connected between two bones, the Golgi tendon organ is located at the transition between muscle and tendon. It senses any active tension produced by the muscle fibers, being in series between muscle and tendon. The muscle spindle is located in parallel with the muscle fibers. It signals the muscle length and dynamic changes in muscle length. Both the muscle spindle and the Golgi tendon organ have fast conducting afferent nerve fibers in the range of  $\sim 100$  m/s. The muscle spindle activates  $\alpha$ -motoneurons directly, which causes the muscle fibers to contract. The sensitivity of the muscle spindle can be actively regulated by  $\gamma$ -motoneurons, which are more slowly conducting. The muscle spindle provides negative feedback. If the muscle with its muscle spindle is lengthened, the afferent activity from the muscle spindle increases, exciting the  $\alpha$ -motoneurons and leading to an increased muscle contraction, which in turn counteracts the lengthening. This is called the stretch reflex. The Golgi tendon organ provides force feedback. The more the muscle contracts, the more the Golgi tendon organ and its afferent are activated. In the diagram the intercalated interneuron between afferent nerve fiber and motoneuron is inhibitory. Thus increased muscle force leads to inhibition of the  $\alpha$ -motoneuron, which results in a decrease of muscle force. The efficacy of length and force feedback can be regulated independently in the spinal cord and via  $\gamma$ -motoneurons. Thus their respective contributions can vary considerably between different patterns of motor behavior.

of the body in relation to each other and to the external world. Such information is critical when initiating a voluntary movement. For example, to move a hand toward a given object, it is important to know the initial position of the arm and the hand in space. Depending on whether the hand is located to the left or the right of the object, different types of motor commands must be given to bring the hand to the target. Sensory information about the initial position of the hand (or any other body part) in relation to the rest of the body, as well as the target for the movement,

is thus important for eliciting an effective neural command signal.

To summarize, the sensory contribution to motor control is very important in many different contexts. If sensory control is incapacitated, motor performance will in most cases be degraded. Without sensory information in different forms, movements can usually still be executed, but as a rule with much less perfection.

## Feedback and Feed Forward Control

If a perturbation occurs when an object is held in the hand, or when standing in a moving bus, it will be detected by different sensory receptors. This sensory signal will be fed back to the nervous system and be used to counteract the perturbation rapidly. This represents feedback control that is a correction of the actual perturbation after it has occurred. A limiting factor for the efficacy of feedback control in biological systems is the delay involved. A sensory afferent signal must first be elicited in the receptors concerned. It then has to be conducted to the central nervous system and be processed there to determine the proper response. The correction signal must subsequently be sent back to the appropriate muscle(s) and make the muscle fibers build up the contractile force required. In large animals, including humans, the delays involved can be substantial, and during fast movement sequences there may be little or no time for feedback corrections. In less demanding, more static situations, such as standing, sensory feedback is of critical importance.

In many cases a perturbation is anticipated before it is initiated, and correction begins before it actually has occurred. This type of control often is called feed forward control, in contrast to feedback. Such anticipatory control mechanisms are often automatic and involuntary, and are part of an inherent control strategy. For example, when standing on two legs and planning to lift up one leg to stand on the other, the body position begins to shift over to the supporting leg before the other leg is lifted. The projection of the center of gravity will fall between the two feet initially and will have to shift over to a projection through the supporting limb. In most instances, movement commands are designed so that the corrections of body posture required for a stable movement occur before the particular movement has started, as when lifting a heavy object. If the converse situation occurred, and body position was corrected only after a perturbation had taken place, movements would become much less precise than with feed forward control.

## MOTOR PROGRAMS COORDINATE BASIC MOTOR PATTERNS

Both vertebrates and invertebrates have preformed microcircuits—neuronal networks that contain the necessary information to coordinate a specific motor pattern such as swallowing, walking, or breathing. When a given neuronal network is activated, the particular behavior it controls will be expressed. A typical network consists of a group of interneurons that activate a specific group of motoneurons in a certain sequence and inhibit other motoneurons that may counteract the intended movement. Such a group of interneurons often is referred to as a central pattern generator (CPG) or motor program. This CPG can be activated by will, as at the start of walking, or be triggered by sensory stimuli, as in a protective reflex or swallowing. In most types of motor behavior, sensory feedback may also form an integral part of the motor control circuit and may determine the duration of the motor activity such as the inspiratory phase of breathing (Fig. 28.4).

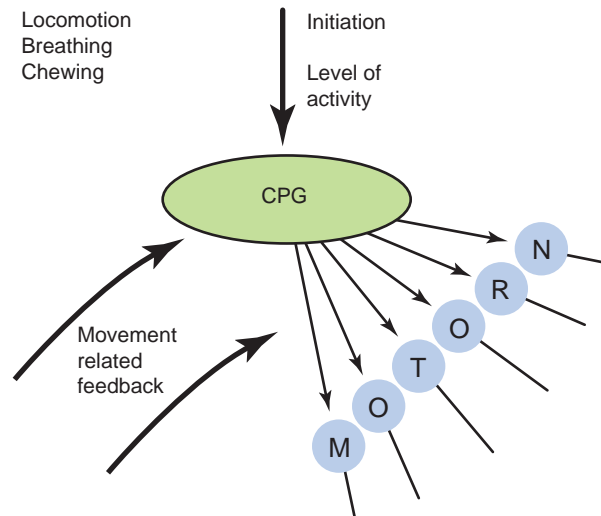

There are several different types of motor coordination, as described next.

### Motor Patterns Triggered as a Reflex Response

Protective skin reflexes lead to withdrawal of the stimulated part of the body from a stimulus that may cause pain or tissue damage. The central program consists in this case of a group of interneurons that activate motoneurons and muscles, giving rise to an appropriate withdrawal movement. Motoneurons to antagonistic muscles are inhibited (reciprocal inhibition). The withdrawal reflexes of the limbs often are referred to as flexion reflexes, but in reality they represent a family of specific reflexes, each of which is designed to remove the specific skin region involved from the painful stimulus.

Coughing and sneezing reflexes remove an irritant from the nasal or tracheal mucosa by inducing a brief pulse of air flow at very high velocity (at storm or hurricane speeds). This is caused by an almost synchronized activation of abdominal and respiratory muscles, coordinated by a CPG, the activity of which is triggered by afferents activated by the irritant.

Swallowing reflexes are activated when food is brought in contact with mucosal receptors near the pharynx. This leads to a coordinated motor act with sequential activation of different muscles that propel the food bolus through the pharynx down the esophagus to the stomach. In this case the CPG is able to

**FIGURE 28.4** Motor coordination through interneuronal networks: central pattern generators. The brain stem and spinal cord contain a number of networks that are designed to control different basic patterns of the motor repertoire, such as breathing, walking, chewing, or swallowing. These networks often are referred to as central pattern generator networks (CPGs). CPGs contain the necessary information to activate different motoneurons and muscles in the appropriate sequence. Some CPGs are active under resting conditions, such as that for breathing, but most are actively turned on from the brain stem or the frontal lobes. For instance, the CPG coordinating locomotor movements is turned on from specific areas in the brain stem, referred to as locomotor centers. These descending control signals not only turn on the locomotor CPG, but also determine the level of activity in the CPG and whether slow or fast locomotor activity will occur. In order to have the motor pattern well adjusted to external conditions and different perturbations, sensory feedback acts on the CPG and can modify the duration of different phases of the activity cycle, providing feedback onto motoneurons. Although vertebrates as well as invertebrates have CPGs for a great variety of motor functions, the intrinsic operation of these networks of interneurons constituting the CPG is unclear in most cases. In invertebrates, a few CPG networks have been studied in great detail, such as the stomatogastric system of the lobster and networks coordinating the activity of the heart and locomotion in the leech. In vertebrates detailed information concerning locomotor networks is only available in lower forms, such as the frog embryo and the lamprey.

coordinate the motor act over several seconds, in contrast to the previous motor acts in which the activity occurs almost simultaneously.

### Rhythmic Movements

Walking movements (or locomotor behaviors in general) are produced by CPGs in the spinal cord (or ganglia of invertebrates). These spinal CPGs are turned on by descending control signals from particular areas in the brain stem (locomotor areas), which also determine the level of locomotor activity (e.g., slow walking

versus trot or gallop). The CPG then sequentially activates motoneurons/muscles that support the limb during the support phase and then move it forward during the swing phase. Sensory stimuli from the moving limb also contribute importantly to regulate the duration of the support phase and the degree of activation of different muscles that are sequentially activated in each step cycle. The relative importance of the sensory component varies between species and with the speed of locomotion. During very fast movements, there is actually no time for sensory feedback to act, and adjustments need instead to be performed in a predictive mode.

Chewing movements are controlled by brain stem circuits that in principle are designed in a similar manner to those of locomotion, and generate alternating activity between jaw-opener and -closer muscles.

Breathing movements are continuously active from the instant of birth to the time of death, except for short voluntary interventions when speaking, singing, or choosing not to breathe for some other reason, like diving. The level of respiration (depth and frequency) is driven by metabolic demands (e.g.,  $p\text{CO}_2$ ) detected by chemosensors in the brain stem where the respiratory CPG is also located. Sensory stimuli from lung volume receptors contribute by setting the level at which the inspiration is terminated and expiration takes over.

## Eye Movements

Fast saccadic eye movements are used when looking rapidly from one object to another and are represented with a much more complex organization in the superior colliculus (mesencephalon) than the motor patterns discussed earlier. Saccadic eye movements with different directions and amplitudes can be generated by the stimulation of different microregions in the superior colliculus, according to a well-defined topographical map. Each microregion is responsible for activating a subset of brain stem interneurons, which in turn activates the appropriate combination of eye motoneurons in order to move the two eyes in a coordinated fashion from one position to another. The purpose is to bring the visual object of interest into the foveal region so that it can be scrutinized in the greatest detail. To recruit a saccadic eye movement to a specific site, cortical or subcortical areas have to access the appropriate microregions within the superior colliculus to trigger the specific eye movement desired.

Other types of eye movement control are used when tracking an object that is moving, as when watching a game of tennis. These tracking movements are represented in the cerebral cortex and the brain stem.

## Posture

Animals, including humans, have the ability to position the body in a variety of postures. The most stable position is lying horizontally in bed, which requires little activity from the nervous system. The situation is very different when standing and even more so when supporting oneself on one leg. This requires a very structured command to handle the activation of different muscles in the legs, trunk, shoulders, and neck. The nervous system issues this complex motor command to achieve a certain position. The ability to maintain a stable position standing on one leg is then critically dependent on feedback from a variety of sensory receptors that detect falling to one side or the other. These receptors activate reflex circuits that try to counteract the impending loss of balance. Of great importance are the vestibular receptors located in the head, which sense head movements in the different directions. Vestibular reflexes act on the neck muscles to correct the position of the head, and vestibulospinal reflexes act on the trunk and the extensor muscles of the limbs. In addition, vestibular effects also are mediated indirectly by the reticulospinal system. Muscle receptors in neck and limb muscles are of equal importance. They also play a critical role in detecting and compensating for postural perturbations, in particular around the ankle, where skin receptors on the bottoms of the feet are activated. Finally, visual feedback may contribute as when one is standing on a moving surface such as the deck of a boat.

The body can be arranged in a number of ways, sitting in a relaxed way on a sofa, stiffly on an uncomfortable chair, or standing with the body and the legs held in a range of postures. In one sense the postural system is essentially automatic in that there is no conscious thought about how to achieve a given position. However, one can decide at will what posture to assume. In that sense it is a voluntary motor act organized to a large extent on the brain stem level, but is also affected by areas in the frontal lobe located just in front of the motor cortex.

## ROLES OF DIFFERENT PARTS OF THE NERVOUS SYSTEM IN THE CONTROL OF MOVEMENT

The different basic motor patterns are present in different forms in most vertebrates and invertebrates. In the former, the underlying neural networks are located either in the brain stem or in the spinal cord, and in the latter, in the chain of ganglia. In vertebrates,

from fish to mammals the basic organization of the nervous system is similar with regard to the spinal cord, brain stem (medulla oblongata and mesencephalon), and diencephalon. Each species and larger group of vertebrates may have specializations related to particular types of functions, and complexity increases during evolution. The cerebral cortex, with its distinct lamination, is present in mammals and most highly developed in primates, including humans (Fig. 28.5).

### Basic Motor Programs Are Located at the Brainstem–Spinal Cord Level

The brainstem–spinal cord is, to a large extent, responsible for the coordination of different basic motor patterns. The spinal cord contains the motor programs (CPGs) for protective reflexes and locomotion, whereas those for swallowing, chewing, breathing, and fast saccadic eye movements are located in the brain stem (mesencephalon and medulla oblongata). In most cases, however, both the brain stem and the spinal cord are involved to some degree. In mammals as well as lower vertebrates, the brain stem–spinal cord, isolated from the forebrain (di- and telencephalon), is able to produce breathing movements and swallowing, as well as walking and standing. These brain stem–spinal cord animals (referred to as decerebrate models) can thus be made to walk, trot, and

gallop with respiration adapted to the intensity of the movements and to swallow when food is put in their mouths. However, they perform these maneuvers in a stereotyped fashion, such as a robot or a reflex machine. The movements are thus not goal directed nor adapted to the surrounding environment, but nevertheless are coordinated in an appropriate way.

### Diencephalon and Subcortical Areas of Telencephalon Are Involved in Goal-Directed Behavior—Hypothalamus and Basal Ganglia

Mammals that are devoid of the cerebral cortex but have the remaining parts of the nervous system intact have been used to investigate the importance of these areas. Such animals display a more advanced behavioral repertoire when compared to the brain stem animals described earlier. At first glance, these decorticate animals look surprisingly normal. They move around spontaneously in a big room and can avoid obstacles to some extent. They eat and drink spontaneously and can learn where to obtain food and search for food when supposedly hungry. They may also display emotions such as rage and attack other animals; however, they appear unable to interact in a normal way with other individuals of the same species. Even without the cerebral cortex, a surprisingly large part of the normal motor repertoire can be performed,

**FIGURE 28.5** Location of different networks (CPGs) that coordinate different motor patterns in vertebrates. The spinal cord contains CPGs for locomotion and protective reflexes, whereas the brain stem contains CPGs for breathing, chewing, swallowing, and saccadic eye movements. The hypothalamus in the forebrain contains centers that regulate eating and drinking. These areas can coordinate the sequence of activation of different CPGs. For instance, if the fluid intake area is activated, the animal starts looking around for water, walks toward the water, positions itself to be able to drink, and finally starts drinking. The animal will continue to drink as long as the stimulation of the hypothalamic area is sustained. This is an example of recruitment of different CPGs in a behaviorally relevant order. The cerebral cortex is important, particularly for fine motor coordination involving hands and fingers and for speech.

including some aspects of goal-directed behavior. Thus the cerebral cortex is not required to achieve this level of complex motor behavior (however, see later discussion).

The diencephalon and subcortical areas of the telencephalon of the forebrain contain two major structures that are important in this context: the hypothalamus and the basal ganglia. The hypothalamus is composed of a number of nuclei that control different autonomic functions, including temperature regulation and intake of fluid and food. The latter nuclei become activated when the osmolality is increased (fluid is needed) or the glucose levels become low (food is required). Stimulation of the paraventricular nucleus involved in the control of fluid intake results in a sequence of motor acts involving a number of different motor programs. Continuous activation of this nucleus by electrical stimulation or local ejection of a hyper-osmotic physiological solution leads to an alerting reaction. The animal first starts looking for water (perhaps experiencing a feeling of thirst). It then starts walking toward the water, positions itself at the water basin, bends forwards, and starts drinking. The animal will continue drinking as long as the nucleus is stimulated. These hypothalamic structures thus are able to recruit a sequence of motor acts that appear in a logical order. Other parts of this region can elicit rage and attack behavior, as was first described by the Nobel laureate Walter Hess.

Basal ganglia constitute a second major structure. They are present in all vertebrates and are of critical importance for the normal initiation of motor behavior. They are subdivided into an input region (the dorsal and ventral striatum) activated by the cerebral cortex, thalamus, and the brain stem and an output region (the pallidum). The output neurons are inhibitory and have a very high level of activity at rest. They inhibit a number of different motor centers in the diencephalon and also influence the motor areas of the cerebral cortex via the thalamus. The input stage of the striatum determines the level of activity in the different pallidal output neurons. When a motor pattern, such as a saccadic eye movement, is going to be initiated, the pallidal output neurons that are involved in eye motor control become inhibited by the striatum. This means that the tonic inhibition produced by these neurons at rest is removed, and the saccadic motor centers in mesencephalon (superior colliculus) are relieved from tonic inhibition and become free to operate and induce an eye saccade to a new visual target.

In contrast to the tonically active output neurons of the basal ganglia (pallidum), the striatal neurons are silent at rest and have membrane properties that make

it difficult to activate them from cortex or thalamus unless the dopamine system is active. The level of activity in the striatum is strongly modulated by dopaminergic neurons in the substantia nigra and associated nuclei. If the level of dopamine activity is reduced, as in Parkinson's disease, it becomes very difficult to activate the striatal neurons and thereby to initiate and carry out most types of movements. This is a severe handicap characterized by paucity of movement (hypokinesia). The converse condition with enhanced levels of dopamine in the basal ganglia (which can occur as a side effect of medication) results instead in a richness of movements, and even in unintended movements (hyperkinesias). These movements may be well coordinated, but are without a purpose, and occur without the conscious involvement of the patient. Dopamine neurons are thus of critical importance for the operation of the striatum and they regulate the responsiveness of the striatal circuitry to input from the cerebral cortex and thalamus. The striatum in itself clearly has a key role for the operation of the entire motor system.

### The Cerebral Cortex and Descending Motor Control

In the frontal lobe there are several major regions that are involved directly in the execution of different complex motor tasks, such as the skilled movements used to control hands and fingers when writing, drawing, or playing an instrument. Another skilled type of motor coordination is that underlying speech, which is served by Broca's area. These different regions are organized in a somatotopic fashion. In the largest area, referred to as the primary motor cortex or M1 in the precentral gyrus, the legs and feet are represented most medially and the trunk, arm, neck, and head are represented progressively more laterally. Areas taken up by the hands and the oral cavity are very large in humans, and are much larger than that for the trunk. This is explained by the fact that speech and hand motor control require a greater precision and thus a larger cortical processing area than the trunk. The latter is important for postural control but is less involved in the type of skilled movement controlled by the motor cortex (Fig. 28.6).

The large pyramidal cells in the motor cortex send their axons to the contralateral side of the spinal cord and are able to activate their target motoneurons directly, but a number of interneurons in the brain stem or spinal cord also are influenced. These long projection neurons are called corticospinal neurons. Corticospinal neurons of the arm region in M1 thus project to arm motoneurons in the spinal cord, as well

## Gyrus precentralis (M)

**FIGURE 28.6** Organization of the primary motor cortex (M1). The different parts of the body are represented in a somatotopic fashion in M1, with the legs represented most medially, arms and hand more laterally, and the oral cavity and face even more so. Note that the two areas that are represented with disproportionately large regions are the hand with fingers and the oral cavity. They are represented in this way due to the fine control required in speech and fine manipulation of objects with the fingers. Adapted from Penfield and Rasmussen (1950).

as interneurons involved in the control of arm, hand, and fingers. In addition to M1, other areas in the frontal lobe, such as the supplementary motor area and prefrontal areas, are involved in other aspects of motor coordination (Fig. 28.7).

The cortical control of movement is executed in part by the direct corticospinal neurons but also by cortical fibers that project to brain stem nuclei, which in turn contain neurons that project to spinal motor centers such as the fast rubrospinal, vestibulospinal, and reticulospinal pathways. The brain stem contains a large number of descending pathways that can initiate movements and correct motor performance, or provide more subtle modulation of the spinal circuitry. The former act rapidly in the millisecond time frame that is required in motor control. Examples of the latter are

the slow-conducting and slow-acting noradrenergic and serotonergic pathways. These pathways set the responsiveness of different types of neurons, synapses, and spinal circuits. In addition, there are direct projections from the cerebral cortex to the input area of the basal ganglia, the striatum. The cortical control of motor coordination thus is achieved through both direct action on spinal and brain stem motor centers but also to a significant degree by parallel action on a variety of brain stem nuclei. The execution of movements that are initiated from the cortex is, to a large degree, a collaborative effort of many parts of the nervous system. The reticulospinal and vestibulospinal pathways mediate the control of posture, and the former take part in the initiation of locomotion, via the CPG located in the spinal cord (Fig. 28.8).

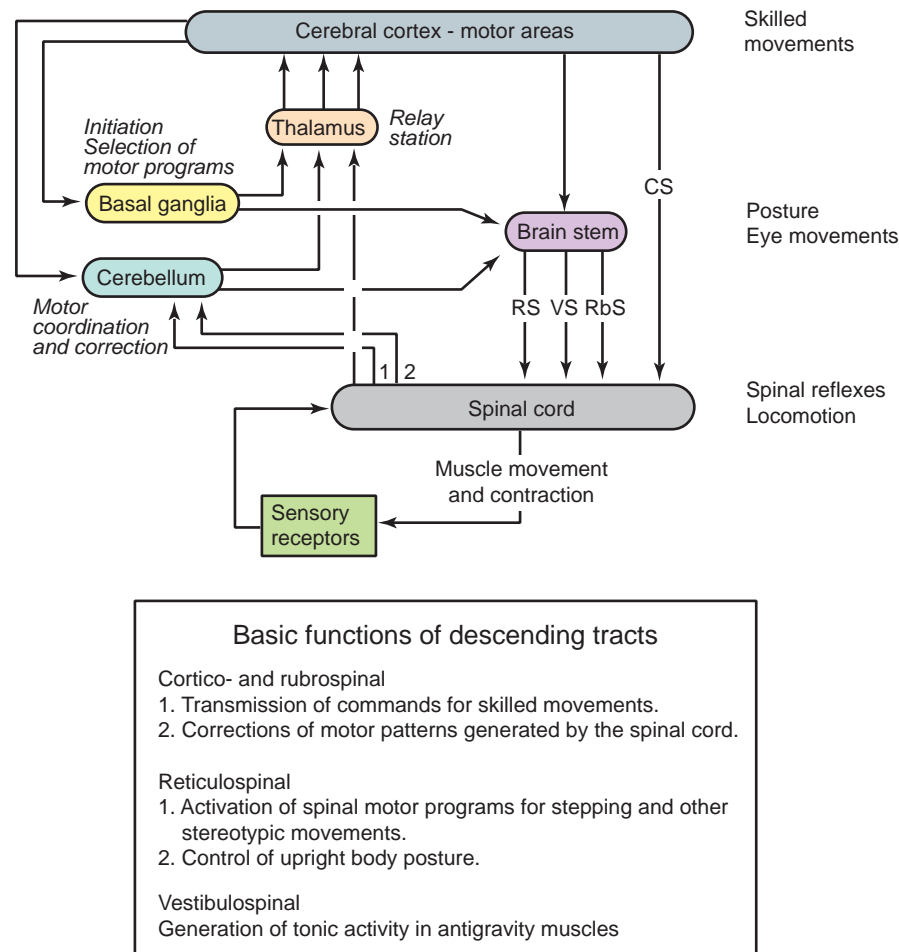

**FIGURE 28.7** Descending pathways projecting from the brain that mediate motor actions to the spinal cord. From the cerebral cortex, including M1, a number of neurons project directly to the spinal cord to both motoneurons and interneurons. In addition, they also project to different motor centers in the brain stem, which in turn send direct projections to the spinal cord. One of these centers is the red (rubrospinal) nucleus, which influences the spinal cord via the rubrospinal pathway. Corticospinal and rubrospinal pathways act on the contralateral side of the spinal cord and have somewhat overlapping functions. They are sometimes referred to as the lateral system, as most of the fibers descend in the lateral funiculus of the spinal cord. Vestibulospinal and reticulospinal pathways are important both for regulating posture and for correcting perturbations, and mediate commands initiating locomotion. The different reticulo- and vestibulospinal pathways are sometimes lumped together as the medial system, as most of the axons project in the medial funiculus of the spinal cord.

Judging from experiments on mammals and primates, and patients that have suffered focal lesions of the frontal lobe, the cortical control of movement is of particular importance for dexterous and flexible motor coordination, such as the fine manipulatory skills of fingers and hands and also for speech. It is very difficult for a casual observer to see the difference between a normal monkey moving around in a natural habitat and a monkey that is lacking the corticospinal direct projections to the spinal cord but has all other cortical circuits intact. They are able to move around, climb, and locomote as normal monkeys. It is only when special tests are performed that one can see that delicate independent movements of the individual fingers

are incapacitated. This is a type of motor coordination that is needed in monkeys and other primates for skilled manipulations of the environment, such as picking fine food objects from small holes.

The most flexible types of motor coordination, such as the skilled movements of the fingers and hands or in speech, involve the frontal lobes. These types of movements often are referred to as voluntary because they are performed at will. This terminology is commonly used, although inappropriate in that more basic types of motor coordination, such as the ones used when walking, chewing, or positioning ourselves in a relaxed posture, are also controlled by will, although motor coordination is handled to a larger degree by

**FIGURE 28.8** Summarizing scheme of the interaction between different motor centers. The different major compartments of the motor system and their main pathways for interaction are indicated. The basic functions of the different compartments and descending tracks are summarized on and below the scheme. CS, corticospinal; RbS, rubrospinal; VS, vestibulospinal; RS, reticulospinal.

motor programs located at the brain stem–spinal cord level. Thus it appears important not to draw a clear-cut dividing line between the different types of movements, at least with respect to the voluntary aspect of their control.

It is also useful to realize that, to some degree, simple reflexes can also be modulated by will. For instance, the simple skin avoidance reflex (flexion reflex) that causes rapid withdrawal of a finger after touching something painful is subject to such control. Knowledge that the object will be sufficiently hot to be somewhat painful enables this modulation if it is important. If, however, the object is touched without knowing that it is hot, the hand will be withdrawn with the shortest possible latency. Thus, in the entire motor apparatus from the simplest reflex to a skilled movement, there is the possibility for modulation and flexibility. The human nervous system allows a remark-

able combination of movements, adapted to different situations. This flexibility is perhaps greater for primates and humans than for any other species. However, other species may perform much better in particular types of specialized movements. A cheetah runs faster, a hawk catches prey at higher speeds, and a fly walks upside down on the ceiling.

### Visuomotor Coordination—Reaction Time

Visuomotor coordination is very demanding and requires complex processing. When visualizing an approaching object like a ball, a rapid calculation provides information to bring the arms to the appropriate spot to grasp the ball at just the right time. This is an amazing achievement considering the necessity of predicting where and when the ball will arrive, the details about joint angles from hand to head that need to be

considered to elicit the appropriate commands to the different muscles involved, and the time constraints. There are extensive projections to the frontal lobes from the areas in the parietal lobe processing visual information about movement.

It is clear that in order to arrive at an accurate and precise motor command, a large amount of information of different types needs to be processed about the dynamic and static conditions of the different parts of the body in relation to each other and the surrounding world. The processing time under different conditions has been investigated experimentally by having a subject respond to a signal and perform a movement, such as pressing a button when a light goes on. The delay is around 0.1 to 0.2s and is called the reaction time. It represents a minimal delay for a given test situation that cannot be shortened by training (Fig. 28.9).

The more complex the situation is, the longer the reaction time. If a choice is involved, such as responding by pressing different buttons to light stimuli of different colors, the time delays become much longer than in the simple reaction time task. The choice reaction task time increases in proportion to the level of complexity and the number of choices (Fig. 28.9). When young children are tested, their reaction times are much longer than in adults. The simple reaction time for a 6-year-old can be three times that of a 14-year-old, and the difference with choice reaction times may be even larger. This condition may have severe consequences in everyday life. In an unexpected traffic situation, a 6-year-old requires at least three times longer time to interpret what he or she sees, such as an approaching car. Whereas an adult may have sufficient time to respond, a child may have no chance.

**FIGURE 28.9** Reaction time tasks of different complexity and in different age groups. The choice reaction time is plotted versus the number of choices the subject is exposed to for six different age groups. A simple experimental situation with two choices takes an adult 0.3s to initiate, but a 6-year-old needs around 1.0s. A 10-year-old falls in between at around 0.7s. An increase in the number of choices causes a marked increase in reaction time. From a practical standpoint, this provides important information when one considers the possibility for a child to cope with different demanding situations, such as moving around in a modern city. Data replotted from Conolly.

This is the basis for recommending that children below 11 years of age not bicycle in open traffic. It is noteworthy that this is a gradual maturation process and that training cannot shorten the reaction time. During aging the choice reaction time tends to increase again, a factor that can be important when driving a car.

## Cerebellum

The cerebellum is a structure that is also involved in the coordination of movement. Although the cerebellum is smaller than the cerebral cortex in volume, it contains as many nerve cells as the latter. It is characterized by a very stereotyped neuronal organization with two types of inputs from mossy and from climbing fibers. These inputs not only carry information from the spinal cord about ongoing movements in all different parts of the body, but also information from the different motor centers about planned movements even before a movement has been executed. The cerebellum also interacts with practically all parts of the cerebral cortex. This means that it is updated continuously about what goes on in all parts of the body with regard to movement and also about the movements that are planned in the immediate future. Lesions of the cerebellum lead initially to great problems with postural stability and with the accuracy of different types of movements. It is noteworthy that movements in general can be carried out, but their quality is reduced drastically. Therefore, the cerebellum originally was thought to be involved exclusively in the coordination of movement. In addition to motor control, evidence has accumulated that the lateral parts of cerebellum may also be involved in different cognitive tasks.

The cerebellum is subdivided into a great number of different regions that process different kinds of information. These different regions respond via their output neurons, called Purkinje cells. The cerebellar cortex contains only inhibitory interneurons, and the two input systems, climbing fibers and mossy fibers (via granule cells), provide the excitatory components. All Purkinje cells are inhibitory and project to the cerebellar nuclei, which in turn are excitatory and project to different motor centers in the brain stem and to the cortex via the thalamus.

Each granule cell receives very specific input from only a few mossy fibers, which are able to make them fire. The granule cell axons form parallel fibers in the cerebellar cortex, and thousands of parallel fibers impinge on each Purkinje cell that has a very extensive dendritic tree. It is believed that only a small portion of these parallel synapses are functional in any given moment, but that they are available to become recruited

in learning situations. In contrast, there is only one climbing fiber for each Purkinje cell. The climbing fibers can serve as "error detectors," at least under some conditions. Through the interaction of climbing fibers with the parallel input, the synaptic efficacy of the input of the latter synapse onto the Purkinje cell can be regulated (depressed). This change in efficacy can last over many hours and possibly much longer and is therefore referred to as long-term depression (LTD). It is generally thought that this LTD can contribute to motor learning (see later). With regard to basic movements such as posture, walking, and the much-studied eye-blink reflex, the cerebellum clearly is involved through each movement phase. It is likely that the fine-tuning and modification of movements that are required in different behavioral contexts involve the cerebellum. With regard to the eye-blink reflex, motor learning has been demonstrated in terms of associating an unconditioned stimulus with a conditioned one. It requires that the cerebellar cortex is intact, which strongly suggests that the cerebellar cortex contributes importantly to this type of motor learning. The cerebellum is clearly of importance for the long-term adaptation of different patterns of basic motor coordination.

There is still, however, much to learn about the actual processing that goes on in the cerebellum, a structure that regulates the quality of motor performance and appears to be involved in one form of motor learning. A variety of complex motor tasks, including speech and handwriting, can still be performed, but with less accuracy. Thus, the motor programs for these learned tasks cannot be stored exclusively in the cerebellum. When new types of movements are learned, such as riding a bicycle, playing an instrument, or typing at a keyboard, the new stored programs for sequences of motor acts must also involve other structures in the brain, most likely the basal ganglia and the cerebral cortex.

## Motor Learning

All vertebrate and invertebrate species with a nervous system have a motor infrastructure that is determined evolutionarily. In the case of primates including humans, there are preformed circuits (e.g., CPGs) that allow performance of a basic movement repertoire (e.g., locomotion, posture, breathing, eye movements), as well as basic circuits that underlie reaching, hand and finger movements, and sound production as in speech. This constitutes the motor infrastructure that is available to a given individual, after maturation of the nervous system has occurred.

The motor system is in addition characterized by its ability to learn, in what is referred to as motor or procedural learning. The cortex and basal ganglia play an important role for learning of new motor sequences and skills, and cerebellum is indispensable for the quality of the different motor patterns and the ability to associate two stimuli as during conditioned reflexes. For instance, one can learn how to play an instrument like the flute. The particular finger settings that produce a given tone can be retained in memory, along with the sequence of tones that produce a certain melody. Thus particular muscle combinations that produce a sequence of well-timed motor patterns are stored. Similarly, when learning to pronounce different sounds (phonemes) and combine them in words, muscle activation patterns are stored. A simpler case occurs when learning to recombine basic movement patterns to be able to maintain equilibrium while bicycling. There are a large number of examples involving different types of motor learning and parts of the body.

It is characteristic of a given learned motor program that one can “call” upon it to perform a given motor act over and over again. Despite this, there is generally little awareness of the way in which the movement actually is performed in terms of the muscles involved and their timing. Information thus has been stored in the nervous system with regard to which parts of the infrastructure of the motor system should be used to produce a given learned motor pattern, as well as the exact timing between the different components. However, the details of the complex storage process are not yet fully understood.

## CONCLUSION

---

After this overview of the motor control system, it should be apparent that biological evolution has succeeded in refining remarkable sensorimotor machinery capable of executing the motor tasks required for

the full behavior of a given species. The degree of difficulty involved is apparent when watching the clumsiness and lack of flexibility in robots, characteristic of even the most advanced models that have been developed. Details of the different neural subsystems involved in motor control are dealt with in the following chapters.

# The Spinal and Peripheral Motor System

Most coordinated movements involve the use of several muscles, each with a precisely orchestrated timing and pattern of activation and relaxation. Contraction of an individual muscle is controlled by a pool of motor neurons that innervate that muscle. Patterned contraction of several muscles requires coordination between pools of motor neurons. For many movements, interneurons in the spinal cord provide the means for coordinating activity of different motor neuron pools. A key feature of spinal interneurons is their convergent and divergent connections that allow them to integrate signals from different sources. Interneurons that receive inputs from descending motor systems and sensory afferents, for example, can update a voluntary command for limb movement to incorporate feedback from the moving limb. Spinal interneurons also form connections with other spinal interneurons to create networks that generate rhythmic patterns of excitatory and inhibitory activity. These networks play a key role for organizing rhythmic, repetitive movements such as scratching or locomotion. In this chapter, we will use locomotion as an example of a motor behavior to illustrate how the neural elements of the spinal cord and peripheral neuromuscular system operate together to carry out a movement. As details of the motor neurons, spinal interneurons, muscles, and sensory afferents are presented, the primary focus will be on mammals, but variations that occur in other vertebrates and in invertebrates are highlighted in Box 29.1.

## LOCOMOTION IS A CYCLE

Locomotion is the act of moving from place to place. Walking, swimming, and flying are modes of locomotion. All modes of locomotion consist of a cycle of patterned and rhythmic activity of different muscle groups. Locomotion can be described by the phase relationships between limbs and between muscle groups during the cycle. Nonlimbed vertebrates such as lamprey swim by alternately contracting and relaxing trunk muscles on the two sides of the body—the sides are in opposite phases of the cycle. Along the length of the lamprey's body, there is a slight phase lag between segments, creating the propulsive wave that moves it forward. In contrast, birds activate their wings synchronously in flight—the limbs are in phase, with no lag.

Stepping, the major form of mammalian locomotion, is a cycle with two phases: stance (the extension phase) and swing (the flexion phase). In people, the stance phase begins when the heel strikes the ground and the leg begins to bear weight. As stance progresses, the weight is gradually shifted forward, rolling from the heel to the ball of the foot. The swing phase begins when the toe leaves the ground and the leg moves forward. To accomplish this motor sequence within one leg, muscles acting across the hip, knee, or ankle are activated in a characteristic pattern (Fig. 29.1). In general, muscles that flex the joint are more active

## BOX 29.1

## SPECIES DIVERSITY IN NEUROMUSCULAR SYSTEMS

Not all animals control muscle contraction in the same way as mammals. Differences are found in the proteins and structure of the muscle fiber, the number of neuromuscular junctions on each muscle fiber, the neurotransmitters used at the neuromuscular junction, and the number of motor neurons contacting each muscle fiber. Major differences are found in invertebrates, which often have evolved adaptations that suit their movement patterns or constraints imposed by their environments.

Some invertebrates require muscles that generate great forces or provide mechanical stiffness. One solution used by mussels, the nematode *C. elegans*, and the fruit fly *Drosophila* is the incorporation of molecules of paramyosin into thick filaments, so that additional cross-bridges can be formed. Mussel retractor muscles also have a specialized catch property, in which cross-bridges are tightly bound with low energy expenditure until the catch state is released by neurotransmitter action that leads to phosphorylation of twitchin, a titin-like molecule. Very slow movements can be achieved by long sarcomeres, since  $\text{Ca}^{2+}$  diffusion throughout the sarcomere takes longer. In mammalian muscle fibers, sarcomeres are generally 2–3 microns long, although longer sarcomeres occasionally are found in muscles that stiffen but do not twitch, such as the tensor tympani muscle of the cat eardrum. In contrast, claw muscles of crabs may have sarcomeres from 6–18 microns, and one marine worm was found to have sarcomere lengths of 30 microns.

Most mammalian muscles usually contain a mixture of muscle fiber types, but some animals have distinct muscles for fast and slow movements. Trout, for example, use red muscles composed of slow twitch fibers for sustained swimming and white, fast twitch muscles for leaping and rapid bursts of speed.

Mammals and birds use acetylcholine as the transmitter at the neuromuscular junction. So does *C. elegans*, but many other invertebrates use glutamate, including arthropods such as *Drosophila*, locust, and crayfish. Corelease of glutamate and peptides occurs at some neuromuscular junctions, such as the peptide FMRF-amide in the sea snail *Aplysia*. Crustacean muscles have separate excitatory and inhibitory neuromuscular junctions that use glutamate and GABA.

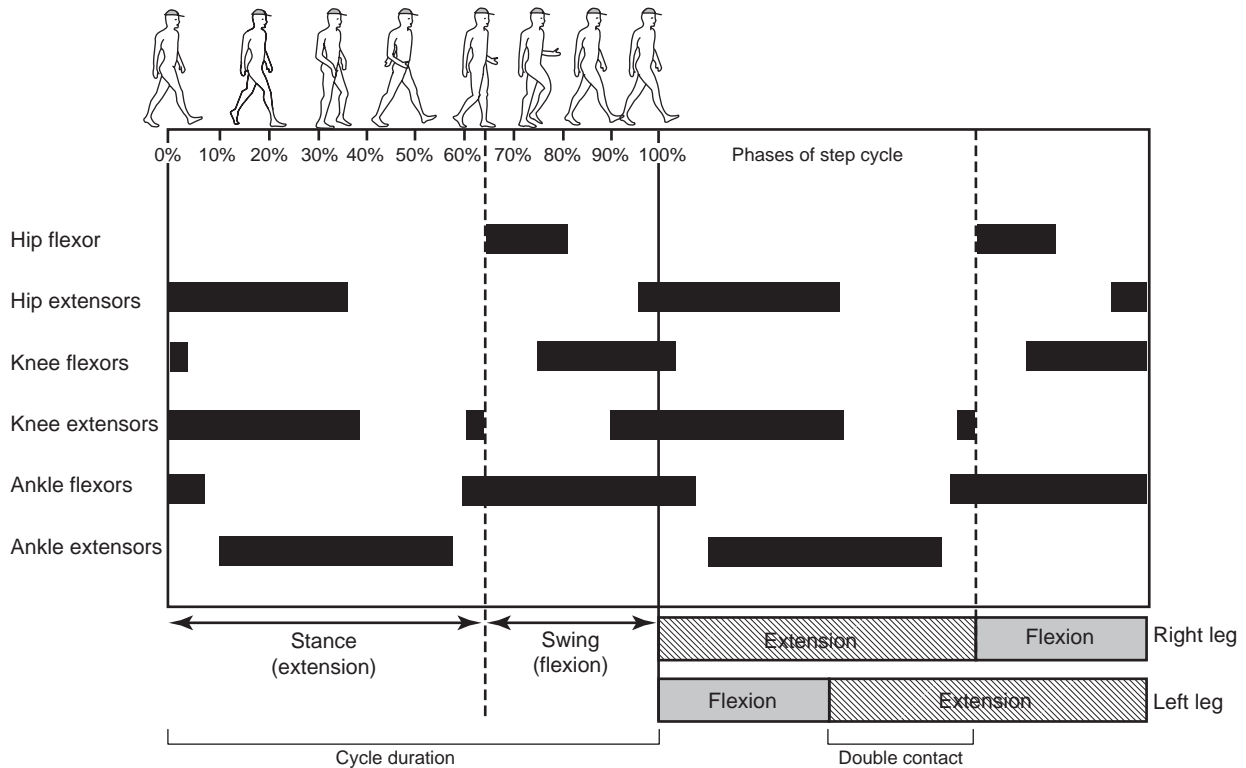

In mammals, most muscle fibers are innervated by a single motor neuron, with a few exceptions, such as laryngeal muscles and spindles. Innervation by more than one motor neuron is seen in some avian muscles, and many invertebrate muscles. The motor neurons may merely have an additive function, as in *Drosophila*, where recruitment of motor neurons produces graded contractions of the muscle. In other animals, the different motor neurons may play distinct roles. The locust jumping muscle has a dual arrangement, with one motor neuron that produces a rapid and powerful excitation and another that produces graded excitation and contraction.

Lastly, the central control of motor neurons differs. In mammals, a motor neuron action potential leads inevitably to a muscle fiber action potential. In crayfish, presynaptic inhibition of motor terminals allows modulation at a more distant site. Structural specializations, such as electrical synapses onto motor neurons and gap junctions between motor neurons, often occur in invertebrates, but generally are found only during development in mammals. The distributed structure of invertebrate systems and rich palette of ion channels expressed by motor neurons is favorable to the formation of motor pattern generating circuits.

Mary Kay Floeter

during the swing phase and extensor muscles during the stance phase. However, within each phase, the individual muscles have a more elaborate and finely graded timing and pattern of activation. Stepping can also be performed with different gaits. Gaits can be characterized by the cycle rate, the relative proportion of the cycle spent in swing and stance phases, and the phase relationships between limbs. At slow or moderate walking speeds (i.e., slow cycle rates), the extensor

phase is longer than flexion and the extension phases of opposite legs overlap. In a walking gait both feet are in simultaneous contact with the ground for some period during the cycle. As the speed of stepping increases and the cycle is shorter, the duration of the extension phase shortens, with briefer periods of double foot contact. At high speeds where there is no overlap of extension phases between the legs, the gait switches recognizably from walking to running.

**FIGURE 29.1** Schematic diagram of two step cycles in human locomotion. Drawings at the top illustrate the position of the limbs during one cycle. Dark horizontal bars below the drawings show the timing of activity in flexor and extensor muscles of the right leg. The division of each step cycle into stance (extension) and swing (flexion) phases is indicated at the bottom of the figure. During walking, the stance phases of the two legs overlap, with both feet in contact with the ground.

## Central Pattern Generating Circuits

Although we are able to exert voluntary control over locomotion, the basic patterns of movement for locomotion can be generated by the spinal cord itself, without descending or sensory inputs. The first demonstration came from Graham Brown (1911), who observed that cats in which the spinal cord and dorsal roots were cut were still able to walk on a treadmill as long as their weight was supported. Because there was no sensory feedback or descending input he suggested that the rhythmic activity in the hindlimb muscles must be generated by a motor program within the spinal cord. The motor program, also known as a central pattern generator (CPG), needed to explain three important features of locomotion: (1) its rhythmic and cyclical occurrence, (2) coordinated alternation between flexor and extensor activity within the same limb, and (3) alternation between opposite limbs. Brown proposed that the CPG consisted of two mutually inhibitory “half-centers,” both under tonic excitation: one half-center drove muscles that flexed the legs

and the other drove muscles that extended the legs. The mutual inhibition between the two half-centers would cause activity to oscillate between them, producing alternating limb flexion and extension.

CPGs are now thought to consist of networks of neurons that are synaptically or electrically connected, with cellular properties that generate rhythmic firing. CPGs are found in many areas of the central nervous system and are responsible for different types of patterned rhythmic activities such as breathing, swallowing, chewing, and walking. The identification and characterization of the neurons that comprise the locomotor CPG in the spinal cord is an active area of research that will be discussed later in this chapter.

## Sensory Contributions to Movement

During a movement, the sensory afferents from muscles, joints, and skin will each be activated in a distinct way, reflecting how that movement displaces joints, produces pressure on regions of skin, and

stretches individual muscles. For rhythmic movements such as walking, these recurring “multisensory” feedback signals often reinforce activity of CPG circuits. However, when a perturbation occurs during the movement, the resulting sensory signal may evoke a reflex motor response that alters the movement. Many of these reflex responses adapt the movement in an appropriate way to proceed under the changed environmental conditions. Most sensory afferents produce these reflex effects through interneuronal circuits. (The stretch reflex is an exception.) The excitability of many of these interneuronal circuits usually is modulated during movement, allowing reflexes to be suppressed or enhanced at different phases. CPGs are one source of this phase modulation. Many reflexes can also be elicited when the organism is not moving, and in these situations the reflex tends to exhibit a more stereotyped motor pattern.

## CONNECTING THE SPINAL CORD TO THE PERIPHERY

Ultimately movement is carried out by muscles, and the motor commands from the central nervous system must be transmitted to motor neurons that innervate the muscles. The organization of motor neurons into pools, and the manner in which motor neuron properties are matched to contractile and metabolic properties of the muscle fibers simplify many of the variables needed to be controlled to produce smooth movements with precise amounts of force. Feedback from sensory receptors of the muscle play a key role in monitoring the force and stretch of the muscle. This section will cover some of the basic properties of motor neurons, muscle, and muscle receptors.

### Motor Neurons

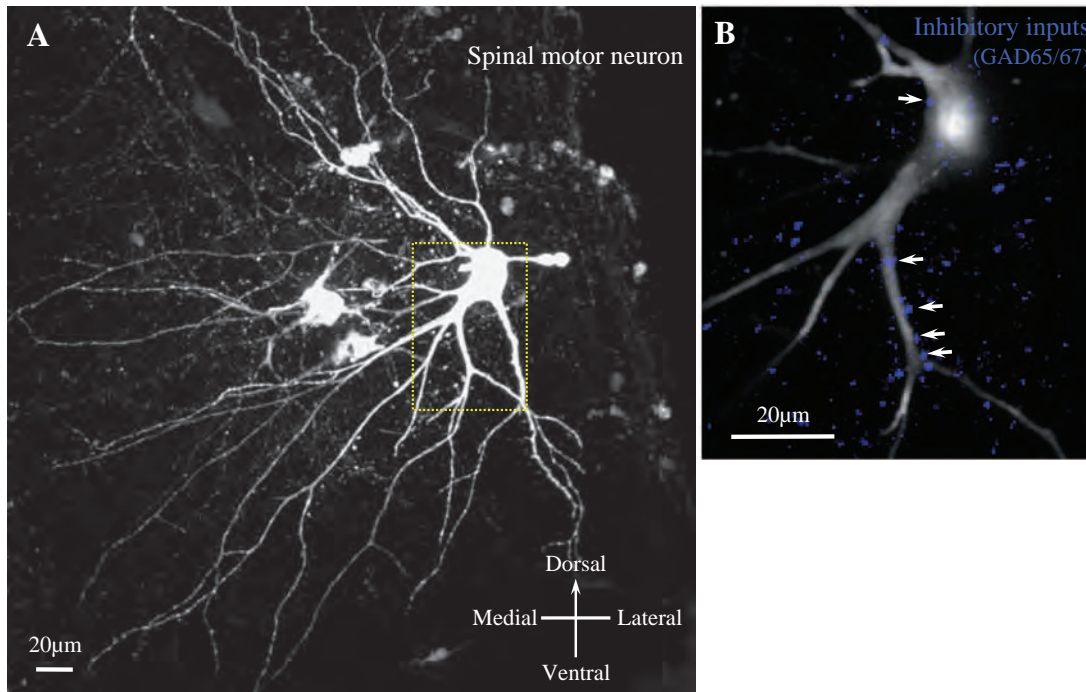

Motor neurons are located in the ventral horn of the spinal cord. The pool of motor neurons that innervates an individual muscle forms an elongated column that typically extends over two or three spinal cord segments. Intermingled among the large  $\alpha$ -motor neurons that innervate skeletal muscle fibers are smaller  $\gamma$ -motor neurons, which innervate muscle spindles, as well as  $\beta$ -motor neurons, which dually innervate skeletal muscle and spindles. The  $\alpha$ -motor neurons are the largest neurons in the spinal cord, with myelinated axons that exit the spinal cord through the ventral roots and travel in peripheral nerves to innervate muscles. Their axons also give off small branches within the spinal cord, called recurrent collaterals, that

synapse on inhibitory interneurons, called Renshaw cells, and motor neurons. The extensive dendritic tree of motor neurons extends into the dorsal and ventral horns, receiving thousands of synaptic inputs from excitatory and inhibitory neurons (Fig. 29.2). At the neuromuscular junction, the synapse between the motor axon and the muscle fiber, acetylcholine is the transmitter used by mammals, but other transmitters, such as the peptide CGRP or glutamate (Mentis *et al.*, 2005; Nishimaru *et al.*, 2005), coexist in many motor neurons, and may play a particular role during development and at the central synapses formed by recurrent collaterals.

### Muscle Contraction

Movement is achieved by the contraction of muscles that are attached to the skeleton or soft tissues, such as muscles producing facial expressions. A skeletal muscle is made up of thousands of individual muscle fibers. Each muscle fiber is a multinucleated cell, a few centimeters long, that contains the contractile proteins, actin and myosin, arranged into thick and thin filaments in repeating units called sarcomeres (Fig. 29.3). The myosin molecule head region contains an ATP-ase enzymatic activity that is sensitive to levels of intracellular calcium. Myosin heads are loosely bound to actin at rest, but when intracellular calcium rises, the cross-bridge strengthens, causing myosin to break down ATP. When this occurs the cross-bridge loosens, and the myosin head swivels along the actin filament to another binding site. The repetition of this swiveling movement in the presence of elevated intracellular calcium and ATP causes thick and thin filaments to slide along each other and shorten the sarcomere length. Shortening of sarcomeres shortens the muscle, or if the muscle is carrying a heavy load, the muscle may only stiffen in an isometric contraction.

The process of muscle contraction begins with an action potential in the motor axon that causes release of acetylcholine at the neuromuscular junction. In mammals, normally every spike in the motor axon produces an action potential in the muscle fiber because an excess amount of acetylcholine is released (Box 29.2). In adult mammals, each skeletal muscle fiber has one neuromuscular junction innervated by one motor neuron. Muscle fiber action potentials lead to the activation of voltage-gated calcium channels in the membrane that interact with calcium release proteins in the sarcoplasmic reticulum, an organelle in the muscle fiber that stores and releases calcium near the sarcomeres. This interaction couples excitation to muscle contraction. Other proteins in the sarcoplasmic reticulum reuptake calcium, leading to relaxation.

**FIGURE 29.2** Motor neuron from a neonatal mouse spinal cord that has been filled with biocytin through an intracellular electrode and visualized by immunocytochemistry. (A) The extensive dendritic arbor is directed into the dorsal, medial, and ventral grey matter of the spinal cord, where dendrites receive thousands of synapses from interneurons, sensory afferents, and descending pathways. (B) Double staining for a marker of GABA-ergic inhibitory terminals (GAD65/.67) shows some of the inhibitory synapses along the proximal dendrites and cell body.

### Three Basic Muscle Fiber Types

Muscle fibers are classified into types according to their contractile and metabolic properties. Contractile properties refer to the muscle fiber's speed of contraction and relaxation, and the specific force it can produce. Contractile properties are mainly determined by the isoform of myosin that is expressed by the muscle fiber, particularly the myosin heavy chain gene, although the genes for other proteins associated with the sarcomere and the sarcoplasmic reticulum are expressed in fiber-type specific patterns that match the properties of the myosin isoform. The contractile properties of a muscle fiber are classified as slow twitch or fast twitch. Metabolic properties refer to whether aerobic or anaerobic pathways are used to produce energy (ATP) from fuels. Muscle fibers with abundant mitochondria are able to use oxidative (aerobic) metabolism, which provides relative resistance to fatigue as long as there is a good blood supply. Muscle fibers with few mitochondria rely on stored fuel, such as glycogen, which can more easily be depleted and also produces lactic acid as a byproduct of glycolysis.

There are three basic muscle fibers types in adult skeletal muscle. Type I fibers have a slow twitch but have a good capacity for oxidative metabolism. Type IIA fibers have a fast twitch and can use both aerobic and anaerobic metabolism, giving them an intermediate resistance to fatigue. Type IIB fibers produce a fast twitch, but rely mainly on anaerobic glycolysis for their energy. Most muscles contain a mixture of all three fiber types, in proportions that reflect the typical usage of the muscle.

### Motor Unit Types

A "motor unit" is defined as one motor neuron and all the muscle fibers it innervates. In mammals, each muscle fiber is innervated by only one motor neuron, but one motor neuron innervates many muscle fibers as its axon branches in the muscle. However, all muscle fibers of one motor unit are of the same fiber type. Motor units cluster into three basic types based on the three physiological properties of twitch speed, the amount of force produced, and fatigability (Fig. 29.4). Type S motor units are defined by the properties of

**FIGURE 29.3** Diagram of the structure of the muscle showing the relationship between the thick and thin filaments that form the sarcomere, the sarcoplasmic reticulum (SR), and the location of the ion channels of the motor axon, neuromuscular junction, and muscle membrane. With permission, modified from Cooper and Jan (1999).

slow twitch, small amounts of force, and high resistance to fatigue. Type FR motor units are defined by fast twitch, moderately large force, and relative resistance to fatigue. Type FF motor units have fast twitch, produce the highest forces, and fatigue quickly.

The physiological properties of the motor neurons and the muscle fibers they innervate are closely

matched. Type S motor neurons innervate Type I fibers. Type S motor neurons have small cell bodies and dendritic arbors, allowing them to be depolarized easily. Afterhyperpolarization following each motor neuron spike promotes a steady rate of firing that allows forces produced by successive twitches of the muscle fibers to summate (Fig. 29.4B). With their

## BOX 29.2

## MYASTHENIA AND MYASTHENIC DISORDERS

Normally every action potential of the motor axon releases more than enough transmitter than is needed to produce a muscle fiber action potential. This occurs because both the amount of transmitter released from the presynaptic motor axon terminal and the density of AChRs on the postsynaptic muscle fiber exceed that needed to produce an end plate potential (EPP) large enough to initiate a muscle fiber action potential. Genetic or acquired diseases that reduce the safety factor of neuromuscular transmission are called myasthenic disorders (Fig. 29.12). Myasthenic disorders cause weakness that fluctuates with use of the muscle. The most common is the acquired autoimmune disorder myasthenia gravis, caused by antibodies that bind to AChRs at the neuromuscular junction. The antibodies interfere with ACh binding and lead to internalization of AChRs and, ultimately, the loss of junctional folds. The reduced numbers of functioning AChRs produce a smaller EPP that fails intermittently to trigger a muscle fiber action potential. However, in myasthenia gravis the presynaptic terminal remains normal, such that a short burst of stimulation will produce facilitation of transmitter release, increasing the concentration of ACh in the cleft and transiently improving neurotransmission. Acetylcholinesterase inhibitors provide symptomatic improvement by blocking the breakdown of ACh, allowing a longer effect on residual receptors. Another autoimmune myasthenic disorder, Lambert–Eaton myasthenic syndrome, is caused by antibodies that bind to presynaptic voltage-gated calcium channels. Less ACh is released at the neuromuscular junction, producing small EPPs that fail to trigger action potentials.

Congenital myasthenic syndromes (CMS) are extremely rare, but provide important insights into the function of components of the neuromuscular junction. Postsynaptic CMS stem from a deficiency and/or altered kinetic properties of the AChR. More than 40 different mutations in subunits of the AChR have been described. Most mutations decrease subunit expression or prevent subunit assembly or glycosylation, leading to reduced numbers of functioning AChRs and thereby smaller EPPs. In fast channel CMS, mutations produce decreased binding affinity for ACh, leading to a smaller quantal response and miniature EPP amplitude, without reducing the numbers of AChRs. In contrast, the slow channel CMS stem from mutations that prolong the channel opening episodes. Slow channel mutations cause depolarization block due to temporal summation of the prolonged EPPs. In the long term, cationic overloading of the postsynaptic region leads to destruction of the junctional folds and loss of AChRs. Presynaptic CMS are less common. They are caused by mutations that lead to a paucity of synaptic vesicles or defects in ACh resynthesis or vesicular packaging. As a result, fewer vesicles are released or fewer ACh molecules are contained in each vesicle, and EPPs are smaller. Identifying CMS as involving pre- or postsynaptic components and understanding how these alterations affect neuromuscular transmission are necessary for developing rational therapies for these disorders.

*Mary Kay Floeter*

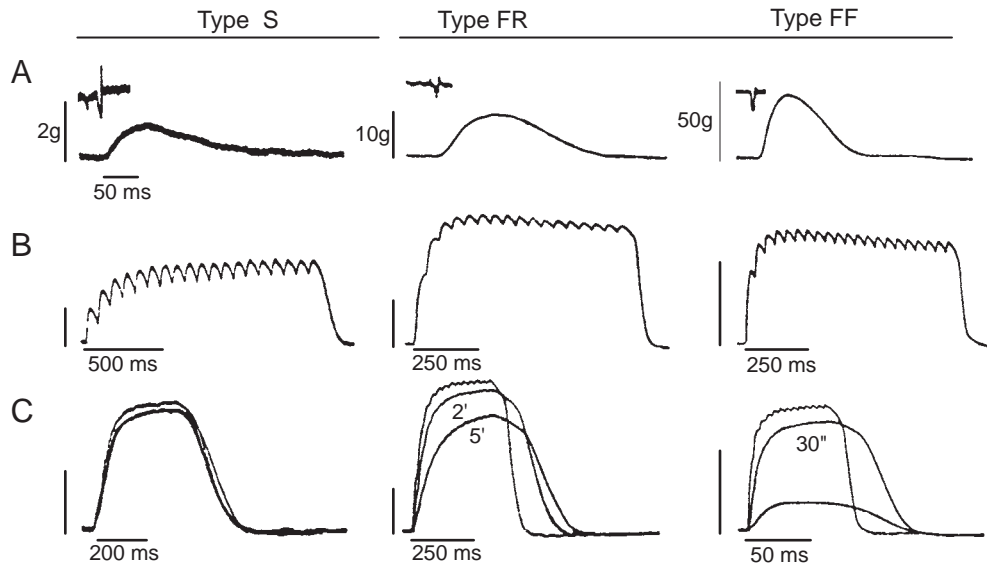

steady firing rates and resistance to fatigue, Type S motor units are optimal for the sustained firing needed for postural and tonic movements. Each Type S unit individually contributes only a small amount of force to a muscle's contraction, but typically Type S units make up a large proportion of the motor units innervating a muscle. In contrast, Type F motor neurons have large cell bodies and dendritic arbors, shorter afterhyperpolarizations and somewhat faster firing rates. Type FR motor neurons innervate Type IIA muscle fibers, and Type FF motor neurons innervate

Type IIB muscle fibers. Type FR motor units are optimal for fast, powerful movements. Type FF units are used mainly in movements that require brief bursts of muscle strength. Most muscles contain a mixture of motor unit types, intermingled in a mosaic pattern.

### The Size Principle and Orderly Recruitment

Most movements don't require a muscle to contract at its maximal strength, and only a fraction of the hundred or more motor neurons in the pool that

**FIGURE 29.4** The three motor unit types (S, FR, and FF) can be defined experimentally by measuring their contractile properties and fatigability. Panels A–C show recordings of muscle force, with insets in A showing recordings of motor neuron action potentials. Note different time and amplitude calibration scales for each of the motor units. (A) Single twitches produced by one action potential of the motor neuron. (B) Maximal force produced by repetitive stimulation of the motor neuron to produce an unfused tetanus. In addition to differences in maximal force, the “sag” property, a dropping off of tension during maintained stimulation, is seen in FR and FF units. (C) Fatigability is demonstrated by a drop in the tension produced by a single twitch after short periods of activation, as noted. Note that S units show little fatigue, whereas FF units fatigue within 30s. Reproduced with permission from Burke *et al.* (1973).

innervates that muscle will need to fire. For most movements, motor units are recruited in an orderly sequence, first described by Henneman (1957), as based on the “size” of the motor neuron. According to the size principle, motor units that produce the smallest amounts of force are the first to begin firing, and motor units that produce larger forces will be progressively recruited as the muscle makes progressively stronger contractions. Many of the anatomical and physiological properties of the motor unit types correlate with measures of size (Table 29.1). These size-related properties favor activation of motor unit types in the following order: Type S → Type FR → Type FF. The pool of motor neuron innervating each muscle contains varying proportions of Type S and Type F motor neurons, although generally Type S motor neurons are more abundant.

Many of the properties that produce orderly activation by size are stable and intrinsic to the motor neuron—cell body diameter, for example. Most extrinsic synaptic inputs also reinforce recruitment according to the size principle. This occurs because a synaptic current will produce a larger postsynaptic potential in a smaller, compact neuron with a higher input resistance. Because most sources of synaptic input are distributed uniformly to a motor pool, EPSP or IPSP

**TABLE 29.1** Size-Related Properties of Motor Neurons

Properties that increase with size	Properties that decrease with size
Diameter of soma and axon	Resistance to fatigue
Conduction velocity	Ia EPSP amplitude
Complexity of axonal collaterals	Input resistance
Membrane area, dendritic extent	Membrane resistance
Rheobase	Time constant
Muscle fiber diameter	Duration of afterhyperpolarization
Maximum force output	Twitch contraction time
	Twitch relaxation time

amplitudes correlate with the motor neuron size—larger in Type S motor neurons than Type F motor neurons. This means, for example, that stretch of a muscle that activates the primary muscle spindle (Ia) afferent will produce the largest Ia EPSPs in Type S motor neurons, and these will be the first units recruited to fire in the stretch reflex. In the less common situation in which synaptic inputs are not uniformly

distributed to every motor neuron in the pool, alternative recruitment sequences are possible.

Stronger muscle contractions are produced not only by recruitment of additional motor units, but also by increasing the firing rates of motor units that are already actively firing. The relative use of recruitment and rate modulation to maintain a desired profile of force varies according to the muscle and the level of force. In some muscles, such as the small hand muscles, several motor units begin firing at low levels of force, and fine gradations of force are controlled by modulating their firing rates. In other muscles, recruitment and rate coding occur together in a more balanced fashion throughout the working force range of the muscle.

### Muscle Afferents

Muscles contain two kinds of specialized sensory receptors that provide feedback to the spinal cord and brain. Muscle spindles sense muscle stretch or length, and Golgi tendon organs (GTOs) sense the load upon the muscle (Fig. 29.5). The spindle consists of an encapsulated bundle of modified muscle fibers, called intrafusal fibers, that lie within the muscle in parallel to the skeletal muscle fibers. The spindle receives both sensory and motor innervation. Sensory innervation is supplied by one primary afferent, the Ia fiber, and several secondary, group II afferents. Ia afferents are more sensitive to quick stretches, such as a tendon tap or vibration, and group II afferents maintain a firing rate proportional to the level of sustained stretch. Intrafusal muscle fibers are innervated by  $\gamma$ -motor neurons and  $\beta$ -motor neurons. The motor innervation of intrafusal fibers adjusts the tension of the spindle to compensate for changes in muscle length when a muscle contracts and shortens. When the muscle shortens the spindle can become momentarily slack, causing a pause in spindle afferent firing. However, during most voluntary movements,  $\alpha$  and  $\gamma$ -motor neurons are coactivated such that the sensitivity of the spindle is maintained during the muscle shortening. Nevertheless, because  $\gamma$ -motor neurons have a separate innervation of intrafusal muscle fibers, the nervous system can separately adjust the sensitivity of the spindle for different types of movement.

Golgi tendon organs lie at the junction of the muscle and tendon, in series with the muscle. GTOs are sensitive to the forces generated by muscle contraction against a load. Each GTO senses the force generated by a small number of motor units that insert onto a local region of the tendon. The axons of the GTOs are called Ib afferents. Like Ia afferents, they are large myelinated axons with fast conduction velocities.

Unlike spindles, GTOs do not have motor innervation.

Muscles are innervated by smaller diameter and unmyelinated afferents, called group III and IV afferents, that respond to extracellular substances, such as the acidic substances released during fatiguing exercise. These slowly conducting afferents relay the sense of muscle pain and soreness and produce reflex actions with a relatively slow time course.

**FIGURE 29.5** Structure and innervation of muscle spindles and Golgi tendon organs. The sensory innervation of the spindle is through primary (Ia) spindle afferents that innervate both nuclear bag and nuclear chain intrafusal muscle fibers and secondary (II) afferents that innervate nuclear chain fibers. Motor innervation of the spindle is supplied by static and dynamic  $\gamma$ -motor neurons and by  $\beta$ -motor neurons.

## Stretch Reflexes

The muscle stretch reflex plays an important role in providing feedback during movements. The stretch reflex consists of a monosynaptic response from the direct connection between Ia afferents and motor neurons, which may be followed by polysynaptic reflex activity. At rest, the stretch reflex can be obtained by a quick stretch, such as by tapping on a muscle tendon, which produces a burst of action potentials in the Ia spindle afferents (Fig. 29.6). In the spinal cord, the Ia afferents synapse on the motor neurons of the muscle containing the spindle (the homonymous motor neurons) and, to a lesser extent, on motor neurons that innervate other muscles (heteronymous motor neurons). The rapid volley of glutamatergic Ia EPSPs caused by a quick stretch can summate in the motor neuron, and if sufficient depolarization occurs, an action potential occurs that produces contraction of the muscle, with a jerk of the limb.

If the stretch reflex is elicited during movement, the Ia EPSPs will summate with inputs from other sources such as CPGs and descending inputs. Stretch during the phase of movement when the muscle is active will add to other sources of motor neuron depolarization, and the reflex motor response will enhance the ongoing contraction. Stretch of the muscle when it is out of its active phase will produce a smaller motor response, if any. In this way, the spatial summation of postsynaptic potentials contributes to phase modulation of the stretch reflex. Additionally, there is modulation of the stretch reflex through presynaptic inhibition of the Ia afferents during movement. This presynaptic inhibition is produced by GABA-ergic spinal interneurons

**FIGURE 29.6** Basic circuitry underlying the knee-jerk stretch reflex. Ia spindle afferents from the quadriceps muscle make monosynaptic, excitatory connections on  $\alpha$ -motor neurons that innervate the quadriceps.

that synapse on the Ia afferent terminals, forming axo-axonic synapses. Presynaptic inhibition reduces the release of glutamate from Ia afferents, leading to smaller Ia EPSPs in the motor neuron, but does not affect the size of other inputs to the motor neuron. The GABA-ergic interneurons mediating presynaptic inhibition are strongly activated by antagonist Ia afferents; that is, spindles from muscles that produce the opposite movement, as well as by CPGs and descending inputs. Thus, presynaptic inhibition of a muscle's stretch reflex is strongest when the muscle contraction is out of phase with the movement cycle, when its antagonist muscle is contracting.

## Summary

Muscles are innervated by motor neurons in the ventral horn of the spinal cord. The motor unit consists of one motor neuron and all the muscle fibers it innervates. Physiological properties of each motor neuron match the contractile and metabolic properties of its muscle fibers. Type S motor units have slow twitch, high aerobic capabilities, and fatigue resistance. These smaller motor units are the first recruited for contraction, and are heavily used for slow, sustained postural movements. Type F motor units innervate muscle fibers with a fast twitch and are recruited for more forceful or ballistic movements. Type FR motor units use aerobic and anaerobic metabolism and are relatively resistant to fatigue. Type FF motor units use anaerobic metabolism and fatigue quickly. In the pool of motor neurons innervating a muscle, motor neurons are recruited in an orderly fashion, beginning with Type S units that generate small amounts of force, followed by units that generate greater forces. As the muscle contracts, changes in its length are detected by spindles, specialized receptors that lie within the muscle. The load on the muscle is detected by a second specialized receptor, the Golgi tendon organ. These sensory receptors of the muscle provide feedback to the spinal cord allowing reflex changes in drive to the muscles.

## SPINAL INTERNEURON NETWORKS

So far, this chapter has discussed how the output of the spinal cord produces muscle actions through the motor neurons. This section will focus on spinal interneurons—neurons with a cell body in the spinal cord and an axon that synapses on another spinal neuron. Spinal interneurons have three important functions for motor control:

- They relay sensory inputs from the periphery that may modulate the motor output.
- They relay as well as modulate signals from the brain via descending pathways.
- They form networks that produce patterned rhythmic activity.

It is important to note that some interneurons may participate in all three functions, switching from one role to another during specific movements or carrying on two roles simultaneously.

Historically, interneurons were identified and named by their axonal projections, the location of their soma, their neurotransmitter, or by a physiological effect or reflex that they mediated. Later, populations of neurons were identified by their pattern of activity during movements, visualized using activity-dependent dyes. More recently, molecular biology tools have enabled scientists to identify interneurons based on their gene expression pattern and cell lineage. Molecular markers have been used to identify several classes of interneurons and motor neurons. Four distinct populations of interneurons, designated as V0, V1, V2, and V3, have been identified in the ventral spinal cord by

their developmental pattern of expression of transcription factors, proteins that regulate gene expression (Jessell, 2000; Goulding and Pfaff, 2005). The “V” denotes the *ventral* location, and each subclass appears at a distinct position along the dorso-ventral axis (0 most dorsal, 3 most ventral) of the ventral spinal cord (Fig. 29.7).

### Models for Studying the Locomotor CPG Network

At the beginning of the chapter we noted that the CPG network needed to produce three fundamental features of locomotion: generation of a cyclical rhythm, coordinated alternation between antagonist flexor and extensor muscles, and coordination between limbs. Figuring out what makes up a CPG—the neurons involved, the connections between these neurons, the synaptic interactions, and the contributions from cellular ion channels—is challenging. To tackle this problem, researchers construct models that can be tested and refined by experimental observations. As noted earlier, Brown (1911) first proposed a model

**FIGURE 29.7** Cross-sectional schematic of the spinal cord depicting on the right side the origin of interneuron and motor neuron populations defined in developmental studies using molecular markers for cell identification. The ventral interneurons (V) are marked as V0–V3 based on the distinct position along the dorso-ventral axis (0 most dorsal, 3 most ventral) of the ventral horn. The left side of the spinal cord depicts the general location of commissural interneurons (CINs) and the Rexed’s laminae. CINs are characterized based on the projection of their axons, as ascending (a), descending (d), or both (ad).

## BOX 29.3

## MOTOR NEURON DISEASES

There are several neurological disorders that selectively affect motor neurons. Spinal muscular atrophy (SMA) is a hereditary disorder in which motor neurons develop normally but begin to degenerate not long after birth. Autosomal recessive SMA was described by neurologists long before its cause was known, and several different clinical phenotypes were described. SMA causing weakness in infancy was called Werdnig-Hoffman disease; SMA causing weakness later in childhood was called Kugelberg-Welander disease. Both forms of SMA are caused by a mutation in a gene called “survival of motor neuron” or SMN gene. The SMN protein is widely expressed in neurons and has a role in processing mRNAs. It is not known why motor neurons are more vulnerable to mutations of SMN than other cells. In an X-linked SMA, called Kennedy’s disease or spinal and bulbar muscular atrophy (SBMA), weakness begins in adult life in affected males. Motor neurons innervating facial and jaw muscles often are affected early on. The mutation in SBMA is a triplet repeat expansion in the androgen receptor gene that leads to expression of an abnormal androgen receptor. The androgen receptor is expressed in motor neurons, and over time accumulation of the abnormal receptor leads to degeneration of the motor neuron.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig’s disease, is a disease with degeneration not

only of the motor neurons, but also of corticospinal neurons of the motor cortex. In most patients with ALS, the disease is not hereditary and its cause is unknown. There are a few hereditary forms of ALS that make up a small percentage of all patients with ALS. Nevertheless, the identification of familial ALS (FALS) genes has provided ideas about pathways that may be responsible for causing sporadic ALS. The first gene mutation identified in FALS encoded the enzyme superoxide dismutase, SOD1. Studies using transgenic mice expressing the mutant SOD1 gene showed that FALS was not caused by loss of enzyme activity, but by abnormal properties of the mutant SOD1 protein. Studies expressing mutant SOD1 in different cell types are revealing that glial and inflammatory cells may also contribute to motor neuron degeneration in FALS (Boillee *et al.*, 2006). The ability to manipulate the expression of mutant genes in animal models promises to provide an invaluable contribution to finding causes and treatment of ALS.

with mutually inhibitory half-centers driving flexors and extensors. Grillner (1985) proposed three important modifications: (1) that at each joint, movement in one direction was produced by a “burst generator” unit, a half-center capable of independent rhythmic activity; (2) as in Brown’s model, that flexion and extension at each joint were controlled by reciprocally connected burst generators to form a unit CPG; and (3) that multijoint coordination was achieved by loose or adjustable coupling between the mosaic of unit CPGs controlling each of the joints (Fig. 29.8).

Experimental findings have led to further refinements of the proposed organization of the CPG network. For example, the rhythm and timing of the network may be controlled separately from the patterning of the network output. In studies of locomotor rhythms in the neonatal rodent spinal cord, the CPG appears to be distributed among several spinal segments. Studies in the isolated neonatal rodent spinal cord preparation maintained *in vitro* (Fig. 29.9) show a

difference in the rhythmogenic capacity between the rostral (upper) and the caudal (lower) segments of the lumbar spinal cord. The upper lumbar (L1–L3 in rodents) segments seem to be most important for rhythm generation compared to caudal lumbar segments. In experiments using calcium dyes to visualize motor neuron activity, rhythmic signals from different parts of the lumbar (L1, L2) and sacral (S1–S3) segments rose, peaked, and decayed in a rostrocaudal sequence, giving rise to a rostrocaudal “wave” of motor neuron activation during each locomotor cycle (Bonnot *et al.*, 2002) (see video\*). The importance of the upper and mid-lumbar cord for rhythm generation has also been observed in the spinalized cat and is consistent with case reports in humans noting that irritative lesions of the upper lumbar cord produce stepping movements.

**FIGURE 29.8** Scheme for multijoint coordination within the leg using a mosaic of “unit CPGs.” Burst generators produce movement in one direction, extension or flexion, at the hip (HE, HF), knee (KE, KF), ankle (AE, AF), or foot (FE, FF), with a separate generator for the muscle that lifts the toes (EDB). Burst generators for flexion and extension at each joint are mutually inhibitory, forming a unit CPG that produces alternation. The strength of excitatory (triangles) and inhibitory (circles) connections between unit CPGs can vary to create a variety of different gaits. Reproduced with permission from Grillner *et al.* (1985).

### Excitatory Interneurons Responsible for the Rhythm

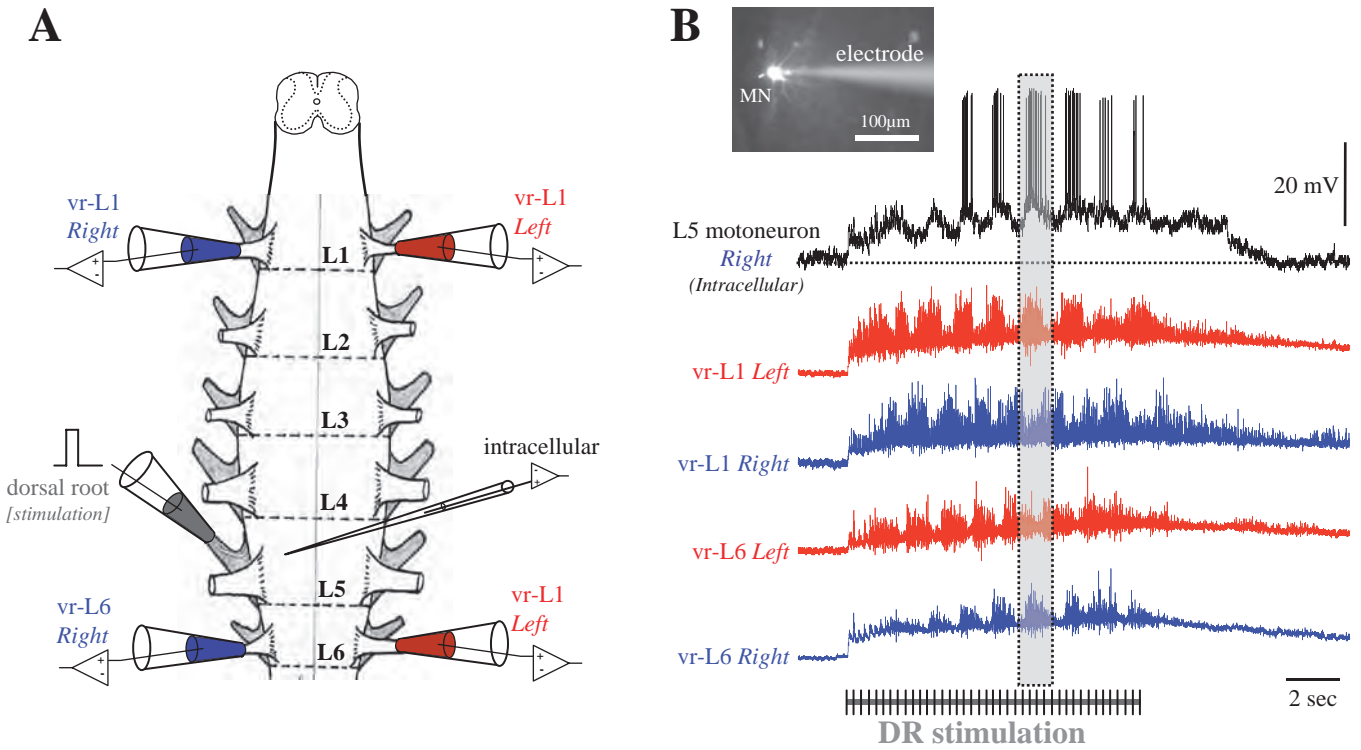

Maintaining rhythmic bursting in an interneuronal network requires a source of excitatory drive. Although this drive could be provided by tonic excitation, such as from descending pathways, a more robust rhythm is possible if there are excitatory cells within the network that have intrinsic properties that allow rhythmic and repetitive firing (Box 29.4). At least three classes of rhythmically active excitatory interneurons have been identified in the spinal cord and proposed as candidates for CPG rhythm generators. The first is a population of glutamatergic neurons located throughout the rostrocaudal extent of the spinal cord that are mutually excitatory and project to neurons that inhibit their counterparts on the opposite segment of the cord. In lamprey and other nonlimbed vertebrates, these neurons play a role in generating the swimming rhythms (Grillner, 2003). Another candidate popula-

tion of excitatory interneurons were first identified in mice with deletions in the genes for two axon guidance molecules, *EphA4* and *ephrinB3* (Kullander *et al.*, 2003). These mice had an abnormal hopping pattern of gait. Subsequent study of interneurons expressing *EphA4* receptors showed that these were glutamatergic and rhythmically active during locomotor behavior. Most of the interneurons were “last order” interneurons, interneurons that synapse on motor neurons. The third candidate thought to participate in the CPG is a recently defined excitatory interneuron in the lumbar spinal cord that is rhythmically active in locomotion and expresses the transcription factor HB9, which is also expressed in the motor neuron lineage during development (Fig. 29.10).

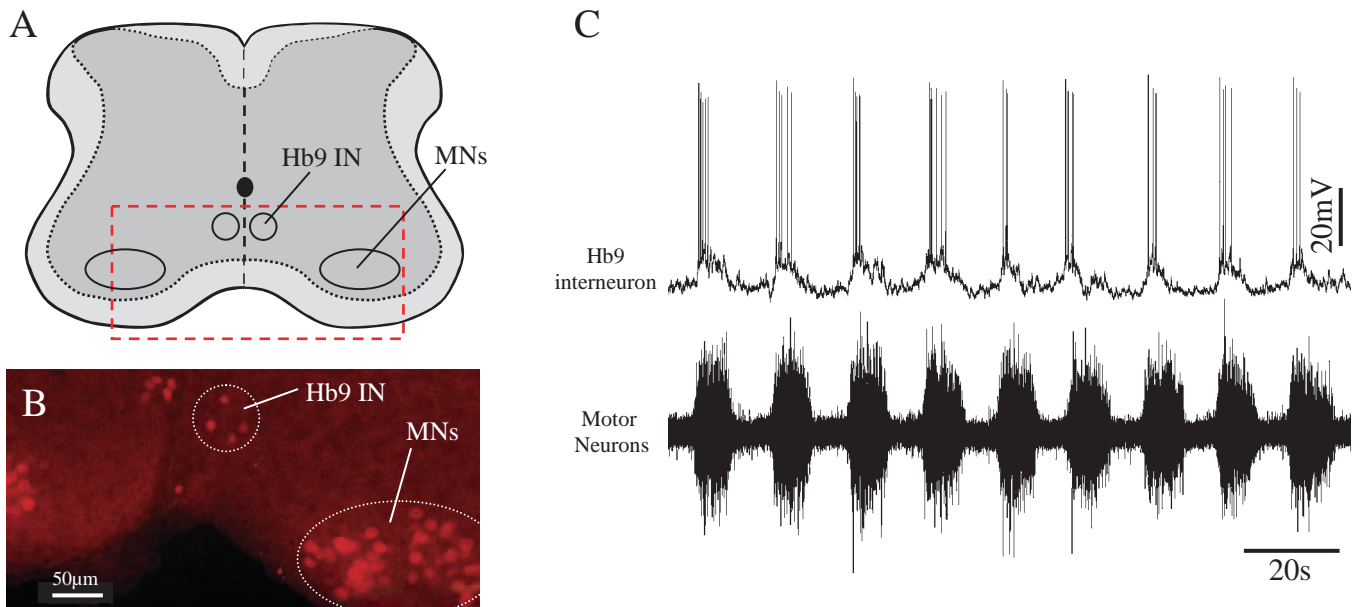

Although these interneurons have been proposed as candidates forming the rhythm generating circuitry of the CPG, it is important to note that more work needs to be done to prove their essential role in rhythmogenesis. Not all rhythmically active neurons are components of the CPG network. Some may receive rhythmic output from CPG neurons. The critical test is to show that temporarily removing a population of interneurons affects the locomotor rhythm. Recent strategies using genetic markers that identify specific populations of interneurons to drive selective expression of reversible inhibitors of activity provide a potential tool to test the contribution of distinct interneuron populations to CPG networks (Lechner *et al.*, 2002).

### Reciprocal Inhibition between Flexor and Extensor Muscles

Alternation between flexor and extensor muscles that act across the same joint is another fundamental feature of locomotion, as well as of many other limb movements. There are several spinal interneuron circuits that act in different ways to produce reciprocal inhibition between antagonist muscles. Presynaptic inhibition of antagonist Ia afferents by GABA-ergic interneurons, described earlier, prevents spindle afferents from activating a muscle when it is stretched by the contraction of its antagonist. Another interneuron, the glycinergic Ia inhibitory interneuron (IaIN), produces postsynaptic reciprocal inhibition. The IaIN was so named because it is activated by the muscle’s Ia afferents and inhibits motor neurons innervating the antagonist muscle. The IaIN synapses on the soma and main dendrites of motor neurons, producing a fast, potent IPSP that lasts only for several milliseconds. The IaIN develops from the V1 cell lineage, and can be recognized by its expression of the transcription factor *En1*. Almost every input that excites a motor neuron will also excite the IaINs that project to its antagonist’s

**FIGURE 29.9** (A) Drawing of an isolated neonatal mouse spinal cord used in *in vitro* experiments. Suction electrodes are placed in the ventral lumbar (L) roots to record motor neuron activity (blue and red) or in the dorsal root (gray) to stimulate sensory afferents. Glass electrodes are used to record intracellularly from individual neurons in the spinal cord. (B) The image shows a motor neuron (MN) filled with a fluorescent dye and visualized with a microscope during intracellular recording. Sustained electrical stimulation of sensory afferents can evoke rhythmic activity in motor neurons (intracellular record) characterized by rhythmic membrane depolarization, which reaches the threshold for action potentials. This stimulation also results in alternating rhythmic activity between the left and right side of the spinal cord (compare the activity in L1-left (red) and L1-right (blue)). It also produces alternating activity between the upper (L1) and lower (L6) segments of the spinal cord (compare the 2 red traces or the 2 blue traces), as highlighted in the dotted box. The duration of afferent stimulation is indicated by the graded bar.

## BOX 29.4

NONLINEAR PROPERTIES OF MOTOR NEURONS  
AND CPG INTERNEURONS

Experimental evidence from animal work indicates that motor neurons can participate actively in generating the rhythmic pattern observed during locomotion. Some motor neuron properties can be turned *ON* during locomotion due to synaptic inputs, which in turn produce nonlinear input-output relationships.

For example, there is a locomotor-dependent reduction in the threshold for spike generation, resulting in higher motor neuronal excitability. Two other motor neuronal properties susceptible to interact significantly with afferent inputs are the membrane potential oscillations known as *locomotor-drive-potentials* (LDP) and *plateau potentials*. LDPs are membrane potentials in motor neurons, in which a wave of depolarization during the active phase alternates with a wave of hyperpolarization during the antagonist phase of locomotion. Experiments in the cat have shown that the depolarizing phase is due to an excitatory synaptic drive and the hyperpolarizing phase is due to an inhibitory drive.

Plateau potentials are a behavior of the membrane potential in which the potential jumps between two states (bistable behavior). This motor neuron behavior has been observed in animals such as the turtle, mouse, and cat. This behavior is mediated mostly by a persistent inward current which at least in part is mediated by calcium channels. Ionic currents responsible for the generation of plateau potentials in motor neurons are predominantly occurring in dendrites because they possess voltage-

sensitive L-type calcium conductances. These currents are turned *ON* by some neuromodulators such as serotonin or noradrenalin. Data from animal experiments have shown that synaptic inputs on dendrites can recruit plateau potentials and evoke sustained discharge. It is possible therefore that dendritic activation can amplify the effect of synaptic inputs from either sensory or descending afferents. Although the role of plateau potential is still unclear during normal development, one hypothesis is that motor tasks like posture or stepping recruit fatigue-resistant motor units readily with sustained discharge produced by persistent inward currents without continuous network inputs.

From animal experiments there are some preliminary data that indicate that plateau potentials and sustained discharge are also found in some spinal interneurons. As in motor neurons, these plateaus are facilitated by serotonin and noradrenalin. In a similar fashion as in motor neurons, plateau potentials activated in interneurons by neuromodulators released during locomotion may act as an amplification step of synaptic inputs in particular dendrites. It is possible therefore, because interneurons integrate sensory and supraspinal information, for this mechanism to be very effective in the transmission of inputs relevant for the generation of motor neuronal activities.

George Z. Mentis

motor neurons. For this reason, voluntary contraction of a muscle will produce inhibition of its antagonist muscle, and, likewise, the stretch reflex of a muscle will produce inhibition of its antagonist. The excitability of IaINs is determined by their many inputs, and the strength of reciprocal inhibition can be varied to allow movements that use cocontraction. IaINs are

rhythmically active during locomotion, even without feedback from muscle stretch (Pratt and Jordan, 1987). This observation led to the proposal that IaINs were involved in producing the flexor-extensor alternation of the locomotor CPG. However, this proposal is not supported by more recent studies using neonatal mice in which the V1 lineage neurons were reversibly

◀ **FIGURE 29.10** (A) Drawing of a transverse section of the upper lumbar spinal cord from a neonatal mouse showing the location of the Hb9 interneuron nuclei bilaterally (annotated as Hb9 IN) as well as the motor neuron nuclei (annotated as MNs). The dotted box is shown in (B) as a fluorescence image revealing the Hb9 protein visualized by immunohistochemistry. The protein is present in motor neurons (dotted oval) and the small but distinct population of Hb9 interneurons in the ventro-medial part of the spinal cord (dotted circle). (C) Rhythmic firing in an Hb9 interneuron recorded intracellularly, and correlated rhythmic activity from a ventral root. The Hb9 interneuron activity was characterized by rhythmic membrane depolarizations underlying action potentials. This activity was in phase with the activity recorded from motor neurons (ventral root recording). Modified from Hinckley *et al.* (2005).

inactivated. In this study, the locomotor rhythms became slower, but still exhibited alternation of flexors and extensors (Gosgnach *et al.*, 2006).

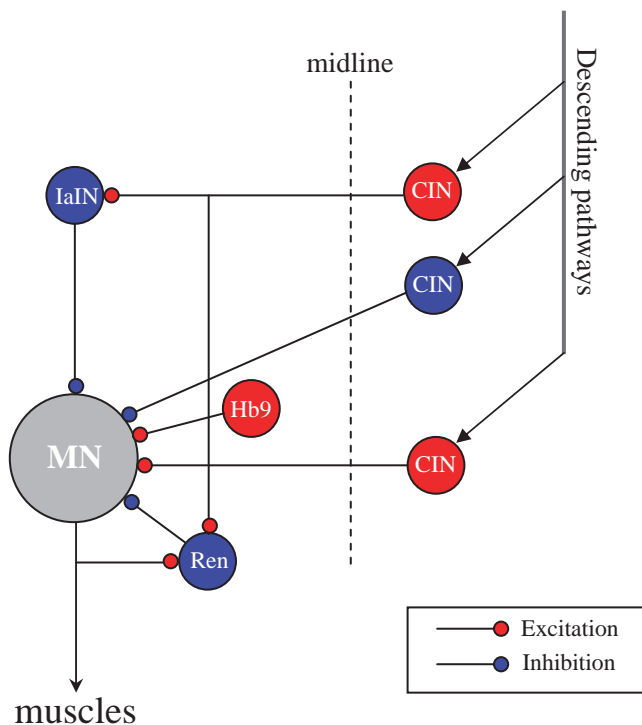

### Interneurons Involved in Left–Right Coordination

Interlimb coordination is the third fundamental feature of locomotion. To date, the leading candidate interneurons for coordinating activity between the limbs during locomotion are several populations of commissural interneurons (Fig. 29.11). Commissural interneurons have axons that cross the midline of the spinal cord at the level of the ventral commissure. They can be subdivided into three classes based on the direction of their axon: descending, ascending, or both (bifurcated axon). Descending commissural interneurons have been extensively studied in the rodent spinal

cord during early development. Their axons project at least two spinal segments away from their soma to make contacts with other ventral horn interneurons and motor neurons. Some ascending commissural interneurons are cholinergic and are thought to transmit information to the upper parts of the spinal cord. Many of the commissural interneurons arise from the V0 and V3 cell lineage. The V0 lineage gives rise to ascending commissural interneurons, whereas the V3 lineage comprises a mixed population of commissural as well as ipsilaterally projecting neurons. In transgenic mice lacking the V0 commissural interneurons, the coordination between left and right legs was disrupted during locomotor rhythms, with episodic synchronous activation between sides (Lanuza *et al.*, 2004). These results suggest that this class of ascending commissural interneurons contributes, in part, to side-to-side interlimb coordination.

### Recurrent (Renshaw) Inhibition

The recurrent collaterals of motor neurons synapse on a population of inhibitory interneurons in the ventral horn, called Renshaw cells. Renshaw cells use glycine or GABA as their transmitter and during development may contain both transmitters. Renshaw cells project back to homonymous motor neurons and synergist motor neurons in adjacent segments. They provide a negative feedback reflex called recurrent inhibition that limits the firing of motor neurons. During locomotor rhythms, Renshaw cells are rhythmically active, as expected since they receive rhythmic synaptic inputs from motor neurons. Their role in voluntary movements is uncertain, but one possibility is that they enhance the contrast between the active motor neurons and quiescent synergist motor neurons in adjacent segments. Renshaw cells arise from the V1 cell lineage, as do IaINs. During development, Renshaw cells, like IaINs, receive input from Ia afferents (Mentis *et al.*, 2006). In the studies in neonatal mice, mentioned earlier, reversible inactivation of the V1 lineage neurons that produced slowing of locomotor rhythms included Renshaw cells and IaINs (Gosgnach *et al.*, 2006).

**FIGURE 29.11** Schematic model with some of the known candidate interneurons that are involved in the modulation of the mammalian locomotor CPG. Excitatory interneurons (red) with rhythmic activity include classes of commissural interneurons (CIN) and the interneurons identified by expression of the HB9 transcription factor. Inhibitory interneurons (blue) that participate in termination of excitatory bursts include the Renshaw (Ren), the Ia interneuron (IaIN), and some commissural interneurons (CIN). Modified from Grillner (2006).

### Summary

In addition to serving as relays for sensory and descending pathways, interneurons of the spine interconnect to form CPG networks that can produce rhythmic firing. Several models of the CPG network have been proposed to guide experimenters. There has been significant progress in unraveling the interneuronal network that forms the spinal central pattern generator for locomotion. New experimental techniques have

allowed the identification in neonatal rodents of candidate interneurons for mediating some of the fundamental properties of locomotion: rhythmicity, alternation of antagonist muscles, and interlimb coordination.

## DESCENDING CONTROL OF SPINAL CIRCUITS

Neural circuits in the brainstem, cerebellum, and cerebral cortex are activated with locomotion and other movements. For locomotion, the cerebral cortex not only formulates conscious decisions about initiating and maintaining walking, but plays a role in adaptations of gait, particularly visually guided walking. Recordings from corticospinal neurons in cats as they stepped over obstacles placed in their field of vision showed that many corticospinal neurons changed their firing rates, often with a timing appropriate for driving the altered contraction patterns of specific muscles (Drew *et al.*, 2004). Corticospinal input, affecting motor neurons directly or through spinal CPG interneurons, can alter the limb's trajectory with a high degree of precision, in a similar manner to a goal-directed reaching movement. In people, clinical observations and experimental studies suggest that supraspinal regions play a more active role in locomotor control than in lower mammals (Box 29.5).

### **Brain Stem Control of Spinal Interneuron Networks**

The brain transmits signals for movement to the spinal cord through several descending fiber tracts: corticospinal, vestibulospinal, and reticulospinal, as described in earlier chapters. For locomotion, supraspinal regions are thought to activate spinal cord CPGs through brainstem relays. In decerebrate cats, electrical stimulation of several areas of the brain can elicit stepping. These include the diencephalon and cerebellum, but the most critical region is an area in the brain stem near the pedunculopontine nucleus known as the mesencephalic locomotor region (MLR). The MLR receives inputs from several forebrain regions, including the basal ganglia. The MLR does not connect directly to spinal CPG neurons, but synapses on reticulospinal neurons in the pons and medulla that receive a wide variety of sensory and descending inputs. Some of the reticulospinal axons in the pontomedullary formation travel in the ventral and ventrolateral tracts (funiculi) of the spinal cord. Lesions of these funiculi disrupt the ability to initiate and maintain locomotion.

Sparing of at least some fibers in the ventrolateral funiculus markedly improves locomotor recovery after spinal lesions in cats (Rossignol *et al.*, 1999) and could be critical for the recovery of locomotor movements after spinal injury in humans.

In addition to their role in triggering rapid changes in locomotion and regulating postural balance, descending fiber systems also modulate physiological properties of spinal neurons. For instance, the plateau potentials and bistability in motor neurons (Box 29.4) depend on tonic activity in descending serotonergic pathways. Stimulation of the dorsolateral funiculus of the spinal cord in turtles, an area which is thought to contain descending pathways from the raphe nucleus, increased the excitability of motor neurons and promoted plateau potentials.

## SENSORY MODULATION

Although spinal CPGs can generate the basic pattern of neural activity that organizes muscle contractions into a recognizable movement such as locomotion, the final pattern is fine-tuned by sensory inputs as well as descending systems. As noted earlier, most sensory inputs affect motor neurons through polysynaptic, interneuronal circuits. The interneurons that process sensory information typically integrate sensory signals with inputs from a variety of sources, including from CPG networks and descending pathways. As a result the reflex motor response can vary depending on the phase of the movement cycle, or it may occur only when the animal is in the "state" of moving, or it may even be reversed between resting and active states. Earlier we discussed the muscle sensory receptors and some of the reflex changes they mediate. This last section will present a sampling of other sensory reflex pathways.

### **Flexor Reflexes**

A wide variety of sensory stimuli can evoke reflex flexion of the limb. Flexor reflexes may have several roles: they serve a protective function, reflexively withdrawing the limb from potentially harmful stimuli, and they may be used in movements that require coordinated multijoint flexor movements. Usually the reflex consists of contraction of muscles that flex several joints coupled with relaxation of muscles that extend those joints. Extension of the contralateral limb may also occur. Flexor reflexes can be elicited by group II and III muscle afferents, joint afferents, and high- and low-threshold cutaneous afferents. Because these

## BOX 29.5

## NEURAL CONTROL OF HUMAN WALKING

Human walking is a complex behavior that is based on integration of activity from descending supraspinal motor commands, spinal neuronal circuitries, and sensory feedback. Accumulating evidence suggests that humans, as well as other species, have a network in the spinal cord that is capable of generating basic rhythmic walking activity. Rhythmic leg movements can be induced by epidural electrical stimulation after a clinically complete spinal cord injury (SCI). Also, spontaneous involuntary rhythmic leg movements have been reported after a clinically complete and incomplete SCI. However, even though this evidence points to the existence of a CPG network in humans, in all these cases sensory input likely contributed to the rhythm generation. Furthermore, clinically complete injuries are not always anatomically complete. Therefore, the evidence for existence of a CPG in humans remains indirect.

Noninvasive electrophysiological techniques have provided information about how certain brain structures contribute to human walking. For example, the involvement of the primary motor cortex, where the corticospinal tract originates, has been demonstrated, in part, with transcranial magnetic stimulation (TMS). Several groups have found changes in the size of motor evoked potentials (MEP) in lower limb muscles elicited by TMS during walking, showing that transmission in the corticospinal tract is modulated during the gait cycle. However, TMS of the motor cortex activates cells with monosynaptic or polysynaptic connections to the spinal motor neurons. The size of the MEPs elicited by TMS reflects not only cortical excitability changes, but also changes at a subcortical level. To more precisely identify the various sites activated by the magnetic stimulus, Petersen and collaborators (1998) tested the effect of TMS on the H-reflex, an electrical homologue of the monosynaptic stretch reflex, during walking. They found that at least part of the MEP modulation was caused by changes in the excitability of corticospinal cells with direct monosynaptic projections to the spinal motor neurons. They also found that TMS over the motor cortex at intensities below the threshold for activating spinal motor neurons depressed ongoing muscle activity in the tibialis anterior muscle of the leg during walking. This effect was thought to be caused by activation of cortical inhibitory interneurons targeting cortical pyramidal tract neurons (Petersen *et al.*, 2001).

During human walking, sensory feedback plays an important role in driving the active motor neurons and providing error signals to the brain that can be used to adapt and update the gait pattern. In healthy humans, a study in which a plantarflexion perturbation was induced during the stance phase of the gait cycle provides clear evidence for this. This experiment showed a drop in electromyographic (EMG) activity in the plantarflexor muscles, even when the common peroneal nerve that innervates the ankle dorsiflexor muscles was blocked by local anesthesia (Sinkjaer *et al.*, 2000). These results demonstrated that sensory feedback from plantarflexor muscle contributed to the active drive of motor neurons during walking. Additional information about the contribution of sensory feedback for the control of locomotion has been gathered from studies that investigate changes in EMG responses in lower limb muscles after stimulation of cutaneous and proprioceptive afferents during walking. The amplitudes of the EMG responses to electrical stimulation are dependent on the phase (or time) of stimulation during the gait cycle. For example, electrical stimulation of the human sural nerve results in facilitation of the ankle flexor muscle tibialis anterior during early swing, but leads to suppression when delivered during late swing (reflex reversal). It has been proposed that the phase-dependent modulation of EMG responses may have functional relevance at various times in the step cycle. For example, a flexor reflex is appropriate at the onset of the swing phase when the leg is flexed, but the same reflex is not convenient at the end of the swing phase when the foot is ready to take up body weight. To some extent this modulation is mediated by supraspinal centers. To examine this possibility, a combination of cutaneous input and activation of supraspinal pathways by TMS has been used during the gait cycle. Available data suggest that long-latency reflexes elicited by cutaneous electrical stimulation are in part transcortically mediated.

In summary, in recent years a combination of neurophysiological techniques has provided important insights that have improved our understanding about the neural control of human walking. Human walking is based on the integration of activities from spinal circuitry, sensory feedback, and descending motor commands.

Monica A. Perez

afferents elicit a common action, they are sometimes called *flexor reflex afferents* (FRAs). The muscles activated by the sensory stimulus respond with short and long latency bursts of contraction. These contraction components are thought to be generated by distinct interneuron circuits. The late components can be differentially enhanced by treatment with L-dopa in spinalized animals. It has been suggested that interneurons mediating the late flexor reflex could function as a half-center for flexion, as proposed in models of the locomotor CPG.

### Cutaneous Reflexes

In contrast to the widely distributed flexor reflex, there are a number of reflexes in which stimulation of small areas of skin evokes a reflex limited to a few muscles. One example of a local cutaneous reflex is the stumbling corrective reaction. When the skin on the top of the foot is stimulated during walking, the foot is lifted higher, as if to step over an obstacle. The stumbling corrective reaction is phase dependent, occurring only when the limb is in the swing phase of the step

cycle. This and several other local cutaneous reflexes are oligosynaptic, involving only a few interneurons. The last-order interneurons in these cutaneous reflexes connect with relatively limited sets of motor neurons. It has been proposed that such interneurons offer a means to control or alter activity of specific muscles during movement without involving the interneurons of pattern generating circuitry.

### Summary

Several areas of the brain give rise to descending pathways that connect to spinal interneurons and, to varying extents in different species, motor neurons. Areas of the brainstem are critical for relaying descending commands for locomotion. Volitional movements also seem to employ spinal interneuron circuits for organizing routine patterns of muscle contraction, within the context of a planned goal. Sensory feedback from skin, joints, and most muscle afferents also provide fine-tuning of basic movement patterns. The reflex motor responses evoked by most sensory afferent are relayed through interneurons.

## BOX 29.6

## PLASTICITY IN SPINAL CORD CIRCUITS

Over the last decade many studies have reported adaptive changes in spinal cord reflex circuits in animal and humans. Short- and long-term adaptations have been associated with the acquisition and learning of new motor skills. One of the pathways that has been investigated is the spinal stretch reflex (SSR) and its electrical analog, the H-reflex (Hoffman reflex). Operant conditioning has been used to show that descending activity from the brain can induce adaptations of the SSR and the H-reflex. In an operant conditioning protocol, monkeys, humans, and rats can gradually decrease (down-conditioning) or increase (up-conditioning) the size of the SSR or the H-reflex (Wolpaw and Tennissen, 2001). The acquisition of these simple motor skills can occur over days and weeks of practice.

The size of the SSR and the H-reflex is also affected by the nature, intensity, and duration of past physical activity and by the specificity of training. For instance, a cross-sectional study demonstrated smaller H-reflex sizes in ballet dancers than in nonathletic persons. This may be related to the frequent use of cocontraction of antagonistic ankle muscles to ensure stability when dancing (Nielsen *et al.*, 1993). A short-term depression of the H-reflex size has been shown to occur during learning a novel motor task that requires a high degree of precision and attention. Individuals that trained to perform a task that required complex association between a visual and a motor response showed smaller reflexes than individuals training a task of similar duration and intensity but without any learning requirements (Perez *et al.*, 2005). Other complex training paradigms, such as walking backward, stepping over obstacles, and cycling against changing levels of resistance have been shown to induce temporary changes in the H-reflex that are partly associated with the skill acquisition process.

The mechanisms underlying short- and long-term adaptations in the H-reflex during motor skill learning are incompletely understood. Since changes in descending drive and in the spinal cord itself occur during the learning process, it is likely that the mechanisms involve changes at multiple sites. On one hand, modulation in descending drive may contribute to maintain a tight

control of spinal circuits during acquisition of novel motor skill tasks as part of the sensorimotor integration process. Also changes in presynaptic inhibition of the synapses between sensory afferents and motoneurons are important in the adaptation of the reflex circuitry during motor learning. Habituation of the monosynaptic gill-withdrawal reflex in *Aplysia* is caused by a depression of synaptic transmission between the sensory afferents and motoneurons through changes in presynaptic inhibition (Kandel *et al.*, 2000). In rats and monkeys, short-term down-regulation of the H-reflex is likely to be related to changes in presynaptic inhibition, whereas a change in motor neuron firing threshold seems to be a mechanism associated with long-term down-regulation of the H-reflex during classical operant conditioning (Wolpaw and Tennissen, 2001). In humans, recent evidence suggests that acquisition of a visuo-motor skill also is associated with changes in presynaptic inhibition at the terminals of Ia afferent fibers (Perez *et al.*, 2005).

Even though the role of spinal cord plasticity in motor learning remains largely unknown, accumulating evidence has demonstrated that spinal cord plasticity occurs in the course of motor learning and it contributes to skill acquisition. Plasticity in spinal cord circuits may be an important mechanism for establishing motor recovery after motor disorders including spinal cord injury.

## Descending Control of Movement

Four major pathways descend from the brain to the spinal cord to control muscles that move the skeleton. These pathways arise in the vestibular nuclei (vestibulospinal), in the brain stem reticular formation (reticulospinal), in the red nucleus (rubrospinal), and in the cerebral cortex (corticospinal). Although these four descending pathways work together to provide seamless control of movements from postural reflexes to delicate manipulation, they can be separated broadly into two main systems. Vestibulospinal and reticulospinal pathways can be grouped together as a medial system: their axons descend through the brain stem and spinal cord close to the midline, and chiefly innervate axial and proximal limb musculature whose motoneurons lie medially in the ventral horn. The corticospinal and rubrospinal pathways together can be considered a lateral system: their axons descend in the lateral column of the spinal cord and chiefly innervate limb musculature, particularly distal musculature, whose motoneurons lie laterally in the ventral horn.

More than just an anatomical distinction, the medial and lateral systems have different principal functions. The medial system provides postural control (Box 30.1). Monkeys with medial system lesions fall over when they attempt to ambulate and climb, but when supported, they can use their hands and fingers adeptly in retrieving food pieces from narrow holes (Lawrence and Kuypers, 1968b). The lateral system provides fine control of voluntary movement. Monkeys with lateral system lesions rapidly recover the use of all four extremities in activities such as ambulation and climbing, but they are unable to make the fine finger movements needed to extract small pieces of food from narrow holes (Lawrence and Kuypers, 1968a). This chapter examines the contributions of first the medial

and then the lateral descending systems to control of movement.

### THE MEDIAL POSTURAL SYSTEM

#### **Vestibular and Reticular Nuclei Control Posture and Reflex Behaviors**

Early experimenters found that some degree of postural and reflex control remains after higher brain centers are completely cut off from the brain stem and spinal cord, and that the extent of preserved motor function is determined by the level of the transection that disconnects the upper portions of the brain (Fig. 30.1). There is no functional regeneration of central neuronal pathways after damage, and when the spinal cord is separated from all the brain above it, as can occur in motor vehicle or equestrian accidents, the result is quadriplegia, a loss of all voluntary movement and postural control. Only the spinal reflexes discussed in the preceding chapter return, and those return only when spinal cord neurons recover excitability after a prolonged period of limp (flaccid) paralysis called spinal shock.

Transections at higher levels of the neuraxis leave part of the brain stem connected with the spinal cord. Chronic bulbospinal cats, those with medulla and spinal cord below the transection, show primitive attempts at righting themselves when placed on one side. Effective righting may be observed in chronically surviving animals subjected to transection that leaves the mesencephalon intact below the level of the cut. As the level of transection is raised, posture and balance become progressively closer to normal. The decorticate

## BOX 30.1

## NEUROTRANSMITTERS AND POSTURE

Although most of the work on postural reflexes has concerned mammalian responses and neurophysiological mechanisms, invertebrate studies offer simpler systems that may be more directly manipulated, especially by neuropharmacological agents. The work of Kravitz and colleagues exemplifies this approach. They found that systemic administration of the aminergic neurotransmitter serotonin (Chapter 7) causes a lobster to assume a flexed posture characteristic of defensive responses. Octopamine, in contrast, causes the animal to lie flat with its legs extended. These responses are not due to the direct action of serotonin and octopamine on muscles; both

agents stimulate muscular contraction. However, serotonin and octopamine have opposite effects on extensor and flexor motor neurons: serotonin excites flexor motor neurons and is selectively localized in a subset of interneurons. The conclusion is that serotonin acts on the lobster central nervous system to trigger the flexion posture, whereas octopamine triggers extension. In mammals, axons descending from the reticular formation release neurotransmitters, including serotonin, that have analogous modulatory functions.

*Marc H. Schieber and James F. Baker*

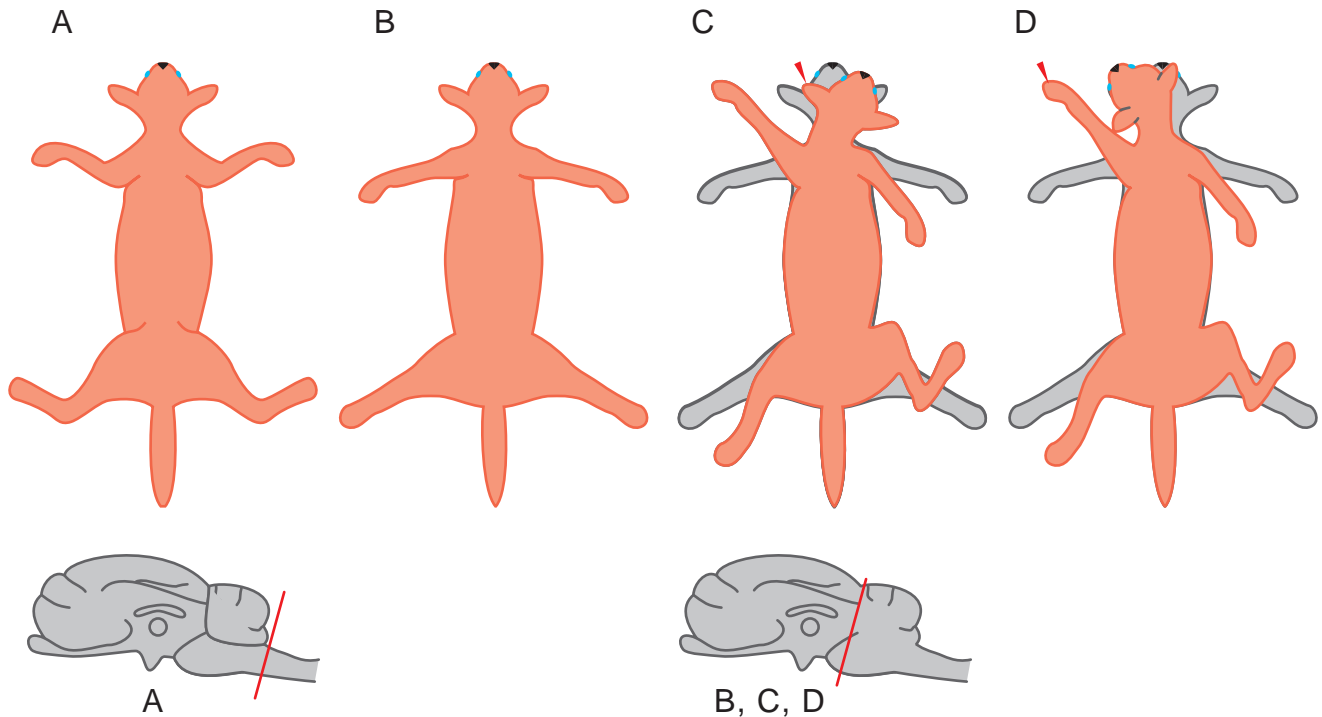

animal produced by the ablation of cerebral cortical tissue has many apparently normal postural reactions, lacking only certain placing and stepping reactions. Progressively higher brain transections enable more of the vestibular (balance) and proprioceptive (muscle and position sense) circuitry that participates in postural control, as well as improving the overall balance between excitatory and inhibitory influences on the spinal cord.

Nuclei of the brain stem reticular formation with intact spinal projections after high brain stem transection include the locus ceruleus and raphe nuclei, the origins of descending noradrenergic and serotonergic neuromodulatory axonal projections that alter excitability of neurons in the spinal cord, as discussed in the preceding chapter. Parts of the raphe nuclei also have a role in circadian rhythms (Chapters 41 and 42), and projections of the locus ceruleus are involved in attention (Chapter 48) and internal reward (Chapter 43). Other areas of the reticular formation involved in motor control have specific functions in generation of the locomotor rhythm (MLR, mesencephalic locomotor region, Chapter 29) and rapid eye movements (PPRF and MRF, Chapter 33). Nuclei of the reticular formation are studied most often from the perspective of their contributions to specific functional systems described in other chapters and through the actions of their monoamine neuromodulators noradrenalin (norepinephrine) and serotonin. Vestibular nuclei are studied for their contributions to postural and oculomotor reflexes (Chapter 33).

### The Vestibular Apparatus Senses Head Rotation and Tilt

The sensory inputs most important for postural responses are vision, proprioception, and vestibular sense. Vestibular sensory signals from the labyrinth of the inner ear provide direct information about rotations of the head and its orientation with respect to gravity. Two types of vestibular transducer organs—semicircular canals and otolithic maculae—are located within the labyrinth of the ear and respond to accelerations of the head in space. The three semicircular canals and the two otolithic maculae are stimulated by rotational and linear acceleration, respectively. The mechanical structure of the sense organ determines the nature of the effective stimulus (Wilson and Melvill-Jones, 1979).

The labyrinth (Fig. 30.2) (Box 30.2) is outlined by the bony labyrinth, a set of passages in the skull. The bony labyrinth is lined with membranes that contain endolymph (Chapter 26) and that make up the membranous labyrinth. The membranous labyrinth has a large central vessel called the utricle, another vessel called the saccule, and three narrow passages that emerge from the utricle and loop around to rejoin it. These three loops form circular passages for endolymph and are known as semicircular canals. The canals are oriented orthogonal to one another: there is a lateral or horizontal canal, an anterior or superior canal, and a posterior canal. The signals from the semicircular canals are discussed along with the eye movement

**FIGURE 30.1** Posture following transection of the neuraxis. (A) The limp posture of a cat immediately after separation of the spinal cord from the brain. Limbs are neither flexed nor extended. The level of transection is shown below in a sagittal view. (B) The rigid posture of the decerebrate quadruped. All four limbs are extended. The transection, shown below, has been made through the pons. (C) Adjustment of the posture of the decerebrate preparation in response to stimulation of the pinna. All four limbs and the head alter their posture. (D) Adjustment of decerebrate posture in response to stimulation of the forepaw. Again, limbs and neck adjust. In this case the head turns toward the stimulus. Based on reports by Sherrington.

reflexes they generate (Chapter 33), and are introduced here only briefly here. A semicircular canal is excited by rotational accelerations, and the mechanical structure of the canal converts acceleration into a rotational velocity signal. The three canals in each labyrinth are oriented for excitation by rotations toward that side of the body, horizontally, diagonally forward, and diagonally backward for the horizontal, anterior, and posterior canals, respectively. Thus, each labyrinth is excited by head rotation toward its side, called ipsilateral rotation. Canal afferents fire action potentials at a rate approximately proportional to the velocity of head rotation in the direction of the canal orientation. Both labyrinths are excited by purely forward or backward rotation, the anterior canals excited during the forward phase and the posterior canals excited during the backward phase.

There are two otolith organs in mammals, the utricle (utricle) and saccule (sacculus). The names apply to the fluid chambers in which they lie, and the specific locations of the receptors are called the maculae. The two maculae are small regions that contain hair cells innervated by vestibular afferents. Like auditory and semicircular canal hair cells, bending of their cilia is

the excitatory stimulus for macular hair cells, and the cilia are imbedded in a gelatinous mass above the cell bodies. Unlike canal hair cells, the otolithic hair cell maculae rest in large chambers, in which fluid motion is thought to exert little or no force on the cilia. Instead, the gelatinous mass holding the cilia contains dense crystals, the otoconia or statoconia, and the entire mass above the hair cells of a macula is acted on by gravity or linear acceleration because of its higher density than the endolymph. The otoconial mass sags in the direction of a head tilt. This sagging, or the equivalent lagging of the mass behind a linear acceleration, provides the natural stimulus for otoliths.

The utricular macula lies horizontally on the floor of its cavity. When the head is still and held approximately erect with respect to gravity, there is no stimulus to this organ, but tilts from the erect posture will excite utricular afferents. Microscopic examination of the utricular macula shows that the hair cells are not all oriented with their cilia arranged in the same direction, and different directions of tilt excite different populations of utricular afferents. The direction of the hair cell indicated by its structural orientation is called its morphological polarization vector and corresponds

## BOX 30.2

## POSITIONAL NYSTAGMUS

As many as one person in ten suffers from repeated or persistent dizziness at some point in life, typically accompanied by nystagmus (see Chapter 33 for a description of these eye rotations). Often, the dizziness and nystagmus are evoked by a sudden change in head orientation, identifying the disorder as positional nystagmus, also known as benign positional paroxysmal nystagmus (BPPN) or benign positional vertigo (BPV). The usual cause of BPV is debris in the posterior semicircular canal. This debris stimulates the canal receptors when the head is rotated, eliciting a sensation of rotation and a vestibulo-ocular reflex nystagmus. The debris may be otoconia dislodged from the otoliths, and it can be either free-floating (canalithiasis), or stuck to the canal receptor surface (cupulolithiasis). When the head is repositioned, the debris either stirs the endolymph as it falls to a new location in the canal semicircle, or its weight shifts on the receptors, in either case causing abnormal canal stimulation. BPV may be self-correcting after days to months, or its treatment may require a

sequence of head rotations aimed at emptying the debris back into the utricle where it will not stimulate the canal.

A related positional nystagmus experienced by many party-goers is positional alcohol nystagmus (PAN), which is similar to the condition where debris is stuck to the canal receptor surface. Rapid consumption of alcohol leads to decreased blood density, which makes the canal receptors less dense than the more slowly absorptive endolymph. When the intoxicated person lies down and turns the head to one side, the canal receptors float up in the endolymph, as if pushed by a head rotation, and a vigorous nystagmus can occur. PAN is peripheral in origin, not among the central effects of the drug. This has been shown by having subjects drink deuterium water ("heavy water"), which makes the canal receptors sink in the endolymph and causes nystagmus in the opposite direction to PAN.

*Marc H. Schieber and James F. Baker*

to the best direction of tilt for exciting the receptor. Each utricular macula has hair cell orientations capable of responding to any direction of head tilt, but ipsilateral tilt excites a predominant number of afferents. Thus, as for the semicircular canals, we say that ipsilaterally directed head motion is excitatory. The saccular macula is placed vertically on the side of the sacculus, approximately in a parasagittal plane. There is a strong acceleration stimulus to the saccular macula when the head is erect and little or no stimulus when the head is lying on either side. The sacculus responds vigorously when the head bobs up and down, as during locomotion, but the exact functions of the sacculus are debated and are beyond the scope of this chapter. In summary, two types of vestibular signals are available to assist balance: ipsilaterally directed rotational head velocity is signaled by the semicircular canals and ipsilaterally directed head tilt or an equivalent linear acceleration is signaled by the utricular otoliths.

### Vestibulocervical and Vestibulospinal Reflexes Stabilize Head and Body Posture

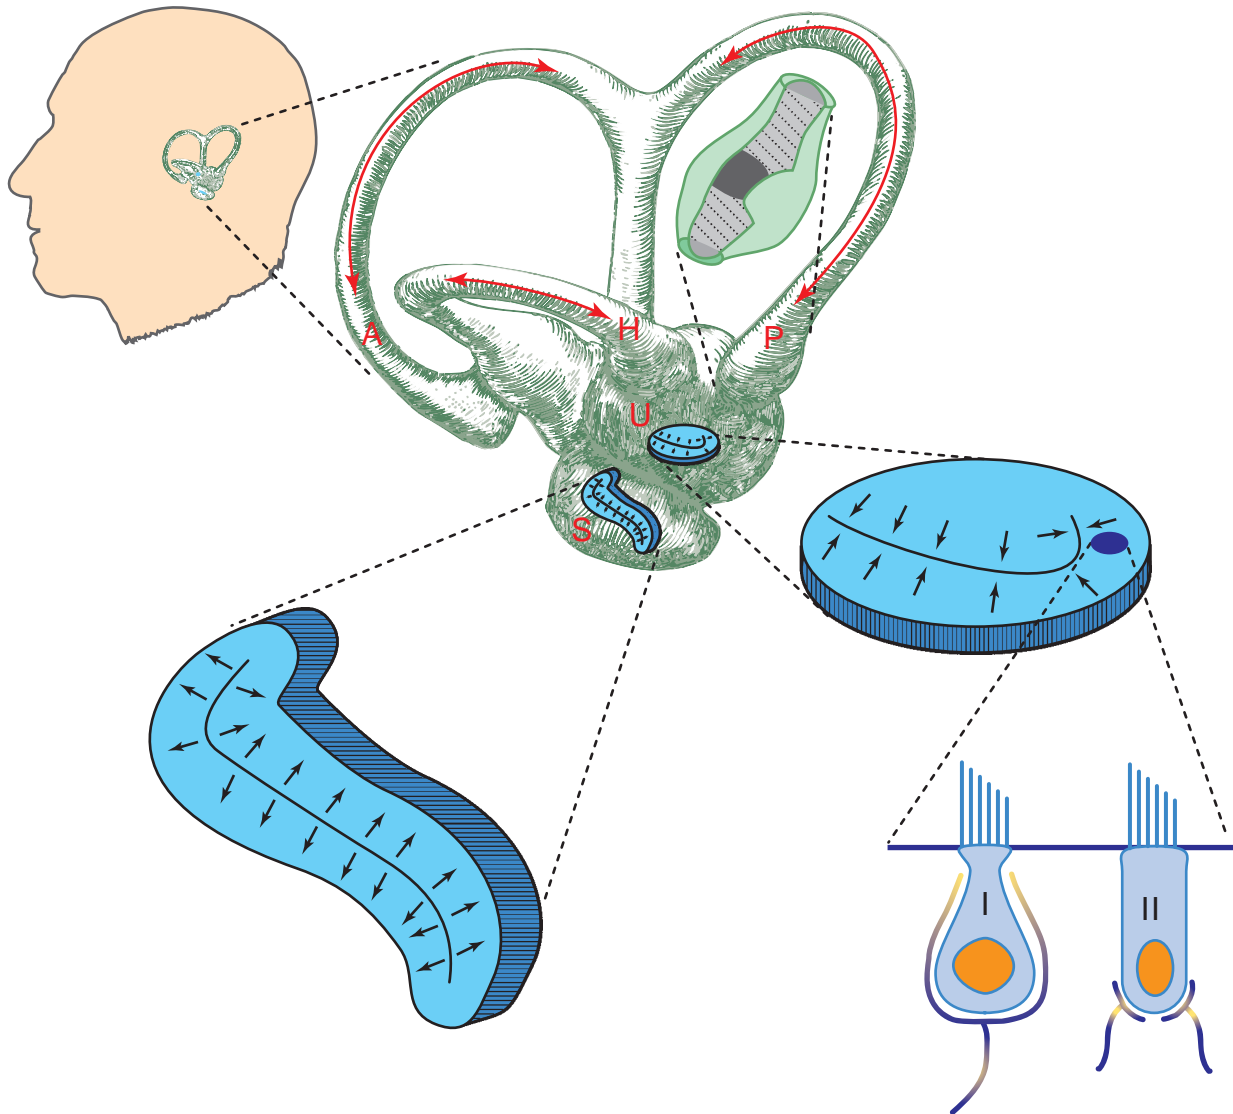

Vestibulocervical (neck or collic reflexes) and vestibulospinal reflexes make use of canal and otolith

signals to stabilize the posture of the head and body. These reflexes are thought to serve two functions, both as stabilizing, or "negative feedback" systems (Schor *et al.*, 1988). First, when the head and body rotate or tilt in any direction, the vestibular stimulus excites pathways that contract neck and limb muscles that oppose the motion so that the undesired movement is reduced or corrected. Second, the biomechanical components of the head have a characteristic resonant frequency of around 2 to 3 Hz at which oscillation is especially likely to occur, and the vestibulocervical reflex effectively dampens this tendency for oscillatory motion. The importance of vestibulocervical and vestibulospinal reflexes is demonstrated by damage to the labyrinth, section of the VIIIth nerve, or mechanical blockage of the semicircular canal passages. Unilateral labyrinthectomy causes an initial postural disability, with leaning or falling toward the side of the lesion. Bilaterally symmetric semicircular canal plugging, which removes head velocity signals with little loss or imbalance in tonic vestibular nerve activity, produces head instability with oscillations that may persist for several days. Note that the vestibulocervical reflex, although discussed separately, is as much a vestibulospinal reflex as vestibular limb reflexes, the difference

being primary action at the cervical versus lumbar spinal levels.

The neuroanatomical pathways that contribute to the vestibulocervical and other vestibulospinal reflex responses (Fig. 30.3) have been elucidated primarily through the use of electrical stimulation and other physiological methods. Of the four brain stem vestibular nuclei that receive the VIIIth nerve, the medial, lateral (Deiters' nucleus), and descending (inferior nucleus) contribute to the medial and lateral vestibulo-

lospinal tracts that provide direct vestibular influence on the spinal cord. The superior vestibular nucleus is concerned primarily with vestibulo-ocular reflexes (Chapter 33). Electrical activation of the vestibular pathways shows that vestibulocervical reflexes are mediated primarily by excitatory and inhibitory connections of the bilaterally projecting medial vestibulospinal tract and that ipsilateral excitation of limb extensors is carried via the lateral vestibulospinal tract. The bulk of the lateral vestibulospinal tract projects

**FIGURE 30.2** Vestibular canals and otoliths. The position and orientation of the labyrinth (not to scale) in the head are shown at the upper left of the figure. An enlarged view of the labyrinth shows the directions of head rotation and endolymph flow (red arrows) that excite each of the three semicircular canals. The horizontal orientation of the utricular macula and vertical orientation of the saccular macula are shown schematically. More highly magnified views of the receptor regions of a canal and of the otolith organs are shown with the cupula of the canal colored dark gray and the best directions for excitation of otolith hair cells marked by black arrows. At the lower right are two anatomical types of hair cell: the calyx or type I and bouton-ending or type II receptor. The tallest cilial extension on each cell is the kinocilium. A, anterior semicircular canal; H, horizontal semicircular canal; P, posterior semicircular canal; S, saccule containing saccular macula; U, utricle containing utricular macula; I, type I receptor; II, type II receptor. Based on studies reviewed by Wilson and Melvill-Jones.

from the lateral vestibular nucleus as far as the lumbar spinal cord for vestibulospinal reflex control of upright body posture. Vestibular nuclei also project heavily to reticular nuclei, and only lesions that impinge on both vestibulospinal and reticulospinal pathways substantially reduce the strength of vestibular reflex responses.

The bilateral, mixed excitatory and inhibitory connections of the vestibulocervical reflex circuits indicate that its actions are complex, and the considerable effort devoted to explicating the exact nature of these actions will be summarized here. The excitatory lateral vestibulospinal tract projection to ipsilateral extensor motor neurons offers a simple example of negative feedback: When the head and body tilt to one side, canals and otoliths of the labyrinth on that side are excited, and the lateral vestibulospinal tract carries this excitation to the ipsilateral leg extensor motor neurons. The ipsilateral leg is thus extended to oppose the tilt and maintain upright posture. An upcoming section will discuss studies of this response in the context of coordinated postural reactions.

Initial quantitative studies of the vestibulocervical reflex used sinusoidally oscillating stimuli and concentrated on the timing of the reflex head torques or the electromyographic activity that accompanied neck muscle contractions, just as response timing had been the focus in studies of vestibular primary afferents. The conclusion from these studies was that vestibulocervical reflex circuitry in the vestibular nuclei introduces central neural processing with two important features. First, at low frequencies a portion of the velocity signal from the semicircular canals is converted to a head position signal, appropriate for repositioning the head in response to a slow change in head angle. Second, at high frequencies, vestibulocervical reflex circuitry appears to introduce an anticipatory or "phase lead" response, which works in conjunction with the canal afferent signal to make very rapid responses so that the behavioral output of the reflex opposes head angular acceleration, as would be appropriate if the inertia of the head were an important factor to be overcome for compensation during rapid head motion. The mechanisms by which neurons in the brain stem accomplish these functions are unknown.

Timing of vestibulocervical responses is reasonable given the function of the reflex and the mechanical properties of the load presented by the head. The mechanical properties of the multijoint system of the limbs and trunk are far more complex, and it is correspondingly more difficult to predict what the timing of the controlling neural signals should be. Electromyographic recordings during vestibulospinal reflexes

in decerebrated animals have shown that limb extensors at low frequencies of oscillation are excited in phase with the position of the head. For example, when the head rolls slowly to the left, the left forelimb extends as if to brace against further displacement. The likely source of signals exciting these responses is the otolith organs. As the frequency of head oscillation increases, the timing of vestibulospinal responses corresponds more closely to head rotation velocity. The value of this timing is debatable, but the implication is that semicircular canal signals begin to predominate over otolith signals in vestibulospinal responses at higher frequencies.

A major focus of work on both vestibulocervical and vestibulospinal reflexes is the spatial organization of the responses and the possible interaction of spatial properties and timing (Baker *et al.*, 1985). Early studies had concentrated on left-to-right motion (yaw) for vestibulocervical reflex studies and on left ear down to right ear down rolling motion for vestibulospinal limb reflex studies. Of course, the vestibular reflexes work to compensate for motion in any direction. The problem of producing the correct direction of reflex response to any direction of disturbance has been considered thoroughly for the case of the vestibulo-ocular reflex that stabilizes the eyes (Chapter 33), but vestibulospinal reflexes present a more difficult situation.

In the case of the vestibulocervical reflex, there are many ways that the more than 30 muscles of the neck could be used to compensate for a particular direction of head rotation. What synergies or coordination of muscle groups does the brain use to generate compensatory vestibulocervical responses? The principles underlying the brain's pattern of coordinated activation of neck muscles to compensate for head rotation are unknown, although some features of spatial organization have been elucidated. Each of the major neck muscles exhibits a characteristic directionality of excitation in response to vestibular stimulation by rotation in many different directions, but that direction does not match the directional sensitivity of any single semicircular canal. Instead, the responses to rapid motions reflect a weighted sum of canal inputs, and various proposals attempt to account for the particular weightings observed.

A complicating feature of vestibulocervical spatial organization is the dependence in some cases of the timing of vestibulocervical neuron or neck muscle activation upon the direction of the vestibular stimulus. This dependence has been termed spatial-temporal convergence and may reflect canal and otolith signal addition to match a varying mechanical load presented by the head for different directions of rotation. Another difficulty in the analysis of vestibulocervical responses

is the presence of signals related to the velocity of eye movement or the direction in which the eyes are pointed within their orbits. Add to this the visual and proprioceptive signals present in vestibulospinal neural circuitry, discussed in the following sections, and the overall picture is one of a rich and complex control system that we are only beginning to understand. Comparable information on the spatial organization of vestibulospinal control of the limbs has begun to reveal a similar complexity.

### The Cervicocervical Reflex Stabilizes the Head by Opposing Lengthening of Neck Muscles

The proprioceptive contribution to reflex stabilization of the head and body has been examined in many of the same ways as vestibular contributions (Peterson *et al.*, 1985). The sensory situation for proprioceptive signals is more complicated than for vestibular signals, as any of the muscles of the neck, trunk, or limbs could provide an input to influence any other muscle or synergistic group of muscles. Only the signals from neck proprioception that activate neck muscles (i.e., the neck stretch reflex or cervicocervical reflex, also called the cervicocollic reflex) have been studied extensively. Like the stretch reflex for limb extensors, the cervicocervical reflex opposes lengthening of the muscles concerned and so is a negative feedback compensatory system. Other proprioceptive systems often are considered postural reactions rather than simple reflexes and are described in turn.

The cervicocervical reflex in alert animals is not consistent, so the reflex has been analyzed by rotating the trunk of decerebrated cats while holding the head fixed in space. This stimulates neck proprioceptors without any vestibular input. The results are reminiscent of the vestibulocervical reflex. At low frequencies of neck rotation cervicocervical reflex muscle contractions correspond to the extent of muscle stretch, but at higher frequencies the responses occur more rapidly, corresponding to the velocity or acceleration of muscle stretch. The directionality of neck muscle responses to stretch matches that of vestibulocervical responses fairly well. Common directionality implies that signals for vestibular and stretch reflexes to neck muscles share some central circuitry. Not only does this directionality not match that of any single semicircular canal, it also does not appear to match the direction of pulling actions of the neck muscles under study. We are left to speculate on the principles of central organization of these reflexes. The central pathways mediating the cervicocervical reflex are more varied still, and less well mapped, than those for vestibulocervical reflex responses. There are homonymous monosynap-

tic stretch reflex connections, heteronymous connections to a muscle from other muscles, and longer pathways that may involve connections through medial, lateral, and descending vestibular nuclei as well as reticulospinal neurons.

### The Brain Stem Controls Coordinated Postural Reactions

A variety of reflexes contribute to the maintenance of overall body posture. All benefit from the integrity of connections with the brain stem, and in some cases higher centers, but not all are characterized as readily by objective measures as the vestibulocervical, vestibulospinal, and cervicocervical reflexes already discussed. The tonic neck or cervicospinal reflexes are the best known of these, but the supporting reactions, placing reactions, righting reactions, hopping or stepping reactions, and others are useful parts of the neural control of posture. The tonic neck reflex adjusts the extension of the limbs in response to the angle of the head on the trunk. Roberts (1967) showed that stretching the neck by rolling the spine to one side elicited tonic flexion and extension of the forelimbs, as if the support surface had been tilted to produce the rotation (Fig. 30.4). The placement of a limb on the ground initiates a set of reflex reactions that stiffen the limb into a supporting pillar. This response is called the "positive supporting reaction" and depends on the integrity of the brain stem. As discussed earlier, righting reactions also depend on the brain stem, and "optical righting reflexes" mediated by vision require an intact cerebral cortex.

Stable posture requires that the feet be not only rigid but placed correctly on a supporting surface, and the placing reactions of quadrupeds contribute to this by moving the feet toward a visible surface (visual placing reaction) or onto a surface that has tactile contact with the top of the foot, chin, or whiskers (tactile placing reactions). Although a tactile placing reaction may be evoked in primitive form in a spinalized animal, it is generally held that at least the lower brain stem must be intact for tactile placing to occur in an effective form. Finally, if balance reactions are insufficient to maintain stable posture, as when the support surface is moved beneath the foot, the limb may hop to a new position where stable posture is possible (hopping reaction).

The action of the righting reflex of cats during falling is familiar to all. Humans show a similar reaction to an unexpected drop, measurable as a short latency electromyographic response in the gastrocnemius muscle. In cats, this response survives blockage of the semicircular canals, but not total labyrinthectomy, and

so appears to be otolith mediated. The action of these many postural reactions in the context of maintenance of posture and balance in intact humans has been the focus of several studies utilizing movable posture platforms.

### Balance Depends on Context-Dependent Postural Strategies

How then do these descending pathways from the brain stem coordinate to produce the postural behaviors of intact animals? The basic problem of standing posture is keeping the center of mass of the body, also called center of gravity, positioned over the base of support provided by the feet so that the body does not topple. The ranges of body positions that rest over the base of support define the limits of stability. When the extremes of body sway extend beyond those limits, the body must reduce them, take a step, or fall. An important tool for exploring body stability is the posture platform, a base on which subjects can stand and be subjected to displacements of the underlying supporting surface. The posture platform is used with body position sensors and electromyography to evaluate standing posture (Nashner, 1982; Horak and Nashner, 1986; Horak and Shupert, 1994). Even on a perfectly stable support surface with vision, somesthesia, and vestibular sense all active, a standing person will sway slightly. This sway will increase as the context is altered by distorting or removing sensory input, showing the importance of the multiple avenues of balance information but also showing the adequacy of limited sensory input in maintaining upright posture. When the eyes are closed (the Romberg test used in clinical evaluation), sway is greater. When the visual surround is linked to the subject's head position in the condition called "sway referencing of vision," visual information is misleading and sway is increased. When the support surface is compliant, proprioceptive feedback is much less useful, and sway is greater. When the support surface tilts along with the body in the condition called "sway referencing of the support surface," proprioceptive information is misleading and sway is increased. When the preceding conditions are combined, sway is greater still but normal subjects can maintain upright posture through the use of vestibular information.

Sudden displacement of the platform on which a subject stands allows measurement of the latencies and patterns of electromyographic activity in the postural muscles of the legs. When the subject is standing on a large platform that is displaced forward or backward, the leg muscles contract in sequence from ankle to thigh to hip, and motion occurs primarily about the

ankle joint. When the platform displacement is forward, the ankle flexor tibialis anterior on the front of the calf is first to be excited (flexion is the toe-up direction), at about 80–100 ms after the displacement. This is followed about 20 ms later by contraction of the quadriceps thigh muscles and then later still by contraction of trunk musculature. Backward displacement first elicits excitation of the gastrocnemius muscle at the back of the calf to extend the ankle, followed by excitation of thigh and trunk muscles antagonistic to those excited by forward displacement (Fig. 30.5). The overall postural reaction of distal-to-proximal excita-

**FIGURE 30.3** Vestibular and proprioceptive reflex signal inputs and major pathways from the brain stem vestibular nuclei. The medial vestibulospinal tract projects bilaterally to the cervical spinal cord to mediate the vestibulocollic reflex. The lateral vestibulospinal tract descends to lumbar levels of the spinal cord to influence limb extensors involved in balance. Neck muscle proprioceptors send signals to vestibular nuclei to participate in cervicocollic reflexes and interactions among reflexes, d, descending vestibular nucleus; l, lateral vestibular nucleus; m, medial vestibular nucleus; s, superior vestibular nucleus; VST, vestibulospinal tract.

tion has been termed an “ankle strategy” for maintaining balance.

Although the ankle strategy was confirmed in all subjects tested with simple forward–backward displacement, other strategies are available, and postural reactions adapt to alterations in the support surface or sensory inputs. Displacement of a support surface that is short compared to the foot, or rotation of the support instead of displacement, demands a different postural response. A second strategy that can be adopted when ankle strategy is contraindicated is the hip strategy, in which the body is bent at the hips so that the lower half of the body moves in the same direction as it does during ankle strategy reactions while the upper body moves in the opposite direction. Thus, during a forward, front downward tilt of a supporting platform, the hips move backward and the head forward. This shifts the center of gravity, which has moved forward due to the displacement, backward so that it is placed over the support again. Other work has questioned the prevalence of ankle strategy and documented a stiffening strategy of muscle cocontraction in response to base rotation and a multilink strategy that includes ankle, hip, and neck joint motions in response to translation. Stiffening, ankle, and hip or multilink strategies are applicable to the sway that occurs during normal standing on commonly encountered kinds of surfaces and may represent basic units of postural reaction.

Like simple reflexes, these postural reactions represent neurally mediated negative feedback responses. However, postural reactions differ from ordinary reflex responses in the degree of their dependence on context and recent experience. It also appears that the postural strategies are not mutually exclusive, but are more like additive units or building blocks. When Horak and Nashner placed subjects on support surfaces intermediate in length between the long surfaces associated with ankle strategy and the short surfaces associated with hip strategy, they found that subjects adopted complex strategies that they believed represented combinations of ankle and hip strategies with different magnitudes and temporal relations. In addition, they found that during the first few trials after switching from one length of support surface to another, the subjects’ responses in part reflected the previous surface, only gradually shifting from one strategy to another over several trials.

The range of postural reactions recorded from standing human subjects argues for a complexity beyond that observed in the vestibulocervical or vestibulospinal reflexes studied during rotation or tilting of animal subjects, but it is not yet clear whether this complexity reflects the rich variety of strategies that

can achieve the single goal of balance or whether there are strong constraints on postural responses that arise from the complicated biomechanics of the multijoint system of the body. Balance is subject not only to the static requirement for location of the center of mass over the support provided by the feet, but also to dynamic factors that accompany the rapid movement of massive body parts. Inertia, viscosity, and elasticity act at each of the major joints, and the task of measuring or modeling these factors and their interactions has barely begun.

Experimental animals can also be placed on posture platforms, which in the case of quadrupeds can consist of four small pads for the limbs (Macpherson and Ingliss, 1993). Among other findings, these experiments confirm the disability of animals with spinal transection in maintaining erect posture. A surprising finding from these animal studies is that even though vestibular information from head motion accompanying body displacement is vigorous and early enough to guide reflex responses, cats are able to maintain apparently good quadrupedal standing posture and responses to unexpected motion after total labyrinthectomy. Clearly, we have a great deal to learn about the management by the brain of the many systems that contribute to posture and balance (Box 30.2).

### **Vestibular Damage Results in Disorders of Postural Control**

Control of posture involves many levels within the nervous system, and it is not surprising that disorders of posture can result from damage to the sensory periphery or to telencephalic, cerebellar, brain stem, or spinal centers. The striking motor consequences of lesions of the basal ganglia may include profound effects on posture, such as the rigidity and general poverty of movement associated with Parkinson’s disease (Chapter 31). Damage to the anterior vermis of the cerebellum can exaggerate decerebrate rigidity, and cerebellar patients show poorer performance in posture platform situations, with less adaptive modification of responses, as might be expected from our knowledge of cerebellar function (Chapter 32).

Many of the more plainly visible postural disorders stem from damage to the vestibular system. Diseases of the vestibular system that affect posture (and generally also cause dizziness) include vestibular neuritis, peripheral or central tumors or infarction, and Meniere’s syndrome (Baloh and Honrubia, 1990) (Box 30.4). Bilateral involvement and acute, episodic, or chronic time courses can occur in many vestibular disorders. The most obvious form of vestibular system damage is unilateral labyrinthectomy, performed

## BOX 30.2

## VESTIBULAR PLASTICITY

The experience of sailors getting their “sea legs” suggests that, in addition to the role of context and choice of strategies we have discussed, postural reflexes and balance are adapted gradually over time for better performance in new circumstances. Clear evidence for this general phenomenon comes from the study of postural control in astronauts. After a space flight, astronauts initially rely more heavily than before on visual cues for postural orientation, and they show degraded performance in their

responses to disturbances generated by a posture platform. Sway during standing is increased dramatically when visual cues are removed, and the body segments move in a less coordinated manner than before space flight. Still, the performance of astronauts after the experience of space flight is quite remarkable; they are able to balance adequately within hours of landing and regain their preflight postural performance within a few days.

## BOX 30.3

## MENIERE SYNDROME

The typical patient with Meniere syndrome develops a sensation of fullness and pressure along with decreased hearing and tinnitus in one ear. Vertigo follows rapidly, reaching a maximum intensity within minutes and then slowly subsiding over several hours. Often the patient is left with a sense of unsteadiness and nonspecific dizziness that can go on for days after the acute vertiginous spell. In the early stages, hearing loss is completely reversible, but as the disease progresses, residual hearing loss becomes a prominent feature. The tinnitus typically is described as a roaring sound similar to the sound of the ocean. These episodes occur at irregular intervals over years, with periods of remission unpredictably intermixed. Eventually, most patients reach the so-called “burnt out phase,” where the episodic vertigo disappears and severe permanent hearing loss remains.

The clinical syndrome was first described by Prosper Meniere in 1861, but Hallpike and Cairns made the initial clinical-pathological correlation with hydrops of the labyrinth in 1938. Patients with Meniere syndrome invariably show an increase in volume of endolymph associated with distention of the entire endolymphatic system. Herniations and ruptures in the membranous labyrinth commonly occur, which may explain the episodes of hearing loss and vertigo.

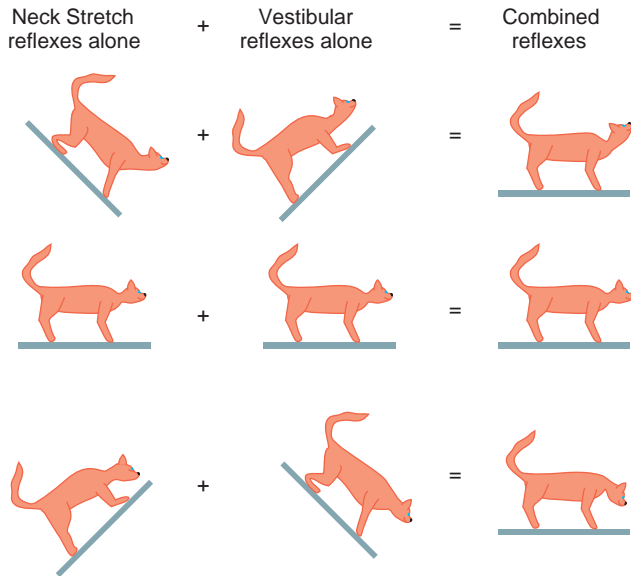

Delayed endolymphatic hydrops occurs in an ear that has been damaged years before, usually by infection. With this disorder, the patient reports a long history of hearing loss, typically since childhood, followed many years later by episodic vertigo but without the typical auditory symptoms. The pathologic findings are remark-

ably similar to idiopathic Meniere syndrome, suggesting a common etiology. A subclinical viral infection could damage the resorptive mechanism of the inner ear, leading to an eventual decompensation in the balance between secretion and resorption of endolymph.

The key to the diagnosis of Meniere syndrome is to document fluctuating hearing levels in a patient with the characteristic clinical history. In the early stages, the sensorineural hearing loss is usually greater in the low frequencies. Some patients with Meniere syndrome develop abrupt episodes of falling to the ground without loss of consciousness or associated neurologic symptoms. These episodes have been called “otolithic catastrophes” because they are thought to result from a sudden mechanical deformation of the otolith receptor organ. Patients often report feeling as though they were pushed to the ground by some external force.

Because the cause of Meniere syndrome is usually unknown, treatment is empiric. Medical management consists of symptomatic treatment with antivertiginous drugs and long-term prophylaxis with salt restriction and diuretics. Many different surgical procedures have been tried but none has been consistently effective. Shunt operations to decrease the endolymph pressure have not been successful because the implanted drain devices are encapsulated rapidly by fibrous tissue. Destructive surgeries (removing the labyrinth or cutting the vestibular nerve) can stop the episodes of vertigo but do not change the tinnitus and progressive hearing loss.

**FIGURE 30.4** Operation of the tonic neck reflex in quadrupeds. The left column shows the operation of neck-to-limb proprioceptive reflexes (cervicospinal reflexes), the center column the static vestibulospinal reflexes, and the right column the antagonistic nature of their summed responses. A straight limb orthogonal to the trunk indicates a neutral posture, as in the middle row and right column of stick figures. A limb extended away from the center of the stick figure represents reflex extension (e.g., forelimb in upper left stick figure), and a reflexively flexed limb is shown in two segments (e.g., hindlimb in upper left stick figure). Based on work by Roberts.

either experimentally in animals or as the result of disease or surgical intervention against disease in humans. The postural symptoms immediately following loss of vestibular input to one side of the brain vary across species, with nonmammalian and “lower” mammalian species typically showing a more prominent tilting of the head and body toward the side of damage. Vestibular afferents have a high level of resting activity, and leaning toward the side of lost vestibular signals makes sense in that the spontaneous or resting activity of the remaining vestibular apparatus is signaling, in effect, motion toward the intact side because it is not balanced by equal resting activity from the damaged side. To counter this neural stimulus, the affected individual tilts away from the directions of apparent motion. This static postural effect of unilateral labyrinthectomy is accompanied by dynamic postural deficits, seen in experimental animals as weakened ipsilateral limb extensor responses and delayed responses to sudden drops. Compensation for unilateral labyrinthectomy occurs over a period of a few weeks, during which there is considerable recovery.

Patients with long-standing bilateral loss may perform well on posture platforms when visual and

**FIGURE 30.5** Sequencing of muscle activation in response to displacement of a supporting platform. When the supporting surface is displaced backward (at 0 ms), flexor muscles are excited first in the distal lower limb segments (gastrocnemius, about 80 ms latency) and then in the proximal segment (hamstrings, about 100 ms latency). Forward displacement of the platform activates lower limb extensors, again in a distal (tibialis anterior) to proximal (quadriceps) sequence. Black arrows mark the first detected electromyographic response to displacement. Based on studies by Horak and Nashner.

somatosensory cues are present, but fail completely to maintain upright stance when the support surface and visual surround both sway with the patient so that only vestibular information is accurate. Patients with recent bilateral vestibular loss or who have not yet compensated for vestibular loss also do poorly when vision and support surface are unreliable, but these patients perform poorly if only one sense, be it vision or somatic sense, is made an unreliable indicator of balance.

## Summary

Axons from vestibular and reticular nuclei in the brain stem descend in pathways located ventromedially in the spinal cord to provide postural tone and balance. Balance is maintained by negative feedback reflexes that are stimulated by the vestibular canals and otoliths. The vestibulocervical reflex excites neck muscles via the medial vestibulospinal tract to oppose head tilt, and vestibulospinal reflexes carried by the lateral vestibulospinal tract excite ipsilateral limb extensors to oppose body tilt. Vestibular, muscle stretch, and other reflexes work together to coordinate posture and balance, and the medial system adopts

different strategies for balance control depending on the body support surface and information from sensory inputs. The medial postural system can adapt to different postural situations, but its actions can be compromised by central neural damage or unbalanced by peripheral vestibular loss. The reflexive control of body stability and posture by the medial descending system allows the lateral descending system to specialize in execution of precise voluntary movements of the extremities.

## THE LATERAL VOLUNTARY SYSTEM

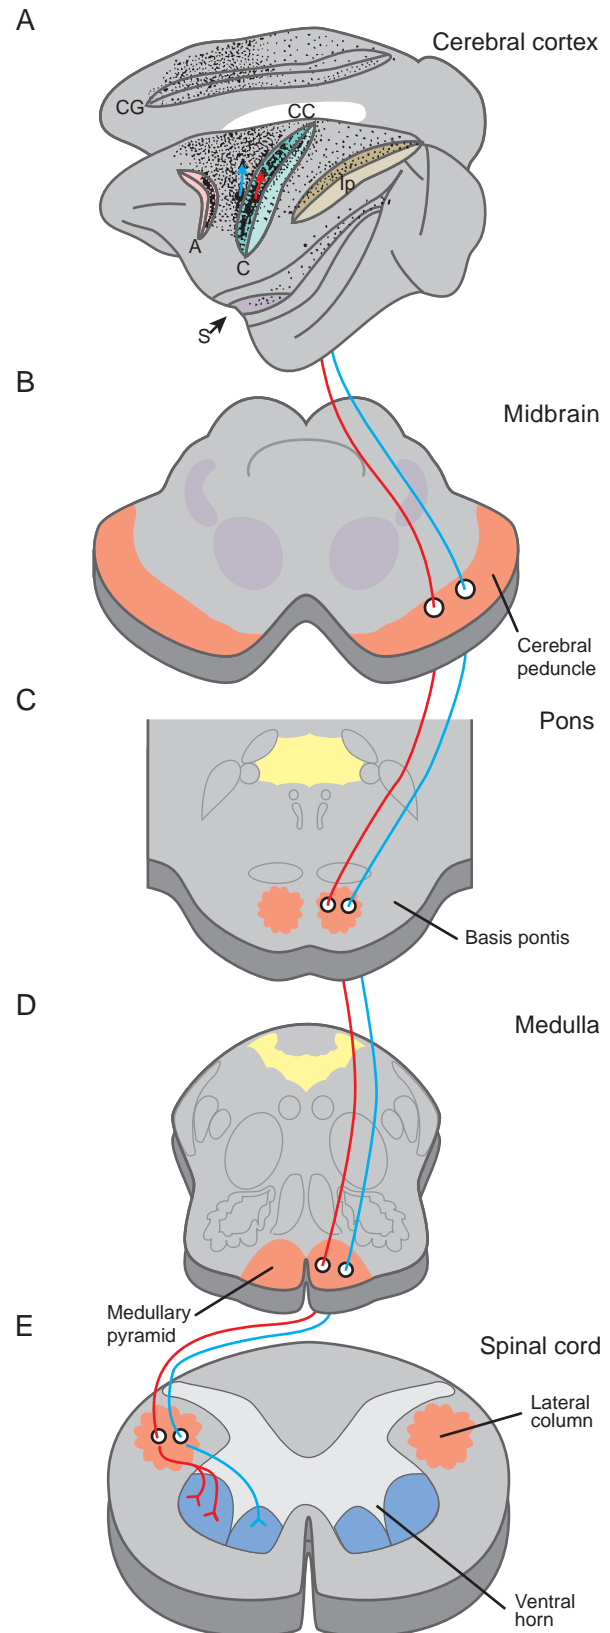

The medial system thus provides underlying postural control for stance, ambulation, and orientation of the head; the lateral system superimposes the ability to make more sophisticated, voluntary movements in response to complex features of the external environment (perceived through the senses) and internal state (stored memories, knowledge, and emotion). Much of this control is mediated by specialized regions of the cerebral cortex. Outflow from this motor cortex dominates the lateral descending system, particularly in primates and humans.

### Components of the Lateral Voluntary System

#### *The Corticospinal Projection Is the Most Direct Pathway from the Cerebral Cortex to Spinal Motor Neurons*

For more than a century, electrical stimulation of a limited portion of the frontal lobe of the cerebral cortex has been known to evoke movements. Electrical stimulation of this "excitable cortex" evokes movements readily because this region has relatively direct connections to spinal motor neurons. In primates with a central sulcus (Rolandic fissure) in the neocortex, cortical neurons with axons projecting to the spinal cord are found most densely in the anterior bank of the central sulcus. The density of such neurons decreases from there rostrally to the precentral sulcus (posterior bank of the arcuate sulcus in macaque monkeys) and medially to the cingulate sulcus (Fig. 30.6). This territory corresponds to cytoarchitectonic areas 4 and 6 of Brodmann. Additional corticospinal neurons in areas 1, 2, 3, 5, and 7 of the parietal lobe project to the dorsal horn of the spinal cord to regulate sensory inflow.

The axons of neurons that project from the cerebral cortex to the spinal cord constitute the corticospinal tract. Corticospinal neurons have large pyramid-shaped somata in cortical layer Vb. Their axons leave the cortex, pass through the centrum semiovale, and

◀ **FIGURE 30.6** The corticospinal projection in the macaque monkey. (A) The density of corticospinal neuronal somata is shown by stippling in this lateral view of the left cerebral hemisphere; the superior medial surface of the hemisphere is also shown (above) as if reflected in a mirror. The central sulcus (C), arcuate sulcus (A), cingulate sulcus (Cg), intraparietal sulcus (Ip), and Sylvian fissure (S) are drawn as if pulled open to reveal the neurons in their banks. Two schematic corticospinal neurons, one relatively posterior and the other relatively anterior in area 4, send their axons down through the midbrain (B), pons (C), medulla (D), and spinal cord (E), which are drawn in cross-section. In the spinal cord, the former corticospinal axon leaves the lateral column to terminate in the dorsolateral ventral horn, whereas the latter axon terminates in the ventromedial ventral horn.

enter the internal capsule, along with many other axons from other cortical areas. The corticospinal axons are concentrated most heavily in the middle third of the posterior limb of the internal capsule. As axons descend from the internal capsule below the thalamus, they come to lie on the ventral surface of the brain stem. Here, they form the cerebral peduncle of the midbrain, where the corticospinal axons are concentrated in the middle third. The axons of the peduncle become intermixed with pontine nuclear neurons in the base of the pons (basis pontis). Most of these axons synapse on pontine neurons and end here, providing input from the cerebral cortex to the cerebellum. The continuing corticospinal axons collect to form the medullary pyramid (Box 30.4). As the medulla blends into the spinal cord, the vast majority of corticospinal axons cross the midline and enter the lateral column of white matter on the opposite side of the spinal cord. Because of this decussation of the pyramidal tract, the left

motor cortex controls movements on the right side of the body and vice versa. A small minority of corticospinal axons remain uncrossed and continue caudally as the ventral (or anterior) corticospinal tract near the ventral midline of the spinal cord.

As descending corticospinal axons reach their target levels in the spinal cord, they enter the spinal gray matter, where they ramify and synapse. Whereas the majority of corticospinal axons synapse on premotor interneurons in the intermediate zone (Rexed's laminae VII and VIII), a minority of these axons synapse directly on motor neurons in Rexed's lamina IX. The somata of most corticospinal neurons that make such monosynaptic connections to motor neurons lie posteriorly in area 4, and their monosynaptic connections are made on the motor neurons of distal limb muscles, whose somata are clustered in the dorsolateral ventral horn. Corticospinal axons from neurons located more anteriorly typically synapse in the ventromedial portion of the ventral horn, where the motor neurons of proximal limb muscles and axial muscles are located. Some corticospinal axons cross the midline spinal gray matter to reach the ventromedial ventral horn ipsilateral to their origin; such doubly decussating corticospinal axons, along with the uncrossed ventral corticospinal tract, may be partly responsible for the relative preservation of trunk and proximal limb movements after unilateral damage to the cortex.

#### *Indirect Pathways to the Spinal Cord Involve Centers in the Brain Stem*

The corticospinal tract is not the only output pathway through which the cerebral cortex contributes to motor control (Kuypers, 1987). The presence of

#### BOX 30.4

### PYRAMIDS IN THE BRAIN

Inspection of cross-sections through the ventral surface of the medulla reveals a structure that looks like a small pyramid. This medullary pyramid turns out to be the collected bundle of corticospinal axons. The corticospinal tract therefore often is referred to as the pyramidal tract.

Axons of noncorticospinal descending pathways do not pass through the medullary pyramid and therefore can be described collectively as extrapyramidal pathways. At one time these pathways were thought to receive their major controlling inputs from the basal ganglia. Human neurologic disorders that result from dysfunction of the basal ganglia thus came to be known as "extrapyramidal

syndromes." This term is misleading, however. More recent work has shown that many of the brain stem nuclei giving rise to extrapyramidal pathways receive cortical input and that much of the output of the basal ganglia is directed via the thalamus back to cortical motor areas. Many manifestations of extrapyramidal syndromes may therefore be played out through cortical motor areas, even via the pyramidal tract. Indeed, surgical lesions of the pyramidal tract once were used to ameliorate some extrapyramidal syndromes.

*Marc H. Schieber and James F. Baker*

other, indirect pathways in the macaque has been demonstrated by cutting the medullary pyramid on one side. Stimulation of the cortex on that side still evoked contralateral movements. The somatotopic organization of the cortex in the operated animals was similar to that in normal macaques, although the thresholds for stimulation were raised and distal movements were evoked less often.

Intermixed with corticospinal neurons in layer V of areas 4 and 6 are corticorubral neurons, whose axons project to the red nucleus (RN). Some corticospinal axons also send collaterals to the RN. In addition to cortical inputs, the RN also receives considerable input from the cerebellum (Chapter 32). Many RN neurons, particularly those in the caudal, magno-cellular portion, in turn send their axons across the midline and into the lateral column of the spinal cord, terminating most heavily in the dorsolateral region of the ventral horn. These descending axons from the RN constitute the rubrospinal tract. An indirect pathway thus exists from the cortex to the RN to the spinal cord. Although the rubrospinal tract is less prominent in humans than in nonhuman primates and carnivores, the activity of rubrospinal neurons indicates that they also play a significant role during voluntary movements of the arm, hand, and fingers. The rubrospinal pathway thus works synergistically with the corticospinal pathway in controlling limb movements.

A second indirect pathway involves neurons scattered in the medial reticular formation of the pons and medulla. The medial reticular formation receives input from cortical motor areas and projects via the ventral column of the spinal cord to the ventral horn, chiefly its ventromedial portion. The axons that make this projection constitute the reticulospinal tract. Although the reticulospinal tract is also part of the medial descending system, the activity of some reticular formation neurons indicates that they also participate in controlling reaching movements.

## Organization of the Motor Cortex

The original "motor cortex" is now appreciated to be comprised of several cortical areas. These areas are considered "motor" because (1) they project to other motor structures, (2) their ablation causes deficits in movement, and (3) their stimulation evokes or alters movements.

### *The Motor Cortex Is Subdivided into Multiple Cortical Motor Areas*

In addition to its descending projections to spinal motor neurons, the motor cortex has cytoarchitectonic features that distinguish it from other regions of the

cerebral cortex. The somata of many pyramidal neurons in layer V, the output layer, are exceptionally large (Betz cells). In addition, the neurons of layer IV, the granular layer that receives thalamic input, are very sparse compared to other areas of the neocortex, and hence the motor cortex has been described as dysgranular (area 6) or agranular (area 4) cortex. Based on cytoarchitectonics, myeloarchitectonics, and histochemical features, the motor cortex of macaque monkeys can be subdivided into the cortical motor areas shown in Figure 30.7. In general, these subdivisions show three mediolaterally oriented strips of cortex, with the primary motor cortex (M1) most posterior and two premotor strips progressively more anterior. Each of these premotor strips has a subdivision on the medial wall of the hemisphere, a second subdivision on the dorsal convexity, and a third on the ventral convexity. In addition to these subdivisions of Brodmann's areas 4 and 6, areas 23 and 24 in the banks of the cingulate sulcus and on the medial surface of the hemisphere in the cingulate gyrus contain at least two additional cortical motor areas. Cortical motor areas differ, not only in their intrinsic composition, but also in their interconnections with other parts of the central nervous system.

Cortical motor areas differ in their connections with the thalamus. M1, PMv, and SMA, for example, connect primarily with VPLo/VLc, area X, and VLo in the thalamus, respectively. These differences are significant because thalamic nuclei VPLo/VLc and area X receive major inputs from the cerebellum, whereas VLo receives major input from the basal ganglia. Thus, information processed by the cerebellum is directed largely to M1 and PMv, whereas information from the basal ganglia is sent largely to SMA.

Cortical motor areas also differ in their connections with one another and with other regions of the cortex (Fig. 30.7). For example, when horseradish peroxidase (HRP) is injected into the hand region of M1, separate pockets of retrogradely labeled neuronal somata are found in PMv, PMd, SMA, CGc, and CGr, indicating that each of these areas sends a separate projection to the hand region of M1. In contrast, PMvr, PMdr, and pre-SMA do not project directly to M1. Instead, PMvr projects to PMvc, PMdr projects to PMdc, and pre-SMA projects to PMvr.

Different cortical motor areas also receive input from different cortical sensory and association areas: M1 receives input from the primary somatosensory area (S1), PMv receives input from visual association area 7b, and PMd receives input from somatosensory association area 5. Because of these inputs, many motor cortex neurons have somatosensory receptive fields. Neurons located caudally in M1 tend to respond to

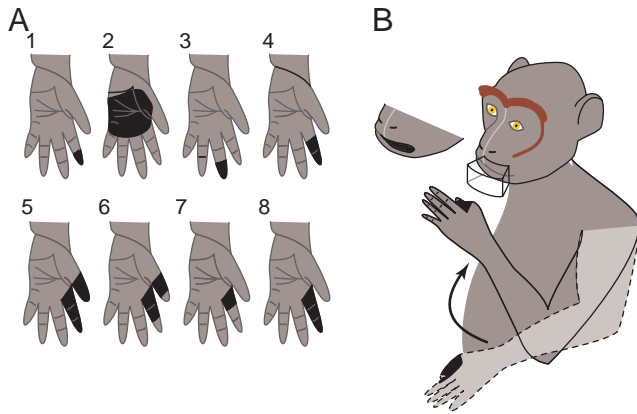

**FIGURE 30.7** Cortical motor areas. (A) Diagram of a macaque brain showing current parcellation of cortical motor areas in the frontal lobe. Modified from Matelli *et al.* (1991). (B) Connections of the cortical motor areas. Most corticocortical connections are reciprocal. CGc, cingulate motor area, caudal; CGr, cingulate motor area, rostral; M1, primary motor cortex; PMdc, premotor cortex, dorsal caudal; PMdr, premotor cortex, dorsal, rostral; PMvc, premotor cortex, ventral, caudal; PMvr, premotor cortex, ventral, rostral; Pre-SMA, presupplementary motor area; SMA supplementary motor area proper. Thin lines to the spinal cord from PMvc, PMdc, SMA, and CGc indicate that corticospinal projections from these areas are not as strong as that from M1.

cutaneous modalities, whereas neurons located rostrally in M1 tend to respond to deep modalities. The somatosensory input of an M1 neuron is generally related to the output function of that neuron. For example, caudally located M1 neurons that control fingers may have cutaneous receptive fields on the fingers (Fig. 30.8A), whereas more rostrally located M1

neurons that control the biceps or triceps may have deep receptive fields in those muscles.

Somatosensory inputs to M1 also help mediate long loop responses; that is, muscular responses that occur too slowly to be mediated by the monosynaptic stretch reflex (Chapter 29) but too quickly to be considered voluntary reactions. For example, when a subject holds

**FIGURE 30.8** Sensory receptive fields in M1 and PMv. (A) Black regions show the tactile receptive fields of eight M1 neurons recorded at loci where intracortical microstimulation evoked flexion of the monkey's index and middle fingers. Other neurons at the same loci responded to passive extension of those fingers. From Rosen and Asanuma (1972). (B) A single PMv neuron responded to visual stimuli moving near the mouth, to tactile stimulation of the lips and of the skin between the thumb and the index finger, and to flexion of the elbow. From Rizzolatti *et al.* (1981).

a handle that suddenly jerks away, extending the elbow and stretching the biceps, three distinguishable waves of contraction may be recorded in the biceps. The first wave is the monosynaptic reflex produced by stretching the muscle; the third wave is the subject voluntarily pulling back on the handle. The middle wave occurs at a latency consistent with the conduction of impulses from muscle afferents to the cortex and then almost directly back from M1 to spinal motor neurons. Many biceps related M1 neurons discharge a burst of impulses at a time appropriate to contribute to this long loop response. Interestingly, the strength of the long loop response may be increased if the subject plans to pull on the handle by contracting the biceps and decreased if the subject plans to push on the handle by relaxing the biceps; parallel changes may occur in the bursts of the M1 neurons. Thus, long loop responses are affected by the motor plans of the subject.

PMv receives both somatosensory and visual input via area 7b. Both the somatosensory and the visual receptive fields of PMv neurons tend to be large, and when single PMv neurons receive both types of sensory information, the fields tend to be related (Fig. 30.8B). A neuron with a somatosensory receptive field covering the forearm, for instance, may respond to visual stimuli moving near the forearm. Interestingly, if the forearm is moved to a different position, the visual receptive field of the PMv neuron moves with the forearm.

### *Somatotopic Organization in the Motor Cortex Is Not a One-to-One Map of Body Parts, Muscles, or Movements*

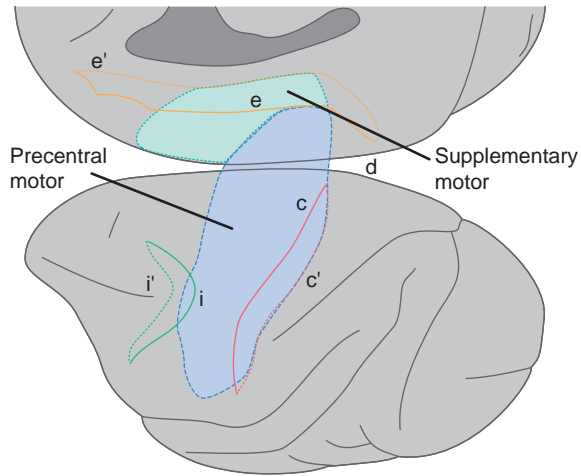

The organization of the primary motor cortex, M1, has been studied more extensively than that of other cortical motor areas. Within the M1 of primates, the face is represented laterally, the lower extremity (or hindlimb and tail) medially, and the upper extremity (or forelimb) in between (Fig. 30.9). This overall organization of M1 according to major body parts is termed somatotopic. The somatotopic organization of M1 becomes evident in clinical neurology. Lesions on the lateral convexity of human M1 cause weakness or paralysis of the contralateral face, more medial lesions on the convexity affect the contralateral hand and arm, and lesions on the medial wall of the hemisphere affect the leg and foot.

Moreover, distal parts of the extremities and acral parts of the face (lips and tongue) are most heavily represented caudally, whereas proximal parts of the extremities and axial movements are most heavily represented rostrally. Those parts of the body that are used for fine manipulative movements (such as lips, tongue, and fingers in primates) are generally represented over a wider cortical territory than body parts used in gross movements such as ambulation. Penfield, in his cartoon of the motor homunculus (little man), and Woolsey, in his cartoon of the motor simiusculus (little monkey), conveyed this apparent magnification of certain body parts with respect to cortical territory by distorting the size of body parts relative to their normal proportions.

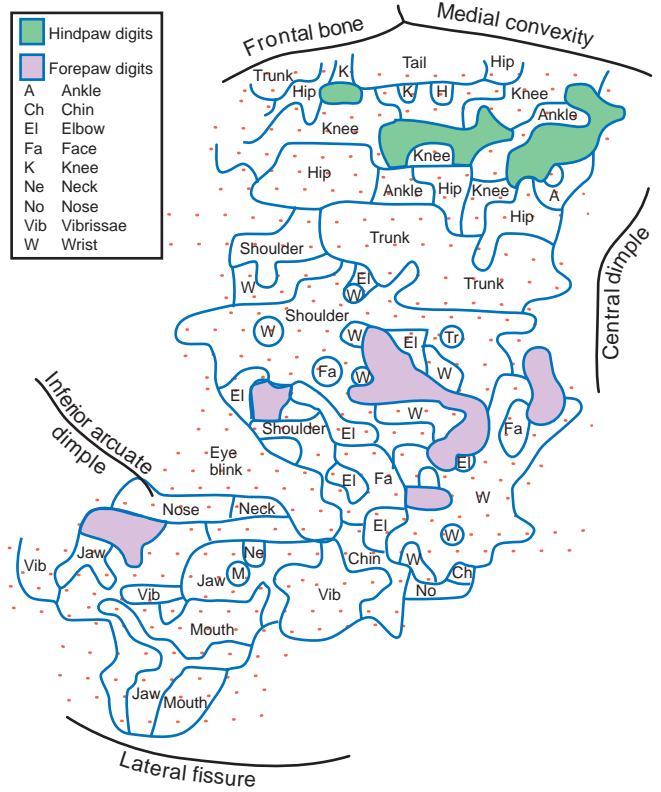

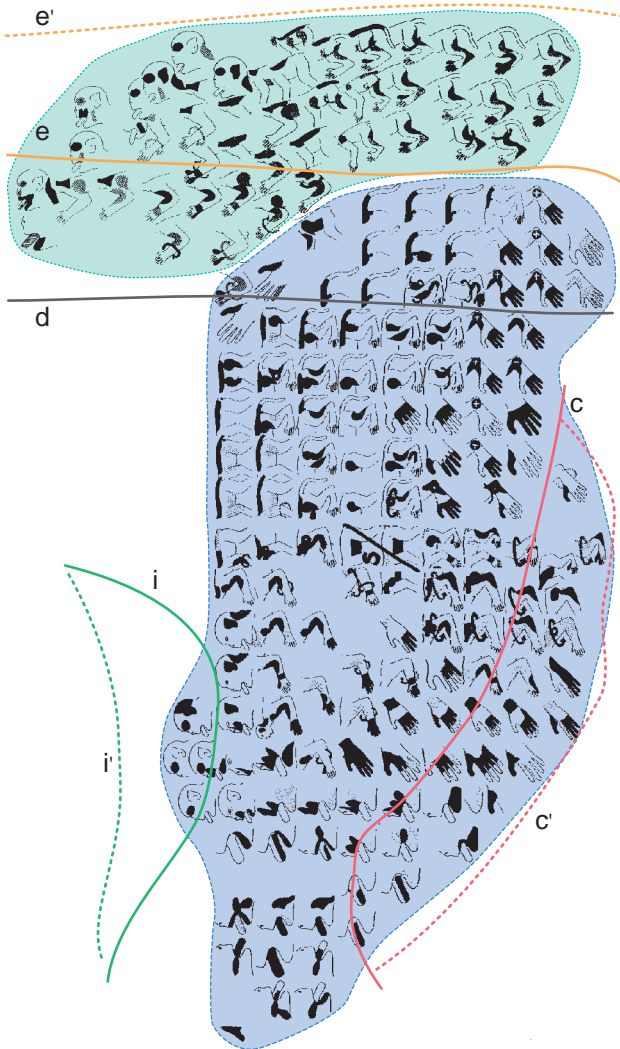

The somatotopic organization of M1 is not, however, a one-to-one mapping of body parts, muscles, or movements. Within the arm representation, for example, the

**FIGURE 30.9** Somatotopic maps in M1. (A) Map by Woolsey and coworkers (1952) in which each figurine represents in black and gray the body parts that moved a lot or a little, respectively, when the cortical surface at that site was stimulated. In addition to the primary representation on the convexity, their map shows a secondary representation on the medial surface of the hemisphere, called the supplementary motor area (SMA). As defined in this study, M1 and SMA each included several of the currently defined cortical motor areas. (B) Intracortical microstimulation of M1 in an owl monkey produced this map, consisting of a complex mosaic of different body parts. In this species, the central sulcus is only a shallow dimple, and M1 is entirely on the surface of the hemisphere. Each dot represents a stimulated locus, and lines surround adjacent loci from which movement of the same body part was evoked. Note that the forepaw digits (purple) and the hindpaw digits (green) are represented in multiple areas separated by areas representing nearby body parts. Modified from Gould *et al.* (1986). In both A and B, the inset at the top indicates the region of the frontal lobe enlarged below.

A

B

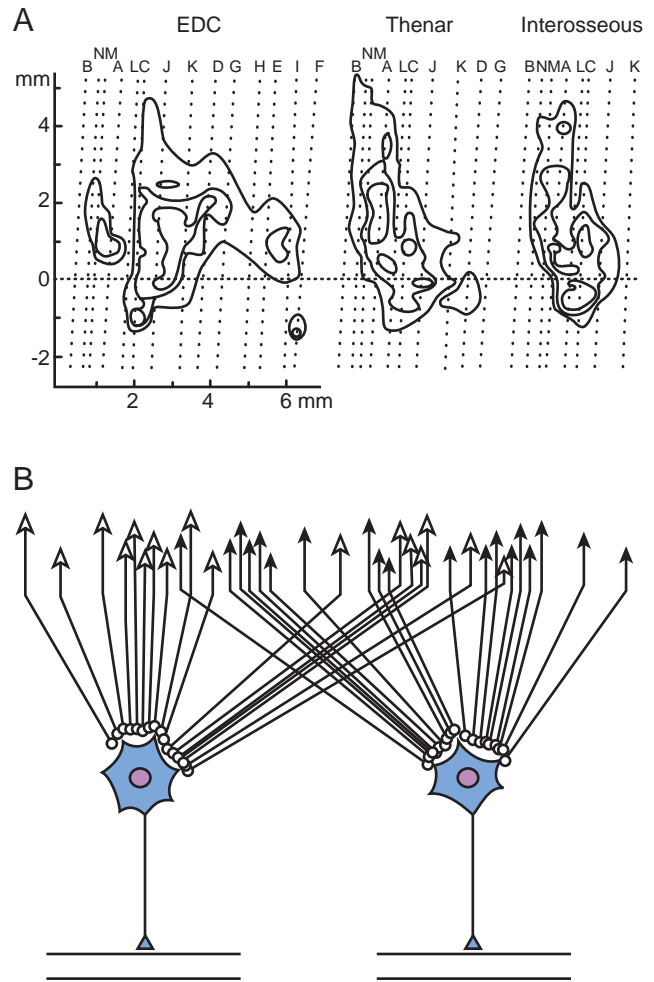

cortical territory representing any particular part of the arm overlaps considerably with the territory representing nearby parts. This overlap results from three features of M1's organization: convergence, divergence, and horizontal interconnection.

M1 outputs arising from a wide cortical territory converge on the spinal motor neuron pool of single muscles. Convergence of M1 outputs has been shown by delivering intracortical microstimulation while observing the body for evoked movements and/or recording electromyographic (EMG) activity from multiple muscles. Maps of which body parts move or which muscles contract upon threshold stimulation at different cortical sites look like a complex mosaic (Fig. 30.9B). As the stimulation current is increased, the mosaic pieces representing a given muscle coalesce into a larger and larger territory that overlaps more and more with the territories of other muscles (Fig. 30.10A). These findings indicate that any given muscle is controlled by a large territory in M1 and that the territories for different muscles overlap (Fig. 30.10B). Using retrograde transneuronal tracing with rabies virus, these large and overlapping cortical territories for different muscles recently have been demonstrated anatomically as well.

A second factor contributing to the overlap of territories in M1 is the divergence of output from single cortical neurons to multiple motor neuron pools. Intracellular staining has shown that a single corticospinal axon may have terminal ramifications within the motor neuron pools of multiple muscles over several segmental levels of the spinal cord (Fig. 30.11A). Moreover, spike-triggered averaging of EMG activity has demonstrated that single M1 neurons can have relatively direct effects on the motoneuron pools of multiple muscles (Fig. 30.11B). These findings indicate that single M1 neurons have output connections to the spinal motoneuron pools of multiple muscles (Fig. 30.11C).

A third factor contributing to overlapping representation is the horizontal interconnectivity intrinsic to M1. Although most horizontal axon collaterals of neurons in layer V extend only 1–2 mm, some extend across the upper extremity representation, interconnecting even the territories of proximal and distal muscles.

Because of convergence, divergence, and horizontal interconnections, neuronal activity is widely distributed in M1 during natural movements, even discrete movements of single body parts. In monkeys trained to perform individuated movements of each finger, single M1 neurons are active during movements of multiple fingers, and neurons throughout the M1 hand area are active during movements of any given finger.

**FIGURE 30.10** Convergence of M1 outputs to single muscles. (A) Isothreshold contours show the points at which EMG responses were evoked in three different muscles—extensor digitorum communis (EDC), thenar, and first dorsal interosseus—by intracortical microstimulation in the anterior bank of the central sulcus. (B) Data shown in A indicate that the cortical input to the motor neurons of any muscle originates from a wide territory in M1 and that the cortical territory providing input to a given muscle overlaps extensively with the cortical territory providing input to other muscles in the same part of the body. Modified from Andersen *et al.* (1975).

Likewise, in humans performing movements of different fingers, activity is distributed over the entire M1 hand representation whether the subject is moving a single finger or the whole hand. Although the entire hand representation may be activated for movement of any given finger, monkey and human studies have shown a tendency for the center of activation during movements of the thumb to be located laterally to that for movements of other fingers, consistent with the somatotopic orientation of the hand in the classic simiusculus and homunculus.

**FIGURE 30.11** Divergence of M1 outputs to multiple muscles. (A) Tracing of a single corticospinal axon ramifying in the ventral horn of the spinal cord shows terminal fields in the motor neuron pools of four forearm muscles. From Shinoda *et al.* (1981). (B) Action potentials in a cortical neuron (top trace) are followed at a fixed latency by peaks of postspike facilitation in EMGs recorded from four of six forearm muscles (lower traces), consistent with monosynaptic excitation of all four motor neuron pools by that cortical neuron. The EMGs are rectified and averaged responses to 7051 action potentials in the cortical neuron. From Fetz and Cheney (1980). (C) These anatomic and physiologic findings indicate that the output of single corticospinal neurons often diverges to influence multiple muscles. From Cheney *et al.* (1985).

The somatotopic representation in M1, like that in the primary somatosensory cortex, has a certain degree of plasticity. The cortical territory representing a given muscle can enlarge when nearby body parts are denervated experimentally. Threshold stimulation in the cortical territory that had represented a denervated body part then comes to evoke movements in nearby body parts. Enlargement of a given muscle's cortical territory occurs as well when that muscle is stretched passively or used intensely for a prolonged period. Furthermore, in normal humans who are actively practicing a complex sequence of finger movements, the cortical territory representing a given finger muscle enlarges as the subjects become skilled at performing the sequence. Because such changes can occur within several minutes, they probably are mediated by long-term potentiation and/or depression at existing synapses. This ability of the M1 cortex to reorganize may in part underlie motor recovery seen in humans after damage to M1 or the corticospinal tract.

### Control of Voluntary Movements by the Motor Cortex

Several methods have enabled investigators to explore how cortical motor areas contribute to the production and control of voluntary movement in awake, behaving subjects. Whereas microelectrodes record the action potentials of single neurons, measurements made by functional imaging or by recording surface potentials reflect the net activity of thousands of cortical neurons and millions of synapses.

#### *Multiple Cortical Areas Are Active When the Brain Generates a Voluntary Movement*

These different methodologies now make it clear that many cortical areas in addition to the primary motor cortex are active during the planning and execution of voluntary movements. During performance of

either a simple key press or a complex movement sequence, for example, functional imaging studies in humans have shown bilateral activation of the primary sensorimotor hand representation, the supplementary motor area, and the ventrolateral premotor cortex, plus contralateral activation of the dorsolateral premotor cortex and the medial cortex rostral to the SMA. Whereas such techniques provide information on the parts of the cortex that are active in a given situation, studies of electrical potentials provide information on the time course of activation. For simple self-paced movements, cortical electrical potentials over the SMA and M1 begin to change as early as 1 s prior to the movement. As the time of movement onset approaches, the amplitude of these bilateral electrical potential shifts increases (the *Bereitschaft* potential). At the time of the movement, a further increase in amplitude occurs over the somatotopically appropriate region of M1 contralateral to the moving body part. Given that many cortical areas are active in controlling movement raises the question: What does each area contribute to control?

### ***M1 Neurons Control Movement Kinematics and Dynamics***

In one of the earliest studies of single neuron activity in awake behaving animals, Evarts recorded the activity of M1 pyramidal tract neurons in monkeys trained to raise and lower weights using flexion and extension wrist movements (Fig. 30.12). The discharge frequency of many M1 neurons changed systematically in temporal relation to either flexion or extension. A typical flexion-related neuron, for example, began to discharge several hundred milliseconds before wrist

flexion began. As the onset of a flexion movement approached, the discharge frequency of the neuron increased, accelerating still more as the flexion movement was made. The neuron was silent during extension. The time course of these movement-related changes in single neuron activity parallels the time course of cortical electrical potential shifts.

Evarts went on to demonstrate that the discharge frequency of M1 pyramidal tract neurons (PTNs) varied in relation to a number of mechanical parameters of the movement the monkey was making. By changing the weights the monkey had to lift, Evarts showed that PTN discharge frequency varied with the force the monkey exerted. Comparison of PTN discharge with simultaneous force recordings revealed that bursts of PTN firing were correlated with sudden increases in the exerted force, indicating a relationship between firing frequency and the rate of change of force. Subsequent studies have confirmed these findings and have also shown that the discharge of M1 neurons can be related to the direction of movement, the position of a particular joint, or the velocity of movement. Cortical neurons whose firing is related to kinematic and dynamic parameters of movement are not found only in M1. Many neurons in the SMA, PMd, and parietal area 5 (which projects to SMA and PMd) fire in relation to movement direction, and some PMv neurons fire in relation to movement force. Therefore, neurons in several nonprimary cortical motor areas participate with those in M1 to control movement parameters such as direction, force, position, and velocity.

Although very strong correlations can be found between the discharge frequency of a given neuron

#### BOX 30.5

### BRAIN-MACHINE INTERFACES: MAKING USE OF THE MOTOR CORTEX

Technological advances now enable our knowledge of neuronal activity during voluntary movements to be applied in creating useful brain-machine interfaces. The activity of dozens of neurons can be recorded simultaneously from electrode arrays implanted in the primary motor cortex, premotor cortex, and/or parietal cortex. The spike discharges of these neuron populations, passed into computers, can be decoded in real time to obtain specific information about the direction and speed of voluntary movements the subject intends to make. This

decoded information then can be used online to control a cursor on a computer monitor, or even a robotic arm. For patients with an amputated extremity or a spinal cord lesion, such brain-machine interfaces eventually may drive neuroprosthetic devices that can be used independently by the patient, replacing the function of missing or paralyzed arms and hands for many activities of daily living.

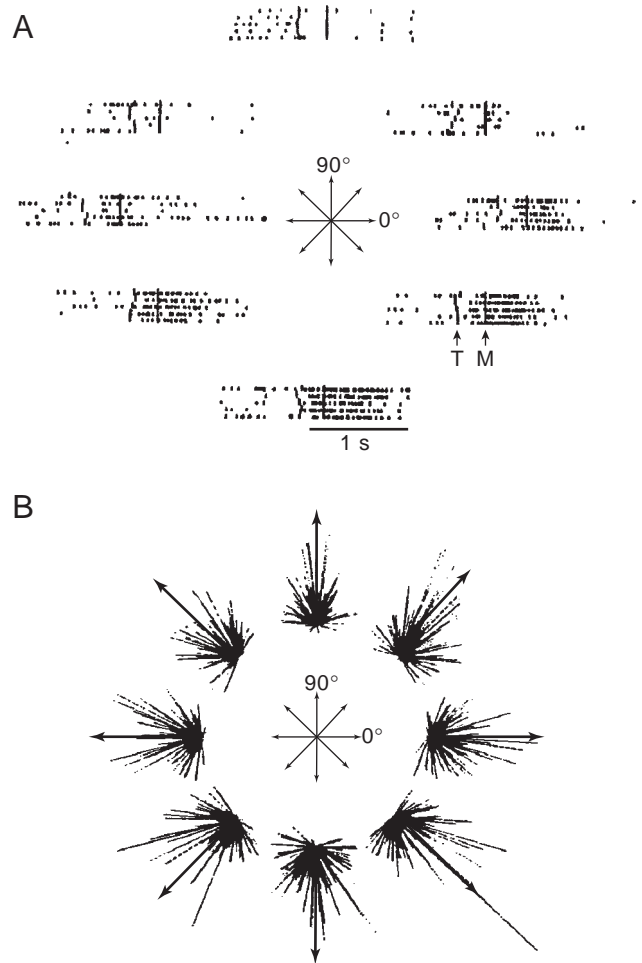

*Marc H. Schieber and James F. Baker*

**FIGURE 30.12** Discharge of a single M1 neuron in a monkey making flexion and extensor muscles wrist movements with wrist flexor muscles loaded (A) and unloaded (B) and with wrist extensors loaded (C). The discharge rate of this neuron was greatest when the monkey used its wrist flexor muscles against a load. Modified from Evars (1968).

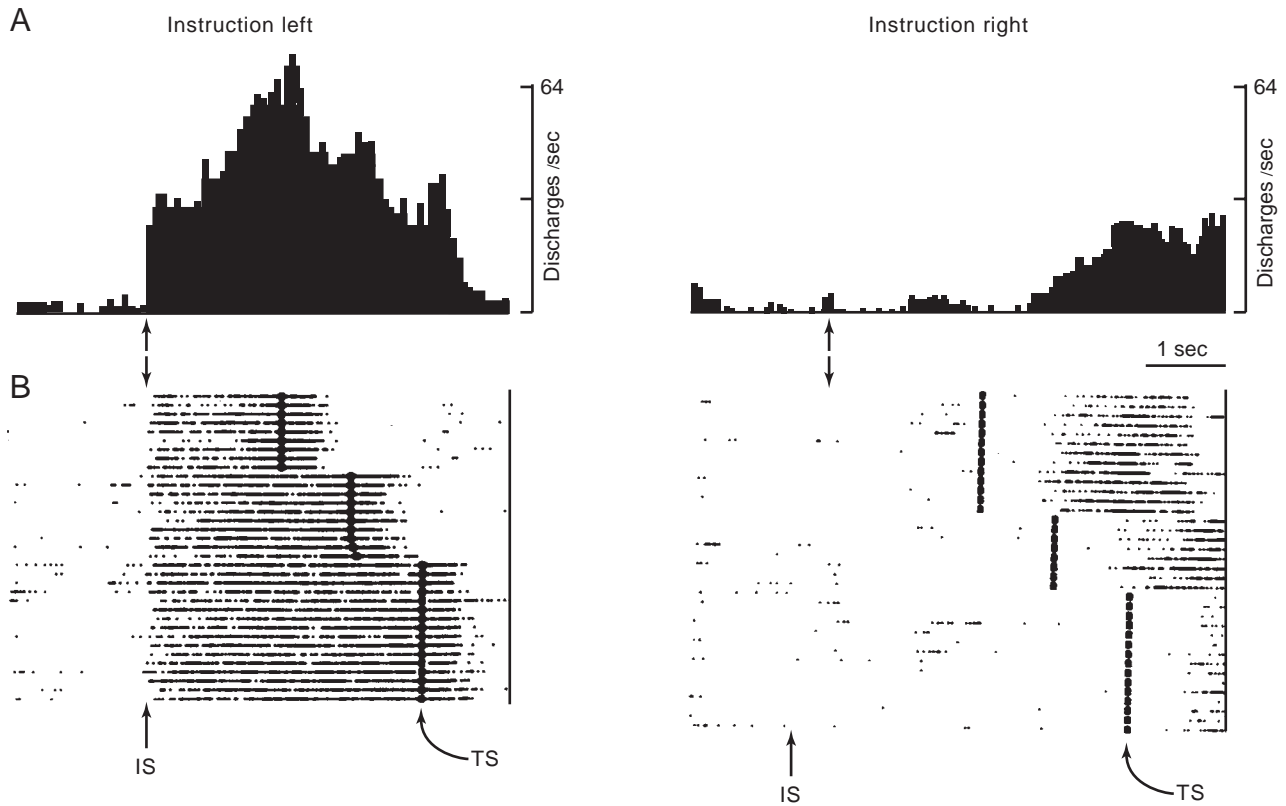

and a particular movement parameter, the discharge of a M1 neuron does not simply encode a single parameter. Rather, single M1 neurons show various degrees of correlation with direction, force, position, and velocity. Thus, the discharge of a single neuron in the motor cortex may influence several movement parameters.

Conversely, any given parameter or other feature of a movement is represented not by the discharge of a single M1 neuron, but by the ensemble activity of a large population of cortical neurons. Although a single M1 neuron typically discharges during reaching movements in several directions, for example, when the activity of many M1 neurons is combined appropri-

**FIGURE 30.13** (A) Discharge of a single M1 neuron before and during arm movements in a monkey. Movements (represented by arrows) started from the same central point and ended at eight different points on a circle. The eight rasters show that the activity of this neuron was related to movements in four of the eight directions. The neuron discharged most intensely for movements down and to the right and was inhibited during movements up and to the left. (B) For each of the eight movements, the discharge of each M1 neuron is shown as a line pointing in the preferred direction of the neuron. Each line starts at the movement end point, and its length is proportional to the intensity of the discharge of that neuron during movement in that direction. Although the discharge of single neurons rarely identified any single movement direction with accuracy, the population vectors (arrows) summing the discharge of an ensemble of M1 neurons adequately specify each of the eight movement directions. From Georgopoulos (1988).

ately, the population of M1 neurons can be shown to represent movement direction precisely (Fig. 30.13). Researchers have correlated the force, rate of change of force, position, and velocity of movements more accurately with the summed, weighted activity of a number of simultaneously recorded M1 neurons than with the discharge of any single neuron.

**FIGURE 30.14** Directional delay period activity in a PM neuron. (A) As a monkey performed a delayed-reaction paradigm, this neuron began to discharge shortly after receiving instructions (IS) to perform a leftward movement. Discharge continued until after the monkey had subsequently received a separate triggering signal (TS, which occurred at three different time intervals after the IS) and performed the movement. During the delay between IS and TS, while the monkey did not move, the discharge of the neuron encoded the direction of the instruction, the direction of the impending movement, or both. (B) When the instruction was for rightward movement, this neuron did not discharge until after the movement had been made, presumably as the monkey was then preparing to move back to its original position. From Wise and Strick (1996).

### *Cortical Motor Areas Prepare Voluntary Movements Based on a Variety of Cues*

Cortical areas outside the primary motor cortex seem to be especially concerned with using a wide variety of sensory and other information as “cues” to select and guide movements. Insight into these cortical processes has been obtained by separating in time a cue instructing which movement to make from a second cue to execute the instructed movement. This creates a period between the two cues during which the subject knows what movement to make, but is not making the movement per se. During such an instructed delay period, many neurons in M1, SMA, and PMd discharge at their highest rate while the subject waits to move in a particular direction (Fig. 30.14). Such directional delay period activity is more common in PMd and SMA than in M1, where activity during movement execution predominates. During the delay between instruction and trigger, PMd, SMA, and other

areas appear to store information on the direction of the impending movement. Indeed, neurons sometimes discharge in error during the delay, as if the monkey has seen a cue other than the one actually given and is preparing to move in the wrong direction. When such error discharges occur, the monkey often does make the wrong movement. The delay period discharge of such neurons thus represents stored information, not about which cue the monkey has seen, but rather about what movement the monkey will make.

The direction instructed usually is the same as the direction of the actual movement. To pick up a pencil, for example, you look at the pencil and then move your hand to the same place. Somehow your brain transforms the visual location of the pencil into the location to which your hand is moved. Insight into how cue direction is transformed into movement direction has come from tasks in which these two features were experimentally dissociated, as if you looked at a pencil in a mirror and then reached to pick up the real

## BOX 30.6

## MIRROR NEURONS: FUNDAMENTAL NEUROSCIENCE

Mirror neurons are a distinct class of neurons, originally discovered in a sector of the ventral premotor cortex (area F5) of the monkey, that discharge both when the monkey *executes* a given motor act (e.g., grasping an object) and when it *observes* another individual (a human being or another monkey) performing the same or a similar motor act. Mirror neurons do not discharge in response to the simple presentation of food or other interesting objects. They also do not discharge, or discharge much less, when the monkey observes hand actions mimed without the target object. Thus, the effective visual stimulus for monkey mirror neurons is the observation of an effector (hand or mouth) interacting with an object.

All mirror neurons have motor properties and, as other neurons located in area F5, discharge in relation to the goal of the motor act, such as grasping an object, rather than to the movements that form it (e.g., individual finger movements). On the basis of their motor properties mirror neurons can be subdivided into various classes. Among them the most common are grasping, manipulating, tearing, and holding neurons.

Mirror neurons are present not only in the premotor area F5, but have also been found in the inferior parietal lobule (IPL). This region receives input from the cortex of the superior temporal sulcus (STS) and sends output to ventral premotor cortex, including area F5. STS neurons are known to respond to the observation of actions done by others, but they are not endowed with motor properties. Thus, the cortical mirror neuron system is formed by two main sectors: the ventral premotor cortex and the inferior parietal lobule.

A large amount of evidence indicates that a mirror neuron system also exists in humans. Evidence in this sense comes from neurophysiological (EEG, MEG and TMS) and brain-imaging experiments (PET, fMRI). The neurophysiological experiments showed that the mere observation of others' actions induces an increase of excitability of the motor cortex. This excitability increase manifests itself in a desynchronization of EEG rhythms recorded from the motor cortex (the "mu" rhythm in particular) similar, although of less intensity, to that observed during active movements. The TMS experiments confirmed these findings. They showed that, during the observation of actions done by others, there is a specific increase of motor evoked potentials in the muscles of the observer that corresponds to those used by the action's agent.

The neurophysiological techniques have been instrumental in demonstrating that a mirror neuron system exists in humans. They could not show, however, its extent and precise localization. This gap has been filled by brain imaging experiments (PET and fMRI). These experiments showed that the observation of object-directed actions activate two cortical sectors that are also active during action execution: the inferior parietal lobule and a caudal sector of the frontal lobe. There is therefore a good correspondence between the localization of mirror neuron system in humans and monkeys.

With brain imaging techniques it has been possible to demonstrate that the human mirror neuron system have a somatotopic, albeit rough, organization. In the frontal lobe, mouth movements are located ventrally in the posterior part of the inferior frontal gyrus (IFG), the hand movement are located more dorsally, partly in IFG and partly in the ventral premotor cortex, and leg movements even more dorsally, in dorsalmost part of the ventral premotor cortex. In the parietal lobe the observation of mouth actions determines activation in the rostral part of the inferior parietal lobule, that of hand/arm actions activates a more caudal region corresponding to area PFG, while that of foot actions produces a signal increase more caudally and dorsally.

Another important results of brain imaging studies was the demonstration that the presentation of emotional stimuli such as disgust or pain elicits, in the observer, the activations, of the same cortical regions that become active when the individual feels the same emotions. The cortical regions forming this "emotional mirror neuron system" are the anterior insula and the rostral cingulate cortex.

What is the functional role of the mirror neurons? A series of hypotheses have been formulated. Among them are action understanding, imitation, intention understanding, and empathy. The question, however, of which is *the* functional role of mirror neurons is an ill posed question. Mirror neurons do not have a unique function. Their properties indicate that they represent a *mechanism* that maps the pictorial description of actions carried out by others onto their motor counterpart. Their functional role depends, first of all, on where this mapping occurs.

This becomes very clear if one compares the activity of the traditional parieto-frontal mirror neuron circuit with that of the insula and anterior cingulate cortex. The

(continues)

### BOX 30.6 (cont'd)

activation of parieto-premotor circuit elicits the motor representation of the observed action. In this way it gives a first person representation of what the others are doing. In contrast, the activation of the insula and cingulate, elicits the visceromotor representation of the observed emotion. In this way, it gives the first person representation of what the others are feeling.

The functional role of mirror neurons is not limited to the recognition of motor acts and emotions. Recent experiments showed that the parieto-premotor circuit, besides the recognition of the “what” of a motor act (e.g., grasping an object), is also involved in understanding the “why” this motor act is done (e.g., grasping for placing or for eating, etc.), that the agent’s intentions. The mechanism underlying this capacity is related to action organization of the parietal and premotor cortices, where successive motor acts are specifically linked in goal-directed action chains. These chains are activated not only during action execution, but also during motor act observation, thus allowing the individual, if relevant clues are available, to “play” internally the not-yet performed series of motor acts of the agent and to understand in this way his or her intention.

Finally, there is evidence that the mirror neuron system plays a crucial role both in imitation and imitation learning. As far as imitation is concerned, the capacity to repeat a simple motor act (e.g., finger lifting) relies on a direct translation of the observed act in the relative motor representation. For imitation learning, the situation is more complex and requires both the mirror neuron system, which codes the observed motor acts, and additional structures that reorganize these acts in new patterns or sequences.

pencil instead of the mirror image. To dissociate cue direction and movement direction experimentally, researchers have trained monkeys to perform mental rotation tasks in which a cue at one location instructs a movement to a different location.

Investigators have used such tasks to study neurons in the area principalis of the dorsolateral frontal lobe, in PMd, in SMA, and in M1. In each of these cortical areas, the activity of some neurons correlates best with the direction of the instructional cue, whereas the activity of other neurons correlates best with the direction of the actual movement. In general, from the area principalis, through the PMd and SMA to M1, the percentage of cue-related neurons decreases and the percentage of movement-related neurons increases. Moreover, as time progresses from the appearance of the instructional cue to the execution of the movement, the discharge of the neuronal populations encode cue direction initially and movement direction subsequently. The transformation of cue direction into movement direction thus involves many cortical motor areas and progresses throughout the reaction time of the subject.

### *Some Cortical Motor Areas Are Involved in Movements in Response to Either Internal or External Cues*

Another aspect of movement preparation that differentially involves certain cortical motor areas has to do with whether the instructions about what to do come from internally remembered or externally delivered cues. In one experiment, for example, monkeys were trained to touch three of four pads in randomly selected sequences that were cued when the pads were lit in sequence. Once a monkey was accustomed to a given sequence, the lights gradually were dimmed until the monkey was performing the correct sequence based only on internally remembered cues. After several of these remembered trials, the pads were lit in a different sequence for several trials. Whereas neurons in M1 showed similar discharge rates during the internally remembered and externally cued trials for a given sequence, SMA neurons were generally more active during the internally remembered trials, and PMv neurons were generally more active during the externally cued trials (Fig. 30.15).

**FIGURE 30.15** Activity of three neurons—one in M1, one in PM, and one in SMA—recorded as a monkey pressed three buttons in sequence. The sequence was first cued visually by lighting the buttons and was then cued internally. The M1 neuron showed similar activity whether the monkey performed from visual or internal cues. The PM neuron, however, was much more active in response to visual than internal cues, whereas the opposite was true for the SMA neuron. Modified from Mushiake *et al.* (1991).

## Summary

Axons from the cerebral cortex and from the red nucleus in the brain stem descend in pathways located dorsolaterally in the spinal cord to control voluntary movements. In addition to corticospinal and rubrospinal pathways, the motor cortex also sends projections to the red nucleus and to the pontomedullary reticular formation, providing indirect pathways for voluntary control. Multiple cortical motor areas—distinguished by their inputs, their cytoarchitecture, and their interconnections with other cortical areas and with the thalamus—make different contributions to the control of voluntary movements. The most detailed motor map is found in the primary motor cortex, M1, but the somatotopic organization is limited by convergence and divergence in the corticospinal projection. Populations of M1 neurons are also in most direct control of movement kinematics and dynamics. Other cortical motor areas participate differentially in the selection of, and preparation for, voluntary movements based on a variety of internal and external cues.

## SUMMARY

The motor cortex, the red nucleus, the pontomedullary reticular formation, and the vestibular nuclei each send major axonal projections descending from the brain to the spinal cord to control bodily movements.

Although these pathways normally provide seamless movement control, different contributions of the medial and lateral descending pathways have been identified experimentally.

The medial system—vestibulospinal and reticulospinal—receives sensory input from the vestibular apparatus and mediates postural responses that keep the head and body stabilized for stance and gait. Additional visual and proprioceptive inputs that reach the vestibular and reticular nuclei via brain stem pathways or after processing in the cerebellum (Chapter 32) also influence postural control. Context-dependent strategies established via centers including the cerebellum and motor cortex further adapt postural responses to the needs of particular complex situations.

The lateral system—corticospinal and rubrospinal—receives, in addition to somatosensory inputs, information processed by the cerebellum (Chapter 32), the basal ganglia (Chapter 31), and associated cortical areas to mediate voluntary movements of the face and extremities. Different cortical motor areas receive different portions of these inputs and therefore make different contributions to controlling voluntary movements. The most elaborate somatotopic representation is found in the primary motor cortex, M1. While the convergence, divergence, and horizontal interconnections of the intrinsic organization of M1 result in considerably distributed activation during voluntary movements, the same substrates enable substantial plasticity. Whereas M1 neurons most directly control the kinematics and dynamics of movement execution,

other cortical motor areas participate in selecting which movement(s) to make on the basis of external cues and internal states.

## The Basal Ganglia

The basal ganglia are large subcortical structures comprising several interconnected nuclei in the fore-brain, midbrain, and diencephalon (Fig. 31.1). Because of certain features, it is generally agreed that basal ganglia participate in the control of movement. The largest portion of basal ganglia inputs and outputs are connected with motor areas. Second, the discharge of many basal ganglia neurons correlates with movement. Third, basal ganglia lesions cause severe movement abnormalities. In addition to their role in motor control, basal ganglia are involved in cognitive and affective functions. This chapter concentrates on the motor functions of the basal ganglia, but participation of the basal ganglia in cognition is discussed after the basic framework of basal ganglia function is presented for motor control. The anatomy of the basal ganglia is discussed first, as it is the anatomy that provides the infrastructure for the physiology. Next we consider the activity of the individual components of the basal ganglia during movement. Then we discuss the effect of placing a lesion in one component while leaving the rest of the nervous system intact. The combined strategy of measuring the activity of a structure during movement and then determining the effect a selective lesion on that movement has been fruitful in studying the function of the motor system. After presentation of current models of basal ganglia motor function, the chapter concludes with a discussion of basal ganglia participation in cognitive function.

### BASAL GANGLIA ANATOMY

The basal ganglia receive a broad spectrum of cortical inputs. The information conveyed to the basal

ganglia then is processed by the basal ganglia circuitry to produce a more focused output to areas of the frontal lobes and brain stem that are involved in the planning and production of movement. The basal ganglia output is entirely inhibitory. Thus, an *increase* in basal ganglia output leads to a *reduction* in the activity of its targets. The fact that the basal ganglia output is inhibitory to thalamocortical and brainstem targets is important to understanding its normal motor function.

At first glance, the anatomy of the basal ganglia may seem confusing. There are several component nuclei at different levels in the brain, and two of the nuclei (substantia nigra (SN) and globus pallidus (GP)) are divided into functionally different components. The names of some structures are different in primates than in other mammals. Furthermore, the terminology has changed over the years so that an individual structure may be known by more than one name. However, with consistent use of modern terminology and a functional context in which to place the anatomy, the organization of basal ganglia can be learned readily. Moreover, once the circuitry is learned, many aspects of its normal function and of the response to injury become much easier to understand.

The basal ganglia include the striatum (caudate, putamen, nucleus accumbens), the subthalamic nucleus (STN), the globus pallidus (internal segment or GPi; external segment or GPe; and ventral pallidum), and the substantia nigra (pars compacta or SNpc and pars reticulata or SNpr) (Fig. 31.2). The striatum and STN are the primary recipients of information from outside of the basal ganglia. Most of those inputs come from the cerebral cortex, but thalamic nuclei also provide strong inputs to striatum. There are no direct inputs to the basal ganglia from spinal or brainstem sensory or

FIGURE 31.1 Location of basal ganglia in the human brain. (A) Coronal section. (B) Parasagittal section.

motor systems. The major outputs from basal ganglia arise from GPi and SNpr and are inhibitory to thalamic nuclei and to brain stem. There are no direct outputs from basal ganglia to spinal motor circuitry.

### The Striatum Receives Most of the Inputs to the Basal Ganglia

The striatum is located in the forebrain and comprises the caudate nucleus and putamen (neostriatum) and nucleus accumbens (ventral striatum). This section focuses on the neostriatum (see Box 31.3 and Chapter 43 for a discussion of the ventral system of the basal ganglia). Embryologically, the striatum develops from a basal region of the lateral telencephalic vesicle. It is named the striatum because axon fibers passing through the striatum give it a striped appearance. In rodents, the caudate and putamen are a single struc-

ture with fibers of the internal capsule coursing through, but in carnivores and primates, the caudate and putamen are separated by the internal capsule. The caudate and putamen receive input from the neocortex, and the size of these nuclei increases in parallel with the neocortex throughout phylogeny.

Four major types of neurons have been described in the striatum. The typing is based on the size of the cell body, presence or absence of dendritic spines in individual neurons that have been stained with the Golgi technique or filled with horseradish peroxidase, and other staining properties. The first and by far the most numerous neuron type is the *medium spiny neuron* (Fig.

31.3). Medium spiny neurons make up 80 to 95% of the total number of striatal neurons, depending on the species. They utilize  $\gamma$ -aminobutyric acid (GABA) as a transmitter and constitute the output of the striatum, sending axonal projections to the GP and SN. Medium spiny neurons have large dendritic trees that span 200 to 500  $\mu\text{m}$  (Wilson and Groves, 1980). They also have extensive local axon collaterals that may inhibit neighboring striatal neurons. The medium spiny neurons are morphologically homogeneous, but chemically

heterogeneous, as discussed later. Second, *large aspiny neurons* make up 1 to 2% of the striatal population. They are interneurons and use acetylcholine (ACh) as a neurotransmitter. They have extensive axon collaterals in the striatum that terminate on medium spiny neurons. The third type of neuron is the *medium aspiny cell*. These are also interneurons and are thought to use somatostatin as a neurotransmitter. The fourth type of neuron is a *small aspiny cell* that uses GABA as a neurotransmitter. These inhibitory interneurons are more prevalent in primates than in rodents and play an important role in regulating the activity of the medium spiny output neurons.

The striatum receives excitatory input from nearly all the cerebral cortex. The cortical input uses glutamate as its neurotransmitter and terminates largely on the heads of the dendritic spines of medium spiny neurons (Fig. 31.4). The projection from the cerebral cortex to the striatum has a roughly topographical organization. For example, the somatosensory and motor cortex project to the posterior putamen and the prefrontal cortex projects to the anterior caudate. Within the somatosensory and motor projection to the

**FIGURE 31.3** Two representations of a striatal medium spiny neuron that has been filled with HRP. (A) The soma and dendritic tree with numerous dendritic spines. (B) The same neuron drawn to show the axonal collaterals, which branch extensively within the same field as the dendritic tree. From Wilson and Groves (1980).

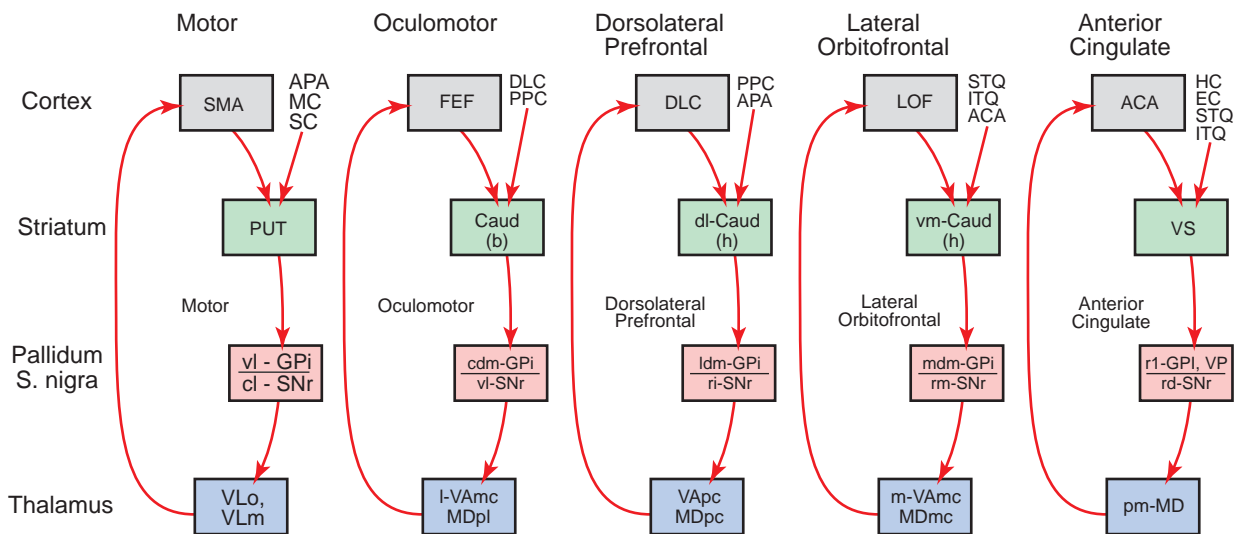

**FIGURE 31.4** Pattern of termination of afferents on a medium spiny neuron. The soma and the proximal dendrites with their spines are shown.

striatum, there is a preservation of somatotopy. It has been suggested that the topographic relationship between the cerebral cortex and the striatum provides a basis for the segregation of functionally different circuits in the basal ganglia (Alexander *et al.*, 1986) (Fig. 31.5). These circuits include somatomotor, oculomotor, cognitive, and limbic connections. Within each circuit there appear to be subcircuits such that the primary motor cortex and premotor cortex have non-identical connections with basal ganglia structures. Likewise, dorsolateral and orbitofrontal circuits have distinct connectivity patterns.

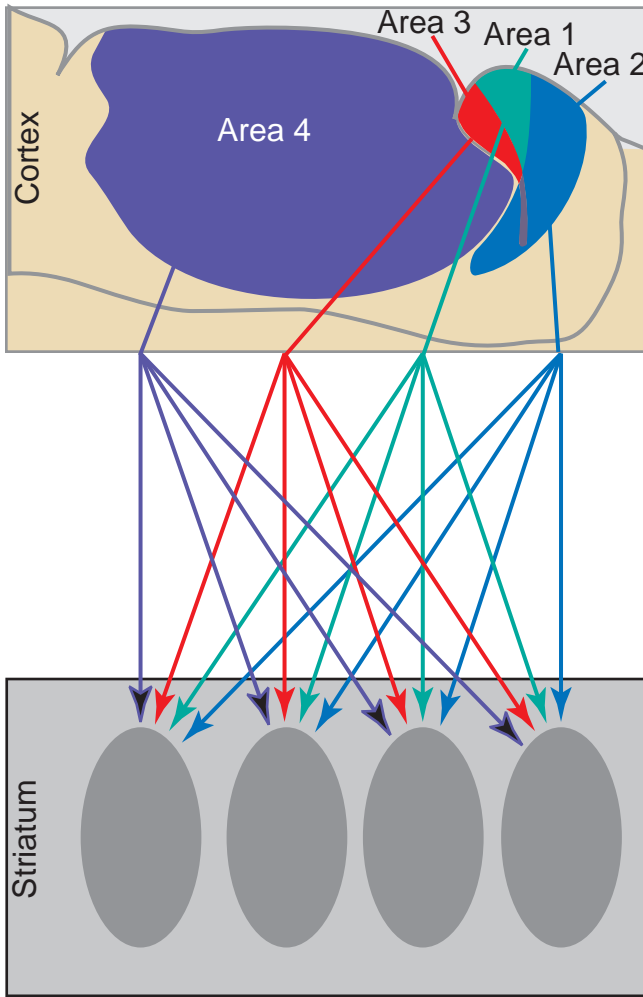

Although the topography and somatotopy imply a certain degree of parallel organization, there is also convergence and divergence in the corticostriatal projection. The large dendritic fields of medium spiny neurons allow them to receive input from adjacent projections, which arise from different areas of cortex. Inputs from more than one cortical area overlap (Flaherty and Graybiel, 1991), and input from a single cortical area projects divergently to multiple striatal zones (Fig. 31.6). This convergent and divergent organization provides an anatomical framework for the integration and transformation of information from several areas of the cerebral cortex.

In addition to cortical input, medium spiny striatal neurons receive a number of other inputs: (1) excitatory and presumed glutamatergic inputs from intralaminar and ventrolateral nuclei of the thalamus; (2) cholinergic input from large aspiny neurons; (3) GABA, substance P, and enkephalin input from adjacent medium spiny striatal neurons; (4) GABA input from small interneurons; and (5) a large input from dopamine (DA)-containing neurons in the SNpc. The DA input is of particular interest because of its role in Parkinson's disease (PD, see later).

The DA input to the striatum terminates largely on the shafts of the dendritic spines of medium spiny neurons (Fig. 31.4). The location of dopaminergic terminals puts them in a position to modulate transmission from the cerebral cortex to the striatum. The action of DA on striatal neurons depends on the type of DA receptor involved. Five types of G protein-coupled DA receptors have been described (D1–D5). These have been grouped into two families based on their response to agonists. The D1 family includes D1 and D5 receptors, and the D2 family includes D2, D3, and D4 receptors. D1 receptors potentiate the effect of cortical input to striatal neurons. D2 receptors decrease the effect of cortical input to striatal neurons (Chapters 8 and 9).

**FIGURE 31.5** Parallel circuits connecting the basal ganglia, thalamus, and cerebral cortex. The five circuits are named according to the primary cortical target of the output from the basal ganglia: motor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate. **FIGURE 31.6** Schematic representation of the sensorimotor cortical projection to the striatum from arm areas in the somatosensory cortex (areas 1, 2, and 3) and motor cortex (area 4). Note that each cortical area projects to several striatal zones and several functionally related cortical areas project to a single striatal zone. After Flaherty and Graybiel (1991).

Medium spiny neurons contain the inhibitory neurotransmitter GABA. In addition, medium spiny neurons have peptide neurotransmitters that are colocalized with GABA. Based on both the type of neurotransmitters and the type of DA receptor they contain, medium spiny neurons can be divided into two populations. One population contains GABA, dynorphin, and substance P and primarily expresses D1 receptors. These neurons send axons to GPi and to SNpr. Although substance P generally is thought to be an excitatory neurotransmitter, the predominant effect of these neurons is inhibition of their targets. The second population contains GABA and enkephalin and primarily expresses D2 receptors. These neurons

**FIGURE 31.7** The two chemically different populations of striatal medium spiny neurons are intermixed. One population (blue) projects to the globus pallidus external segment (GPe) and contains GABA and enkephalin. The other population (red) projects to the globus pallidus internal segment (GPi) and substantia nigra pars reticulata (SNpr) and contains GABA, dynorphin, and substance P (red).

project to GPe and are inhibitory. The two populations of medium spiny neurons are morphologically indistinguishable and are not segregated topographically within the striatum (Fig. 31.7). This commingling of neurons suggests that they receive similar types of input and thus they may convey similar information to their respective targets. However, there is emerging evidence that the two classes of medium spiny neurons may receive input from different classes of cortical neurons within the same cortical area. The neurotransmitter type, dopamine receptor type, and possible differences in cortical input provide one level of functional segregation within the striatum.

Although there are no apparent regional differences in the striatum based on cell morphology, an intricate internal organization has been revealed with special stains. When the striatum is stained for acetylcholinesterase (AChE), the enzyme that inactivates acetylcholine (Chapter 8), there is a patchy distribution of lightly staining regions within more heavily stained regions. The AChE-poor patches have been called *striosomes* and the AChE-rich areas have been called the *extrastriosomal matrix* (Graybiel *et al.*, 1981). The matrix forms the bulk of the striatal volume and receives input from most areas of the cerebral cortex. Within the matrix are clusters of neurons with similar

## BOX 31.1

## CONCEPT OF THE EXTRAPYRAMIDAL MOTOR SYSTEM

Participation of the basal ganglia in normal motor control is an old idea dating back to the early part of this century. The British neurologist S. A. Kinnier Wilson described a disease that included muscular rigidity, tremor, and weakness that was associated with pathological changes in the liver and in the putamen (hepatolenticular degeneration). Wilson noted that several features seen with damage to the corticospinal tracts were not present in this disease and postulated that the motor abnormalities were due to disease of an “extrapyramidal” motor system. Wilson postulated that basal ganglia (striatum and globus pallidus) were the major constituents of this “extrapyramidal” motor system that he viewed to be independent of the “pyramidal” (corticospinal) motor system. In a later writing, Wilson developed the view of two motor systems, the phylogenetically “old” extrapyramidal system and the phylogenetically “new” pyramidal system (Wilson, 1928). He thought that the extrapyramidal system had an automatic, postural, and static function, which was minimally modifiable, and that the pyramidal system had a voluntary, phasic function that could be modified. At the time, it was thought that the output of the basal ganglia went directly to the spinal cord.

In the 1960s, more modern anatomical techniques showed that the bulk of basal ganglia output went via the

thalamus to motor cortical areas. In this sense, basal ganglia output was “prepyramidal,” not extrapyramidal. With the developing model of initiation of movement by the basal ganglia, the prepyramidal location was emphasized as the most important basal ganglia output. More recently, it has been possible to inject a different colored fluorescent dye into each of two downstream targets to find out if individual upstream neurons project to both targets. It was found that the vast majority of neurons in GPi branch and project both to the thalamus and to the brain stem. Hence, the basal ganglia are both prepyramidal and extrapyramidal. Although we now know that the basal ganglia can act through the pyramidal system and that there are many extrapyramidal motor systems that project to the spinal cord independent of the pyramidal tract, the phrase “extrapyramidal motor system” is still used to refer to the basal ganglia and to the disorders that result from basal ganglia damage.

inputs that have been termed *matrisomes*. The bulk of the output from cells in the matrix is to both segments of the GP and to SNpr. The striosomes receive input from the prefrontal cortex and send output to SNpc. Immunohistochemical techniques have demonstrated that many substances, such as substance P, dynorphin, and enkephalin, have a patchy distribution that may be partly or wholly in register with the striosomes (Graybiel *et al.*, 1981). The striosome-matrix organization provides the substrate for another level of functional segregation within the striatum.

### The STN Receives Inputs from the Frontal Lobe

The STN is located at the junction of the diencephalon and midbrain, ventral to the thalamus and rostral and lateral to the red nucleus. Embryologically, it

develops from the lateral hypothalamic cell column. Phylogenetically, it increases in size in proportion to the neocortex. The STN receives an excitatory, glutamatergic input from the frontal cortex with large contributions from motor areas, including the primary motor cortex (area 4), premotor and supplementary motor cortex (area 6), and frontal eye fields (area 8). The STN also receives an inhibitory GABA input from GPe. The output from the STN is excitatory and glutamatergic. STN projects to GPi and SNpr as well, projecting back to GPe.

Although the STN receives input from the neocortex and projects to both segments of GP and to SNpr, it is different from striatum in several ways. Unlike striatum, the cortical input to the STN is from the frontal lobe only. The output from STN is excitatory, whereas the output from striatum is inhibitory. Of the two routes from the cortex to GPi, GPe, and SNpr, the

excitatory route through STN (5–8 ms) is faster than the inhibitory route through striatum (15–20 ms). The pathway from cerebral cortex via STN to GPi and SNpr has been called the “hyperdirect pathway” because it is the fastest route for information flow from cerebral cortex to the basal ganglia output (Fig. 31.2) (Nambu *et al.*, 2002).

### GPi Is the Primary Basal Ganglia Output for Limb Movements

GP lies medial to the putamen and rostral to the hypothalamus. Embryologically, it arises from the lateral hypothalamic cell column. In primates, GP is separated into an internal segment and an external segment by a fiber tract called the internal medullary lamina. In rodents and carnivores, the internal segment lies within the internal capsule and is called the entopeduncular nucleus. GPe is not a principal source of output from the basal ganglia and it is considered later.

The GPi is composed primarily of large neurons that project outside of the basal ganglia. The dendritic trees of GPi neurons radiate from the cell body in a disc-like distribution and are oriented so that the faces of the disc are perpendicular to incoming axons from the striatum. The dendrites of an individual GPi cell can span up to 1 mm in diameter and therefore GPi neurons have the potential to receive a large number of converging inputs.

The principal inputs to GPi are from striatum and the STN. These two types of inputs differ in the neurotransmitters used, in their physiological action, and in their pattern of termination. As noted earlier, neurons projecting from striatum to GPi contain GABA, substance P, and dynorphin, and are inhibitory. Each axon from the striatum enters GPi and sparsely contacts several neurons in passing before ensheathing a single neuron with a dense termination. This pathway has been called the “direct” striatopallidal pathway (Fig. 31.2). The excitatory, glutamate projection from STN to GPi is highly divergent such that each axon from the STN ensheathes many GPi neurons (Fig. 31.8). The striatal projection to GPi is about 10 to 15 msec slower than the STN projection to GPi. Thus, the striatal and STN inputs to GPi form a pattern of fast, widespread, divergent excitation from STN and slower, focused, convergent inhibition from striatum.

The output from GPi is inhibitory and, like the input to this structure from striatum, uses GABA as its neurotransmitter. The majority (70%) of the GPi output is sent via collaterals to both the thalamus and the brain stem. In the thalamus, axons from GPi terminate in the oral part of the ventrolateral nucleus (VLo) and in the

**FIGURE 31.8** The two primary inputs to globus pallidus internal segment (GPi) have different patterns of termination. Axons from the subthalamic nucleus (green) are excitatory and terminate extensively on multiple GPi neurons. Axons from the striatum (red) contact several GPi neurons weakly in passing before terminating densely on a single neuron.

principal part of the ventral anterior nucleus (VApc). In turn, these thalamic nuclei project to the motor, premotor, supplementary motor, and prefrontal cortex. They also project back to striatum in a potential feedback loop. Some evidence suggests that an individual GPi neuron sends output via the thalamus to just one area of the cortex (Hoover and Strick, 1993). In other words, GPi neurons that project to the motor cortex are adjacent to, but separate from, those that project to the premotor cortex. Thus, just as there are parallel inputs from the cortex to striatum, there appear to be potential functionally parallel outputs from GPi.

Collaterals of the axons projecting from GPi to the thalamus project to an area at the junction of the mid-brain and pons near the pedunculo-pontine nucleus,

## BOX 31.2

## PARKINSON'S DISEASE

Parkinson's disease (PD) is the second most common progressive neurodegenerative disorder. Patients with PD experience slowness of movement, rigidity, a low-frequency rest tremor, and difficulty with balance. These major motoric features of PD are due to the degeneration of dopamine (DA) containing neurons in the substantia nigra pars compacta (SNc) with an accompanying loss of DA and its metabolites in the striatum. PD patients may exhibit other symptoms, including cognitive dysfunction, depression, anxiety, autonomic problems, and disturbances of sleep, which may be due to the degeneration of non-DA-containing neurons. PD is characterized pathologically by the cytoplasmic accumulation of aggregated proteins with a halo of radiating fibrils and a less defined core known as Lewy bodies. Measures of increased oxidative stress are also seen, including glutathione depletion, iron deposition, increased markers of lipid peroxidation, oxidative DNA damage and protein oxidation, and decreased expression and activity of mitochondrial complex 1 in the SNc. This mitochondrial complex 1 defect is specific to the SNc, as it has not been observed in other neurodegenerative diseases. Thus, in sporadic PD, oxidative stress and mitochondrial dysfunction appear to play prominent roles in the death of DA neurons. The majority of PD appears to be sporadic in nature, however, an estimated 10% of cases are familial, with specific genetic defects. The identification of these rare genes and their functions has provided tremendous insight into the pathogenesis of PD and opened up new areas of investigation.

Two genes have been clearly linked to PD:  $\alpha$ -synuclein and parkin.  $\alpha$ -Synuclein is a presynaptic protein and a primary component of Lewy bodies. Very rare missense mutations at A53T and A30P cause autosomal-dominant PD. How derangements in  $\alpha$ -synuclein lead to dysfunction and death of neurons is not known. However, aggregation and fibrillization are thought to play a central role, perhaps leading to a dysfunction in protein handling by inhibiting the proteasome. The second "PD gene" parkin is an E3 ligase for the ubiquitination of proteins. Mutations in parkin include exonic deletions, insertions, and several missense mutations and result in autosomal recessive PD. Parkin mutations are now considered to be one of the major causes of familial PD. Substrates for parkin include the synaptic vesicle-associated protein CDCrel-1, which may regulate synaptic vesicle release in the nervous system. Whether CDCrel-1 is involved in the release of dopamine is not yet known. Synphilin-1 is a protein of unknown function that was identified as an  $\alpha$ -synuclein

interacting protein. It is a synaptic vesicle-enriched protein and is present in Lewy bodies. Synphilin-1 is a target of parkin, and expression of synphilin-1 with  $\alpha$ -synuclein results in the formation of Lewy body-like aggregates that are ubiquitinated in the presence of parkin. Parkin is upregulated by unfolded protein stress, and expression of parkin suppresses unfolded protein stress-induced toxicity. The unfolded putative G-protein-coupled transmembrane receptor, the parkin-associated, endothelial-like receptor (Pael-R), is a parkin substrate. When overexpressed, Pael-R becomes unfolded, insoluble, and causes unfolded protein-induced cell death. Parkin ubiquitinates Pael-R, and coexpression of parkin results in protection against Pael-R-induced cell toxicity. Pael-R accumulates in the brains of autosomal-recessive Parkinson's disease patients and thus may be an important parkin substrate.

Ultimately, it would be of interest to link all the multiple genes and the sporadic causes of PD into a common pathogenic biochemical pathway. Derangements in protein handling seem to be central in the pathogenesis of familial PD. Oxidative stress seems to play a prominent role in sporadic PD, and oxidative stress leads to synuclein aggregation and/or proteasomal dysfunction. Data suggest that there may be selective derangements in the proteasomal system in the substantia nigra of sporadic PD. Thus, protein mishandling may be central to the pathogenesis of PD.

In contrast to most other neurodegenerative disorders, there is effective temporary symptomatic treatment for PD consisting of DA replacement with levodopa or DA agonists and adjunctive medications or surgical approaches. Because the neurodegeneration in PD is progressive and there is no proven preventative, restorative, or regenerative therapy, patients eventually become quite disabled. Ultimately, to affect a true cure, the underlying mechanisms of neuronal cell death need to be understood, strategies for enhancing neuronal survival and regrowth need to be developed, and consideration needs to be made toward the replacement of cells lost during the degenerative process. If these goals can be obtained, a full recovery could be achieved.

which has been termed the “midbrain extrapyramidal area.” The midbrain extrapyramidal area projects in turn to the reticulospinal motor system. Other GPi neurons (20%) project to intralaminar nuclei of the thalamus or to the lateral habenula.

### Substantia Nigra Pars Reticulata Is the Basal Ganglia Output for Eye Movements

Like the GP, the SN is divided into two segments. One is a densely cellular region called the pars compacta (SNpc) and the other is more sparsely cellular and is called the pars reticulata (SNpr). The pars compacta contains DA cells and is not a principal output nucleus of the basal ganglia. It is considered later. SNpr has features similar to GPi, including cell size, histochemistry, and connectional anatomy.

Like GPi, the SNpr contains large neurons that project outside of the basal ganglia. The dendritic trees are less disc-like than those of GPi neurons, but like GPi neurons they extend up to 1 mm and thus receive a wide field of inputs. As in the case of GPi, the SNpr receives inhibitory inputs from striatum direct pathways that contain GABA, SP, and dynorphin and excitatory inputs from STN that contain glutamate and provides inhibitory, GABAergic outputs. In the case of SNpr, these outputs are to the medial part of the ventro-lateral thalamus (VLm) and the magnocellular part of the ventral anterior thalamus (VAmc). These thalamic areas in turn project to the premotor and prefrontal cortex. Like the GPi output, SNpr sends collaterals to the midbrain extrapyramidal area and also has a projection to intralaminar nuclei of the thalamus. A primary difference in the outputs of GPi and SNpr is that the lateral portion of SNpr sends an inhibitory projection to the superior colliculus and to the paralamina part of the medial dorsal thalamus (MDpl). MDpl projects in turn to the frontal eye fields. Thus, the lateral portion of SNpr is connected with cortical and brain stem areas that control eye movements.

### GPe Is Connected to Several Other Basal Ganglia Nuclei

The GPe is one of two nuclei that may be viewed as intrinsic nuclei of the basal ganglia. The other is the SNpc, which is considered in the next section. Both GPe and SNpc receive the bulk of their input from and send the bulk of their output to other basal ganglia nuclei.

GPe receives an inhibitory projection from the striatum and an excitatory one from STN. The patterns of termination of the striatal and STN afferents are similar in that the striatal input is focused and convergent

while the STN input is divergent (Parent and Hazrati, 1993). Unlike GPi, the striatal projection to GPe contains GABA and enkephalin but not substance P. The majority of the output of GPe projects to STN. The connections from striatum to GPe, from GPe to STN, and from STN to GPi and SNpr thus are referred to as the “indirect” pathway to GPi and SNpr to distinguish it from the “direct” pathway that runs from striatum to GPi and SNpr (Fig. 31.2) (Alexander and Crutcher, 1990). In addition, there is a monosynaptic GABAergic inhibitory output from GPe directly to GPi and to SNpr and a GABAergic projection back to striatum. Thus, GPe neurons are in a position to provide feedback inhibition to neurons in striatum and STN and feed-forward inhibition to neurons in GPi and SNpr. This circuitry suggests that GPe may act to oppose, limit, or focus the effect of the striatal and STN projections to GPi and SNpr, as well as focus activity in these output nuclei.

### SNpc Provides DA Input to the Striatum

The SNpc is perhaps the most studied structure in the basal ganglia. The SNpc is made up of large DA-containing cells and it is these neurons that degenerate in PD, which is characterized by abnormal movement. DA neurons contain a substance called neuromelanin, which is a dark pigment that gives the SNpc a blackish appearance and appears to represent an oxidation product of DA. This is the basis for its name (substantia nigra = black substance). SNpc receives input from the striatum, specifically from the striosomes and a more sparse input from prefrontal frontal cortex. The SNpc DA neurons project to all of caudate and putamen in a topographic manner. However, nigral DA neurons receive inputs from one striatal circuit and project back to the same and to adjacent circuits (Haber *et al.*, 2000). Thus, they are in a position to modulate activity across circuits. The action of DA depends on the receptors located on target neurons, as was discussed earlier.

### Summary

To review:

1. The striatum receives input from nearly all the cerebral cortex such that several functionally related cortical areas project to overlapping striatal zones and that an individual cortical area projects to several striatal zones. Cortical areas that are not functionally related project to separate zones of the striatum, although there may be some interaction between adjacent zones.

2. The striatum sends a focused and convergent inhibitory projection to the basal ganglia output nuclei, GPi and SNpr.
3. The STN receives input from the frontal lobe, especially from the motor, premotor, and supplementary motor cortex and from the frontal eye fields.
4. The STN sends a fast divergent excitatory projection to GPi and SNpr.
5. There are reciprocal and loop-like connections among basal ganglia nuclei that may play a negative or positive feedback role or may result in focusing of signals.
6. The output from the basal ganglia (GPi and SNpr) is inhibitory and projects to motor areas in the brain stem and thalamus.
7. There are no direct connections between the basal ganglia and the spinal sensory or motor apparatus.

There is some disagreement among basal ganglia experts whether to view the overall anatomic organization of the basal ganglia as convergent or as multiple parallel segregated loops through the basal ganglia, each with a separate output. In support of convergence are (1) the reduction of the number of neurons at each level from the cortex to striatum to GPi and SNpr; (2) the large number of synapses on each striatal neuron; (3) the large dendritic trees of striatal, GPi, and SNpr neurons; and (4) interaction across circuits mediated by SNpc and GPe neurons. In support of parallel segregated loops are (1) the preserved somatotopy with separate representations of the face, arm, and leg in the cortex, striatum, and GPi/SNpr; (2) the relative preservation of topography through the basal ganglia (e.g., the prefrontal cortex to caudate to SNpr to VA thalamus to the prefrontal cortex and motor cortex to putamen to GPi to VLo thalamus to motor cortex); and (3) the finding that separate groups of GPi neurons project via the thalamus to separate motor areas of the cortex. It appears that there is local convergence and global parallelism, but it remains unknown whether the parallel pathways are functionally segregated or to what degree there is interaction at the interfaces between functionally different pathways.

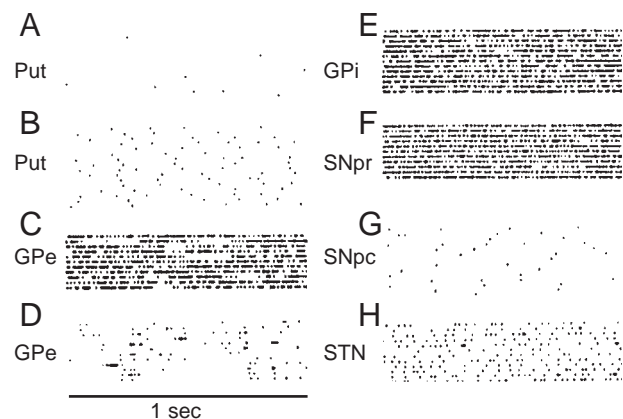

## SIGNALING IN BASAL GANGLIA

Although the anatomic organization may provide some clues as to what might be the function of basal ganglia circuits, inference of function from anatomy is speculative. One approach to studying the function of

an area of the central nervous system is to record the electrical activity of individual neurons with an extracellular electrode in awake, behaving animals. Other approaches involve inferences of neuronal signaling from imaging studies of blood flow and metabolism, or of changes in gene expression. By sampling the signal of a part of the brain during behavior, one can gain some insight into what role that part might play in behavior. Neurons within different basal ganglia nuclei have characteristic baseline discharge patterns that change with movement. If an animal is trained to perform a task consistently, the activity of single neurons can be correlated with individual aspects of the task performance. Furthermore, the timing of neural activity in one part can be compared to the timing of another and to the timing of the movement. This section emphasizes signals in the basal ganglia that are correlated with movement or the preparation for movement.

### The Striatum Has Low Spontaneous Activity That Increases during Movement

In awake animals, the majority of striatal neurons (80–90%) have low baseline discharge rates of 0.1 to 1 Hz (Fig. 31.9). These neurons project outside of the striatum and therefore are probably medium spiny neurons. In general, the activity of these neurons reflects the activity of areas of cerebral cortex from which they receive inputs, but striatal neurons are less modality specific. Thus, neurons in areas of the putamen that receive input from the somatosensory

**FIGURE 31.9** Representative neural discharge patterns from several basal ganglia nuclei. In the raster displays, each dot indicates the occurrence of an action potential. Each horizontal raster line represents a 1-s period of discharge. Several such periods are arranged vertically for each nucleus.

and motor cortex have activity correlated with active and passive movement, but not with specific tactile modalities such as light touch, vibration, or joint position. The activity of movement-related putamen neurons is different from corticospinal neurons in the motor cortex, but is similar to the activity of corticostriatal neurons.

Striatal neurons related to movement have a distinct somatotopy with the face represented ventromedially and the leg dorsolaterally. They tend to occur in clusters of neurons with similar discharge characteristics. These clusters of physiologically similar neurons may correspond to the anatomically defined matrixes described earlier. Movement-related activity changes typically are observed as increases above the very low baseline. On average, movement-related striatal neurons fire 20 msec prior to movement (Fig. 31.10). About half of these neurons fire in relation to the direction of movement. Some neurons fire in relation to the start of movement and others in relation to the stop. Some neurons in the putamen fire in relation to self-initiated movements, some in relation to stimulus-triggered movements, and some in relation to both (Romo *et al.*, 1992). Some neurons in the anterior part of the putamen and in the caudate nucleus that receive input from the premotor or prefrontal cortex have

**FIGURE 31.10** Schematic representation of the timing of neuronal activity in three nuclei of the basal ganglia in relation to limb movement and the muscle activity used to make the movement.

activity during the preparation for movement. This activity is time locked to instructional cues but not to the movement itself. Some signals correlate with the instruction of whether to move (“set”). Other signals correlate with the signal to move (“go”). Although some individual neurons have signals that differentially relate to specific tasks or task parameters, as a whole the striatum is not exclusively active in relation to any of these tasks or parameters.

Striatal neurons active in relation to eye movements are located in a longitudinal zone in the central part of the caudate nucleus. This region receives input from the frontal and supplementary eye fields in the cortex. Similar to striatal neurons related to limb movements, striatal neurons related to eye movements may discharge during preparation for the movement or during the movement. Caudate neurons involved in saccades are strongly modulated by reward expectation (Hikosaka, 2007). This context-dependent modulation of activity may be a fundamental property of medium spiny neuronal activity in all circuits, but has been demonstrated best in the oculomotor circuit.

The timing of neuronal activity related to limb or eye movements is important to understanding the function of those neurons in the production of movement. In the putamen, most movement-related activity is late, occurring on average after the onset of muscle activity responsible for producing the movement. When compared to activity in the cerebral cortex, movement-related putamen neurons fire after those in the motor cortex and supplementary motor area. Putamen neurons related to movement preparation also fire substantially later than cortical neurons involved in movement preparation. Caudate neurons related to eye movements fire late relative to oculomotor areas of cortex. The late timing of striatal discharge during movement and movement preparation relative to discharge in cortical areas suggests that the striatum is not involved primarily in the initiation of movement. Instead, it receives information from cortical areas that are responsible for movement generation and may use that information for facilitation, gating, or scaling of cortically initiated movement.

A subset of striatal neurons (10%) is tonically active with discharge rates of 2 to 10 Hz. These neurons are distributed throughout the striatum and their discharge bears no specific relation to movement. These tonically active neurons (TANs) fire in relation to certain sensory stimuli that are associated with reward. For example, a TAN will fire in relation to a clicking sound if the click precedes a fruit juice reward but will not fire to the click alone or to the reward alone (Aosaki *et al.*, 1994). It has been suggested that these neurons signal aspects of tasks that are related to learning and

reinforcement. TANs are not activated by electrical stimulation of the GP and thus are probably not projection neurons. It is thought that TANs are cholinergic large aspiny interneurons that innervate the medium spiny neurons (see earlier discussions), which would place them in a position to modify the sensitivity of the medium spiny neurons to cortical input in relation to specific behavioral contexts.

Another subset of striatal neurons are the fast-spiking GABAergic inhibitory interneurons (Tepper *et al.*, 2004). These neurons correspond to the parvalbumin-positive neurons described previously. Their role in motor control has not yet been elucidated, in part because their small size makes recording in awake animals difficult. Nonetheless, these neurons are likely to play an important role in regulating the activity of medium spiny striatal neurons.

### STN Has Moderate Spontaneous Activity That Increases during Movement

Neurons in the STN are tonically active with average baseline discharge rates of about 20 Hz (Fig. 31.9). They are organized somatotopically and change activity in relation to eye or limb movement. For 90% of these neurons the change is an increase, occurring on average 50 msec prior to the movement (Fig. 31.10). The majority of movement-related neurons in STN have signals related to movement direction, but little is known about whether they discharge in relation to movement parameters such as amplitude or velocity.

### GPi and SNpr Have High Spontaneous Activity That Increases or Decreases after Movement Initiation

As described earlier, GPi and SNpr form the output of the basal ganglia. Just as they are similar anatomically, they are also similar physiologically. Neurons in these output structures are tonically active with average firing rates of 60 to 80 Hz (Fig. 31.9). They are organized somatotopically with the leg and arm in GPi and the face and eyes in SNpr. Due to the somatotopy, studies of limb movements have focused on GPi and studies of eye movements have focused on SNpr. Because limb and eye movements are controlled differently, these studies are discussed separately.

The discharge of many GPi neurons correlates with the direction of limb movement, but most GPi activity is not correlated with other physical parameters of movement, including joint position, force production, movement amplitude, or movement velocity. Few GPi neurons have activity correlated with the pattern of muscle activity. Like striatum, some GPi neurons have

activity related to movement preparation. During a reaching movement, 25% of GPi neurons are related to movement preparation and 50% are related to movement, but many neurons have more than one type of response. Approximately 70% of arm movement-related GPi neurons increase activity and 30% decrease activity from this tonic baseline during movement. Because the output from GPi is inhibitory, the large proportion of activity increases during movement translates to broad inhibition of thalamic and brain stem targets with more restricted facilitation during movement.

The timing of movement-related GPi activity is late compared to the activation of agonist muscles. The average onset of GPi activity is after the onset of EMG but before the onset of movement (Fig. 31.10). There is a tendency for GPi movement-related increases to occur earlier than decreases, which probably reflects the faster speed of the excitatory pathway from the cortex to GPi via STN compared with the slower inhibitory pathway from the cortex to GPi via striatum. The late timing of GPi movement-related activity suggests that the output of the basal ganglia is unlikely to initiate movement.

Like GPi neurons, SNpr neurons are tonically active. SNpr is the principal basal ganglia output for the control of eye movements, and most studies of SNpr activity have been in eye movement tasks (Hikosaka *et al.*, 2000). Most saccade-related SNpr neurons fire in relation to the direction of the eye movements. Unlike GPi neurons during limb movements, virtually all saccade-related SNpr neurons decrease activity during the saccade. It is not known whether the fact that most GPi limb movement neurons increase and most SNpr saccade neurons decrease indicates a fundamental difference between eye and limb movement control or if it reflects task differences. Other differences between GPi limb movement neurons and SNpr saccade neurons have been noted. GPi limb movement neurons have weak sensory responses, whereas some SNpr neurons have strong responses to visual stimuli. For the visually responsive SNpr neurons, the spatial location of the stimulus seems to be the most salient feature.

Some SNpr neurons have their strongest relation to saccades made to remembered targets. Thus, if a visual target is presented and then removed and a monkey is trained to look to where the target had been, some SNpr cells will fire more in this condition as compared to when a saccade is made to a visible target. Some SNpr neurons have activity related to the preparation for eye movement. One-third of SNpr cells have activity related to saccades to a visual target. Another third of SNpr cells have activity related to saccades to a

remembered target location. During saccades, the time of SNpr activity change is just after that in the superior colliculus, a structure that is known to be involved in the initiation of saccades. Thus, for eye movements, as well as limb movements, the basal ganglia output acts after structures that initiate movement.

### **GPe Has Irregular Activity That Increases or Decreases after Movement Initiation**

Two types of neurons have been described in GPe based on their baseline activity patterns. Most fire at a high frequency (70Hz) that is interrupted by long pauses. A smaller number fire at a low frequency (10Hz on average) and have frequent spontaneous bursts of activity. Both types of neurons change activity in relation to limb movement and, for the majority, these changes are increases in activity. As has been described for GPi, GPe neurons weakly and inconsistently code for movement amplitude, velocity, muscle length, or force. Like the other structures of the basal ganglia, the activity of movement-related activity is late.

### **SNpc Has Low Spontaneous Activity That Does Not Change with Movement, but Changes with Significant Environmental Stimuli**

The activity of single neurons in the SNpc of trained animals is different from the activity of single neurons in the other basal ganglia structures. At baseline, SNpc neurons fire at a low rate (2Hz on average). The activity of these neurons is not related to movement itself and there is no apparent somatotopy in SNpc. The neurons carry little specific information regarding sensory modality or spatial properties. The activity of SNpc neurons does change in relation to behaviorally significant events such as reward or the presentation of instructional cues. The responses to stimuli occur only if the stimulus is presented in the context of a movement task. Furthermore, the activity changes with conditioning. As an example, consider an SNpc neuron that fires in relation to an unexpected reward. If one records from this neuron over several trials while the reward is paired with a tone that precedes the reward, the SNpc neuron will gradually stop firing in relation to the reward and instead will begin to fire in relation to the tone that predicts the reward.

Thus, it appears that SNpc DA neurons can predict the occurrence of a significant behavioral event. In this way, SNpc neurons are similar to the TANs neurons described earlier. Remember that SNpc neurons also

synapse extensively on medium spiny striatal neurons and that DA terminals are on the shafts of dendritic spines. It has been suggested that the DA input changes the sensitivity of striatal neurons to cortical inputs that terminate on the heads of dendritic spines. If so, the activity of SNpc neurons could modify the response of striatal neurons to cortical input that occurs in a specific behavioral context. Such influences may be related to the apparent ability of DA to mediate both long-term potentiation and long-term depression in striatal neurons, which in turn is likely to be an important mediator of learning and plasticity in the striatum (see Chapters 49 and 50).

### **Summary**

Several general statements about basal ganglia movement-related neuronal discharge can be made.

1. Movement-related neurons in the striatum, STN, GP, and SNpr are arranged somatotopically.
2. Neurons in the striatum are quiet at rest and increase during movement. Neurons in STN are tonically active and increase during movement. Recalling the anatomy, this means that GPi neurons receive a widespread, tonically active excitatory input and a focused, intermittent inhibitory input.
3. Neurons in both GPe and GPi are tonically active. Most increase activity, but up to one-third decrease activity during limb movement.
4. Neurons in SNpr are also tonically active. Those that are related to saccadic eye movements decrease activity during the movement.
5. Neurons in SNpc discharge in relation to rewards and behaviorally relevant stimuli, but not to movement. They are likely to play a critical role in some types of motor learning.
6. Changes in the activity of basal ganglia occur at the onset of movement but after the muscles are already active. Thus, they are unlikely to initiate movement.

## **THE EFFECT OF BASAL GANGLIA DAMAGE ON MOVEMENT**

Valuable clues to the function of the basal ganglia have come from recording the activity of single neurons during behavior. However, correlation of neural activity with an aspect of behavior does not necessarily mean that neural activity causes that aspect of behavior. To better determine the role of the basal ganglia in

behavior, one would want to selectively remove a specific component from an otherwise intact system. Certain human neurological diseases involve the degeneration of neurons in the basal ganglia. Historically, these diseases fueled great interest and have provided some insight into basal ganglia function. The movement disorders that result from basal ganglia damage are often dramatic. Depending on the site of the pathology, some basal ganglia diseases cause extreme slowness of movement and rigidity and others cause uncontrollable involuntary movements. Although human diseases are of great interest, they often affect more than one structure. This necessarily limits the power of functional models derived from the study of human basal ganglia diseases. In experimental animals, more selective lesions can be made, but until recently it was difficult to reproduce the movement disorders associated with human basal ganglia disease.

Experimental lesions can be made in a number of ways. Permanent lesions can be made by passing electric current through an electrode to destroy both cell bodies and axons in the area surrounding the electrode. This has the disadvantage of destroying axon fibers that are passing through the area but that are not necessarily part of the structure of interest. Injection of a small amount of certain toxic chemicals into the brain (e.g., kainic acid or ibotenic acid) results in the focal death of neurons with cell bodies in the area of the injection but axons passing through the area are spared. Agonists and antagonists of the GABA have been injected into the brain to cause temporary, focal inactivation or disinhibition of neurons. The effect of these chemicals lasts for several hours followed by complete return to the normal state. Later we discuss the use of toxins to produce a third type of lesion, one that can remove a particular type of neurons, while leaving others intact. This section reviews the results of selective basal ganglia lesions in animals produced by a variety of techniques. We discuss human basal ganglia diseases in the context of these experiments.

### **Damage to the Striatum Causes Slow Voluntary Movements or Involuntary Postures and Movements**

Lesions in the striatum produce variable results that depend on the location of the lesion, the lesion method, and what is measured. Many studies of unilateral striatal lesions in monkeys have described only minimal deficits. In human patients, strokes localized to the putamen often cause dystonia, a syndrome characterized by abnormal sustained muscle contraction causing twisting postures. If the putamen is inactivated phar-

macologically with the GABA agonist muscimol unilaterally, the result is slow movement of the contralateral limb. The slowed movement is associated with an increased activity of antagonist muscles. Although movement is slow after putamen lesions, reaction time is generally normal, indicating movement initiation is intact. Large bilateral electrolytic lesions result in the paucity of movement, severe slowness of movement bilaterally, and postural abnormalities. In other studies, there appears to be little effect of experimental bilateral electrolytic putamen lesions. The reason for this discrepancy is not clear, but it may be due to differences in lesion size.

Huntington's disease (HD) is a genetically based, degenerative disease in humans that results in disabling involuntary movements. These movements are called chorea (Greek for "dance"). They are frequent, brief, sudden, random twitch-like movements that involve all parts of the body and resemble fragments of normal voluntary movement. As the disease progresses, muscular rigidity appears. Despite the excessive involuntary movements, the voluntary movements of patients with HD are slower than normal. The pathologic hallmark of HD is a marked loss of neurons in the striatum. Studies have shown that not all striatal neurons are equally affected in HD (Albin *et al.*, 1989). In early adult-onset HD, the enkephalin-containing neurons that project to GPe are lost first. Clinically, this is associated with the presence of chorea. In late adult-onset and in juvenile-onset HD, both the enkephalin-containing and the substance P-containing striatal neurons that project to GPi and SNpr are lost. Clinically, this loss is associated with the presence of rigidity and dystonia (sustained, abnormal postures). Interestingly, experimental destructive lesions of the striatum in monkeys do not result in chorea. This is probably due to the nonselective destruction of both GPe and GPi projecting striatal neurons. More selective disruption of the striatal-GPe pathway with a GABA antagonist administered into the GPe does produce chorea. The suggested mechanism for chorea is that disinhibition of GPe neurons (pharmacologically, or as a result of selective striatal cell death) causes inhibition of STN and GPi. This results in abnormal overactivity of motor cortical and brain stem mechanisms, resulting in chorea.

### **Damage to STN Causes Large-Scale Involuntary Movements**

In human patients, stroke involving the STN and in monkeys, electrolytic or pharmacological lesions in the STN cause dramatic involuntary flinging movements of the contralateral arm and leg. These movements

have been called hemiballismus. They resemble chorea in their brief, random, and sudden nature, but they tend to be much larger in amplitude. After a lesion in STN, the hemiballism lasts for days to weeks before gradually resolving. Animals and humans with hemiballism can still make voluntary movements and often the voluntary movements appear to be quite normal. It has been suggested that the mechanism underlying the hemiballism is a loss of excitatory input to GPI, resulting in decreased GPI activity and ultimately in the disinhibition of cortical and brain stem motor mechanisms (Albin *et al.*, 1989). Several lines of evidence support this. First, blocking the excitatory transmission from STN to GPI with a glutamate antagonist administered into GPI causes involuntary movements. Second, metabolic activity patterns as shown with 2-deoxyglucose uptake indicate decreased GPI output in hemiballism. Third, neuronal recording during stereotaxic surgical treatment of movement disorders has shown decreased GPI activity in patients with chorea or hemiballism. However, it is likely that chorea or hemiballism is due to abnormal patterns of basal ganglia output signals and not just tonically decreased activity. Thus, if hemiballism or chorea is produced by an STN lesion in monkeys, a second lesion placed in GPI abolishes the involuntary movements. Furthermore, in monkeys with STN lesions, the level of GPI activity is reduced even after the involuntary movements resolve. Finally, destruction of GPI in humans with hemiballism or chorea abolishes the involuntary movements and experimental lesions of GPI in monkeys but do not cause chorea. Therefore, it seems likely that chorea and hemiballism reflect an abnormal fluctuating or bursting output from the basal ganglia rather than a simple reduction of output.

### Damage to GP Causes Slow Voluntary Movements and Involuntary Postures and Does Not Delay Movement Initiation

Lesions of the GPI result in slowing of movement but normal movement initiation. Because of their close proximity to each other, it is difficult to lesion GPI without including part of GPe or vice versa. Therefore, caution must be used in interpreting results of GP lesions. However, in most cases, combined GPe and GPI lesions have a similar effect to the lesion of GPI alone. Unilateral lesions of GPe and GPI result in slowness of movement, with abnormal cocontraction of agonist and antagonist muscles, but normal initiation of movement. Bilateral lesions of GPe and GPI result in even more severely abnormal flexed postures with an apparent inability to move out of them. Electrolytic lesions producing this severe abnormality have tended

to be large, involving both GPe and GPI and part of the internal capsule. Similar abnormalities are seen with carbon monoxide or carbon disulfide poisoning, which results in neuron death in GPI and SNpr.

Lesions restricted to GPI result in slowness of movement of the contralateral limbs. After GPI lesions, reaction time is normal, which indicates that mechanisms involved in the initiation of movement are intact. In some studies, the slowness of movement is accompanied by a cocontraction of agonist and antagonist muscles, which results in abnormal postures (dystonia). In most cases, there is relatively more activity of flexor muscles that is reflected in a tendency of the limbs to assume an abnormally flexed posture. Monkeys with GPI lesions are more impaired when movements are made by turning off active muscles than when movements are made by further turning on active muscles (Mink and Thach, 1991) (Fig. 31.11). Thus, lesions that remove the inhibitory output of the basal ganglia appear to interfere with the ability to turn off unwanted muscle activity.

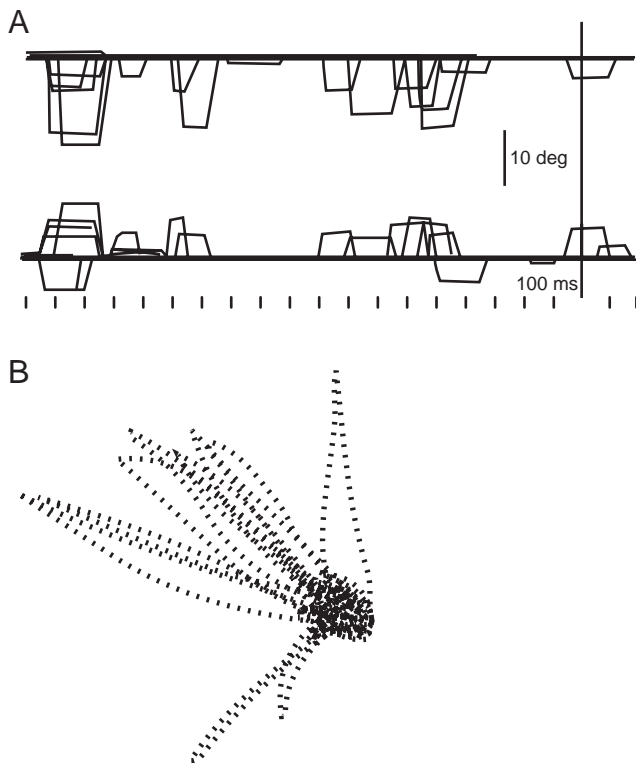

**FIGURE 31.11** Wrist position and velocity in visually guided wrist movements before (black traces) and after (blue traces) a lesion of the globus pallidus internal segment. In each graph, the top traces represent wrist position, the lower traces represent wrist velocity. (A) Flexion with the flexor muscles loaded (movement made by further activating the loaded muscles). (B) Flexion with extensor muscles loaded (movement made by turning off the loaded muscles). (C) Extension with flexor muscles loaded (movement made by turning off the loaded muscles). (D) Extension with extensor muscles loaded (movement made by further activating the loaded muscles). After the lesion, the peak velocity was slower when the movements were made by decreasing the activity of the loaded muscle than when made by increasing the activity of the loaded muscle. From Mink and Thach (1991).

### Damage to SNpr Causes Involuntary Eye Movements

Due to its proximity to SNpc, it is difficult to produce electrolytic lesions exclusively in SNpr. However, with the use of the GABA agonist muscimol, it has been possible to inactivate neurons focally in SNpr. Injection of muscimol into the lateral SNpr inactivates neurons that are normally involved in saccadic eye movements. Inactivation in this area results in an inability to maintain visual fixation because of involuntary saccades (Fig. 31.12). The inability to suppress involuntary saccades appears to result from disinhibition of the superior colliculus. Injection of the GABA antagonist bicuculline into the superior colliculus mimics the effects of muscimol in SNpr. Thus, just as GPi inactivation results in abnormal excess limb and trunk muscle activity, SNpr inactivation results in abnormal excess eye movements.

**FIGURE 31.12** After inactivation of substantia nigra pars reticulata, monkeys are unable to maintain fixation of gaze because of involuntary contraction of the eye muscles. (A) The top line represents vertical eye position, and the bottom line represents horizontal eye position during attempted visual fixation. (B) Lines represent the trajectory of the involuntary eye movement when the monkey was instructed to maintain its gaze in the center dot. From Hikosaka and Wurtz (1985).

### Damage to SNpc Causes Symptoms of Parkinson's Disease

Lesions of SNpc are of particular interest because the DA neurons in this nucleus die in Parkinson's disease (PD). PD is a neurological disease that affects older adults. The main symptoms of PD are (1) tremor at rest that decreases during movement, (2) slowness of movement (bradykinesia), (3) paucity of movement (akinesia), (4) muscular rigidity, and (5) unstable posture. The primary pathology in PD is a progressive degeneration of neurons in the SNpc. Additionally, there is some degree of loss of DA neurons in the ventral tegmental area and of norepinephrine neurons in the locus coeruleus. Although PD has been recognized for over a century, it only has been since the early 1980s that a complete animal model has been available. As noted earlier, the interdigitation of SNpc and SNpr has made selective electrolytic lesions of SNpc or SNpr difficult to produce. In the 1960s, it was found that 6-hydroxydopamine (6-OHDA) produces specific lesions of catecholamine neurons. Therefore, injection of 6-OHDA into the rat SN bilaterally produces a selective loss of SNpc DA neurons. Lesions made in this way result in some of the abnormalities of PD, namely the slowness of movement and rigidity, but they did not produce tremor. In the 1980s, a street drug contaminant called MPTP (Box 31.3) was found to produce all the symptoms of PD in humans and in certain species of monkeys. The MPTP monkey has proven an extremely valuable model with which to explore this disease.

Despite extensive investigation, the fundamental mechanism of the tremor in PD is not known. Some evidence suggests that it results from abnormal bursting of neurons in the thalamus. Other evidence suggests it is due to abnormal synchronous bursting of GPi neurons. The slowness of movement in PD has been associated with a reduced magnitude and duration of muscle activity during movement. In monkeys that have been given 6-OHDA or MPTP, the activity of motor cortex neurons during arm movements is also reduced compared with normal monkeys. In the MPTP monkey model of PD, some animals have abnormally increased activity of STN and GPi and decreased activity of GPi. GPi neurons in the MPTP monkey have abnormal bursting activity and abnormally increased responses to somatosensory stimuli. It has been suggested that the increased activity of GPi causes an excess inhibition of motor mechanisms in the cortex and brain stem and that this excess inhibition causes movements to be slow (Albin *et al.*, 1989). However, recent studies have shown that GPi firing rate can be normal in PD or in MPTP monkeys, but that abnormal

## BOX 31.3

## THE MPTP STORY

Up until the early 1980s, the quest for a complete animal model of Parkinson's disease (PD) was largely unsuccessful. Although some of the abnormalities of PD could be caused by electrolytic lesion of SNpc or by injecting the neurotoxin 6-hydroxydopamine into SNpc, neither of these methods produced the full syndrome of PD. Then, in 1982 an unfortunate, but fortuitous, accident happened. Four young drug users in northern California developed symptoms of PD. Because PD is highly unusual in young adults, the neurologists caring for these patients began a search for the cause (Langston *et al.*, 1983). They discovered that each of the patients had recently obtained a "new" synthetic heroin. This "new heroin" contained an analog of the narcotic meperidine, 1-methyl-4-phenyl-propionoxy-piperidine (MPPP), and a contaminant, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP). It turned out that MPTP was the agent responsible for the parkinsonism. MPTP is oxidized in the brain to MPP<sup>+</sup> by monoamine oxidase. MPP<sup>+</sup> is taken up by DA neurons where it inhibits oxidative metabolism in the mitochondria and ultimately leads to cell death.

Subsequently, it has been found that MPTP produces a Parkinson's-like syndrome in several species of monkeys. Unlike previous models, monkeys given MPTP had not only slowness of movement, paucity of movement, and

rigidity, but also tremor. The Parkinson's-like syndrome in monkeys given MPTP is associated with a nearly complete degeneration of DA neurons in SNpc and the ventral tegmental area and variable degeneration in the locus coeruleus. MPTP monkeys improve when given the DA precursor L-DOPA and have side effects of chorea when they are given too much L-DOPA, similar to what happens in people with PD. Hence, by behavioral, pharmacological, and pathological measures, the MPTP monkey is an excellent model of human PD. It is currently used to study the pathophysiology and pharmacology of PD and it has led to new ideas about possible causes of PD. One such idea is that environmental toxins may play a role in the etiology of PD. In this regard, it is important to note that paraquat and rotenone, two compounds that are used commonly as pesticides and/or herbicides, both have MPTP-like structures and have also been shown to damage DA neurons.

bursting and oscillatory firing is seen more consistently. Thus, it appears that the abnormal patterns of GPI activity may be more important than the more modest increase in average firing rate.

The rigidity of PD has been attributed in part to hyperactivity of the transcortical stretch reflex. Normally, the transcortical stretch reflex is active to resist displacement from an actively held posture. It is inhibited when subjects are instructed not to resist the displacement. People with PD have abnormally increased transcortical stretch reflexes and are unable to suppress them in response to instruction. The inability to inhibit long-loop reflexes may also account for the postural instability of PD. Patients with PD have an inappropriate cocontraction of leg and back muscles in response to perturbation from an upright stance. When the same subjects perturbed from a sitting position, they are not able to inhibit the postural reflexes that were active during stance. This suggests that the mechanism of rigidity and postural instability may be

similar and that they reflect an inability to suppress unwanted reflex activity.

Paradoxically, it is known that lesions of GPI or STN can ameliorate many or all of the signs and symptoms of PD without producing the abnormalities associated with lesions in these areas in normal animals or humans. This is particularly paradoxical for GPI lesions that can produce the signs of PD (flexed posture, slow movement, rigidity) in normal monkeys and in some rare human diseases, but can reduce or eliminate those signs in monkeys and humans with preexisting lesions of the DA system. Why this is the case is not known, but it may relate to long-term changes in basal ganglia physiology that result from chronic DA depletion.

Chronic, high-frequency stimulation of the STN or GPI has been found to be effective for the treatment of symptoms in advanced PD. This has been called deep brain stimulation (DBS). There is active investigation into mechanisms by which DBS works and the exact mechanism is not fully understood. However, it

appears that DBS activates efferents from the site of stimulation and disrupts abnormal patterns of neural transmission (Perlmutter and Mink, 2006). This disruption of abnormal patterns mimics the effects of a lesion in the stimulated area. DBS is now the most commonly used neurosurgical treatment for PD. The growth of neurosurgical treatment of PD is a direct result of knowledge about basal ganglia circuitry.

## Summary

To review the preceding section:

1. Damage to any basal ganglia structure may cause slowness of voluntary movement, involuntary movements, involuntary postures, or a combination of these.
2. Damage to the striatum causes voluntary movements to be slow and may produce involuntary movements or postures depending on the mechanism of damage.
3. Damage to the STN causes large amplitude involuntary limb movements.
4. Damage to the GP causes slowness of movement, abnormal postures, and difficulty relaxing muscles, but does not delay movement initiation.
5. Damage to SNpr causes abnormal eye movements, but does not delay the initiation of eye movements.
6. Damage to SNpc causes tremor at rest, slowness of movement, rigidity, and postural instability, which are the main features of PD.

## FUNDAMENTAL PRINCIPLES OF BASAL GANGLIA OPERATION FOR MOTOR CONTROL

How do the basal ganglia participate in motor control? Several hypotheses have been advanced over the past century, many of which have been mutually contradictory. This has been due in part to models that infer normal function from the abnormalities resulting from basal ganglia disease. There is growing consensus that models based on human disease states may not be sufficient to explain normal basal ganglia function. Regardless, the models based on human disease have been useful in developing new treatments for movement disorders and for the development of testable hypotheses relating to basal ganglia function.

An old model of basal ganglia function is that the basal ganglia initiate movement. This model was based in large part on the manifestation of basal ganglia dis-

eases. The paucity and slowness of movement in PD were attributed to an inability to initiate movements, whereas the involuntary movements of chorea and hemiballism were attributed to a release of normal motor systems from basal ganglia control. This model gained support from the fact that much of the output from the basal ganglia goes to parts of the thalamus that project to the premotor and motor cortex. It was argued that motor programs are stored in the basal ganglia and are called up and sent to the motor cortex for execution. This model is no longer widely accepted because it is now apparent that basal ganglia are active relatively late in relation to movement and to the activation of those brain mechanisms that are known to be involved in initiation. Furthermore, lesions of basal ganglia output nuclei do not delay the initiation of movement.

If basal ganglia do not initiate movement, what do they do? We consider three current hypotheses. One hypothesis states that although basal ganglia do not initiate movement, they contribute to the automatic execution of movement sequences. This hypothesis suggests that other mechanisms initiate the first component in a sequence, but that basal ganglia contain the programs for completion of the sequence. The second hypothesis states that the basal ganglia circuitry is made up of opposing parallel pathways that adjust the magnitude of the inhibitory GPi output in order to increase or decrease movement. According to this hypothesis, increased GPi output slows movements and decreased GPi output increases movement. The third hypothesis states that basal ganglia act to permit desired movements and to inhibit unwanted competing movements.

## Do Basal Ganglia Automatically Generate Learned Movement Sequences?

A popular hypothesis states that basal ganglia are responsible for the automatic execution of learned movement sequences (Marsden, 1987). It has been pointed out that patients with PD have difficulty moving several body parts simultaneously or sequentially, and that this difficulty is more than one would expect from a simple addition of the deficits of each component of the movement. An example of an apparent problem with sequential movements in PD is the phenomenon of micrographia (or small writing). A patient begins to write a sentence with nearly normalized writing, but within several letters, the writing begins to get smaller so that by the end of the sentence, it may be illegible. It has been emphasized that the early components of the sequence are larger and faster than are the subsequent components. One experiment

compared the performance of elbow flexion and hand grip individually or in sequence (Benecke *et al.*, 1986). Patients with PD performed each movement more slowly than normal subjects. However, when the movement was part of a sequence, it was slowed to an even greater degree than when it was performed separately.

Another experiment involved recording the activity of GPi neurons in monkeys trained to perform two successive prompt wrist movements. It was found that some GPi neurons fired after the first component of the movement but before the second component (Brotchie *et al.*, 1991). Proponents of the sequencing hypothesis speculate that the loss of this GPi output signal in PD is responsible for the relatively greater difficulty in producing sequential movements than in producing individual movements.

Additional support for this hypothesis comes from experimental work showing correlation of striatal neuron activity patterns with sequence learning (Fig. 31.13) or with learning a new skill and from a human functional imaging studies showing correlation of blood flow patterns in striatum with procedural learning (Graybiel, 2005).

**FIGURE 31.13** Reorganization of neuronal activity in the sensorimotor striatum during habit learning in a T-maze task. (A) Schematic activity maps representing the average proportion of task-related units responsive to different parts of the task from early to late in training. The maps are based on neuronal firing data and proportion of neurons active according to the color scale shown to the right (red is high and blue is low). From left to right, the maps show activity patterns in relation to the different parts of the T-maze for training stage 1 (day 1), stage 3 (first criterial performance day), stage 5 (average stage of stable learning), and stage 9 (seventh day with above-criterion performance). (B) Schematic activity maps representing the population spike discharge as the percentage of total spike discharges of striatal neurons simultaneously recorded during the same four training stages illustrated in (A). The activity maps were made as those in (A), and the color scales used for (A) and (B) were identical. Note the progressive change in activity such that activity increases at the beginning and end of the behavior as learning progresses. This is thought to represent transition from representation of individual components to representation of the entire sequence (or chunk) of behavior. From Jog *et al.* (1999).

### Do Basal Ganglia Produce or Prevent Movement by Using Opposing Direct and Indirect Parallel Pathways?

This hypothesis emphasizes the two major paths of information flow from the striatum to GPi and SNpr that were described earlier (Fig. 31.14) (Alexander and Crutcher, 1990). To recapitulate, one is an inhibitory “direct” pathway from striatum to GPi/SNpr and the other is a net excitatory “indirect” pathway from striatum to GPe (inhibitory), from GPe to STN (inhibitory),

**FIGURE 31.14** Schematic of proposed “direct” and “indirect” pathways from putamen to GPi. See the text for a description. Red symbols represent inhibitory pathways, and green symbols represent excitatory pathways. From Alexander and Crutcher (1990).

and from STN to GPi/SNpr (excitatory). In this hypothesis, the two pathways are in balance in such a way that increased activity in the “direct” pathway causes decreased GPi/SNpr output and increased activity in the “indirect” pathway causes increased GPi/SNpr output. By adjusting the balance, cortical targets of the basal ganglia can be facilitated or inhibited. The hypothesis predicts that abnormally decreased output results in excessive movements (chorea) and abnormally increased output results in a decreased movement (PD). The “direct/indirect pathway” model has been useful for understanding and developing certain treatments of movement disorders, but it has some shortcomings when it comes to explaining normal basal ganglia function and the mechanism of treatments for involuntary movements. Despite the shortcomings, this has been a central hypothesis in the field of basal ganglia research for over 20 years. If the success of a model can be measured by the amount of research it stimulates, this one has been highly successful.

### Do Basal Ganglia Select and Inhibit Competing Motor Patterns?

The output of the basal ganglia is inhibitory to posture and movement pattern generators in the cerebral cortex (via thalamus) and in the brain stem. The inhibitory output neurons fire tonically at high frequencies. In this hypothesis, the motor output of the basal ganglia is analogous to a brake (Mink, 1996). The hypothesis states that when a movement is initiated by a particular motor pattern generator, GPi neurons projecting to that generator decrease their discharge, thereby removing tonic inhibition and “releasing the brake” on that generator. GPi neurons projecting to other movement pattern generators increase their firing rate, thereby increasing inhibition and applying a “brake” on those generators. Thus, other postures and movements are prevented from interfering with the one selected.

How might this mechanism work? When one makes a voluntary movement, that movement is initiated by the prefrontal, premotor, and motor cortex and by the cerebellum. The premotor and motor cortex send a corollary signal to STN, exciting it. STN projects to GPi in a widespread pattern and excites GPi. In parallel, signals are sent from the cortex to the striatum, which inhibits GPi focally via a direct pathway. Striatum can also disinhibit GPi via two indirect pathways (striatum → GPe → GPi and striatum → GPe → STN → GPi). The indirect pathways further focus the effects of the fast excitatory cortico-STN pathway and the slower inhibitory cortico-striatal pathway to GPi. The net result is to release the “brake” from the selected

voluntary movement pattern generator and to apply the “brake” to potentially competing posture-holding pattern generators (transcortical, vestibular, tonic neck, and other postural reflexes). The result is the focused selection of desired motor patterns and surround inhibition of competing patterns. Disruption of this organization at different nodes can lead to specific movement disorders.

## BASAL GANGLIA PARTICIPATION IN NONMOTOR FUNCTIONS

Although the focus of this chapter has been on motor control, it has become increasingly clear that the basal ganglia participate in a variety of nonmotor functions. These include functions of the limbic system (see Box 31.4 and Chapters 43 and 44) and cognitive functions. The anatomy of basal ganglia circuits has revealed outputs going to all areas of frontal cortex, placing the basal ganglia in a position to influence a wide variety of behaviors. As discussed earlier, specific areas of the basal ganglia are connected preferentially with specific areas of the cerebral cortex. This provides the anatomic substrate for the localization of different functions in the basal ganglia circuits. It is known that focal lesions of the striatum tend to produce deficits similar to those seen after lesions of afferent areas of the cortex. Thus, lesions of posterior putamen cause movement deficits, lesions of inferior caudate produce deficits similar to lesions of the orbitofrontal cortex, and lesions of the dorsolateral caudate produce deficits similar to lesions of dorsolateral prefrontal cortex. The basal ganglia have been implicated in a variety of nonmotor disorders, including depression, obsessive-compulsive disorder (Box 31.6), attention deficit hyperactivity disorder, and schizophrenia. Regardless of the type of function, it is becoming clear that the basic underlying principles of basal ganglia function are similar. Thus, the intrinsic circuitry is the same for cognitive and motor parts of the basal ganglia, the basic neurophysiology appears to be the same, and the effects of lesions are analogous. For example, chorea is characterized by excessive involuntary movements, and obsessive-compulsive disorder is characterized by excessive involuntary thoughts and complex behaviors. The hypothesis of focused selection and surround inhibition has been applied to nonmotor basal ganglia functions (Redgrave *et al.*, 1999) and data support each hypothesis from cognitive science and psychiatric research.

There is increasing evidence for a role of the basal ganglia in procedural learning. Much of the research

## BOX 31.4

## VENTRAL SYSTEM OF THE BASAL GANGLIA

There are nuclei in the brain that historically have not been included with the basal ganglia, but that are analogous to the traditional components. These lie ventral to the neostriatum and GP and are called the ventral striatum (nucleus accumbens and olfactory tubercle) and the ventral pallidum. The ventral striatum receives input from limbic and olfactory areas of the cortex, including the amygdala and hippocampus. Like the neostriatum, the ventral striatum receives a DA input, but it is from the ventral tegmental area (VTA), which lies medial to the SN. The ventral striatum sends a projection back to VTA and to the adjacent SNpr. The ventral pallidum is analogous to both GPe and GPi. It receives input from the ventral striatum and possibly from STN. Unlike the GP, the ventral pallidum receives direct input from the amygdala. The output of the ventral pallidum projects to the dorsomedial nucleus of the thalamus (DM) and from

there to limbic areas of the cortex. By virtue of its inputs and outputs, the ventral system is closely linked to the limbic system. This linkage has led to the suggestion that the ventral system is involved in motivation and emotion (see Chapter 43). The exact nature of this role is not known, but it may be analogous to the motor role of the basal ganglia, with the inhibitory output of the ventral pallidum acting to suppress or select potentially competing limbic mechanisms. In addition, Haber and colleagues have described circuitry by which activity in the ventral system ultimately influences the other circuits of the basal ganglia (Haber *et al.*, 2000). Such circuitry may underlie a more integrative function across basal ganglia circuitry.

*Jonathan W. Mink*

has focused on the learning of tasks or of sequential behavior. There is evidence for a role of the basal ganglia in procedural learning that leads to the formation of habits and the performance of behavioral routines once they are learned (Jog *et al.*, 1999). As described earlier, TANs and SNpc DA neurons fire in relation to behaviorally significant events. The activity patterns of these neurons change as the task becomes learned and when novel stimuli or events are introduced. There is also growing evidence for DA-mediated long-term potentiation and long-term depression in striatal neurons that is likely to play an important role in learning. It has been shown that non-TAN striatal neurons also change activity in relation to learning. In rats performing a T-maze task, striatal neurons changed activity patterns as the task became learned and more automatic (Jog *et al.*, 1999). In monkeys performing a discrimination learning task, striatal neurons changed activity as the animal learned new associations between stimuli and reward (Tremblay *et al.*, 1998). Functional imaging studies have also shown basal ganglia activity correlated with the learning of new tasks. Striatal lesions or focal striatal DA depletion impairs the learning of new movement sequences, and procedural learning has been shown to be impaired

in people with PD. These findings together support a role for the basal ganglia in certain types of procedural learning. However, other brain structures have also been implicated in procedural learning, including the cerebellum (see Chapter 50). Just as the cerebellum and basal ganglia play different roles in motor control, they are likely to play different, but complementary, roles in procedural learning. The exact nature of those different roles is the subject of current research.

### Summary

It is appropriate to consider the basal ganglia as part of the motor system because the largest portion of the basal ganglia is devoted to motor control and the most prominent deficits resulting from basal ganglia damage are motor. However, it has become clear that the basal ganglia play substantial roles in nonmotor function and in more cognitive aspects of movement. These roles are the subject of active research. Ultimately, a unifying theory of basal ganglia function that will encompass all the subdivisions is likely to emerge. Based on the circuitry and known physiology, it is likely that different cortico-basal ganglia-thalamo-cortical circuits employ similar mechanisms.

## BOX 31.5

## HUNTINGTON'S DISEASE

Huntington's disease (HD) is an inherited progressive neurodegenerative disorder that affects about 1 in 10,000 people. Symptoms include abnormal movements (comprising both involuntary movements termed chorea or dystonia and motor incoordination), cognitive difficulties, and emotional difficulties, including depression, apathy, and irritability. Onset is usually in midlife, but can range between childhood and old age. HD is generally fatal within 15 to 20 years after onset. The disease is caused by an expanded CAG repeat coding for polyglutamine in the HD gene product, termed the "huntingtin" protein. CAG repeat lengths between about 10 and 25 are normal, whereas those above 36 cause HD. Within the expanded range, the longer the repeat, the earlier the age of onset. The normal function of huntingtin is poorly understood, but it may be involved with cytoskeletal function, or cellular transport.

Pathologically, HD is characterized by selective neuronal vulnerability. The caudate and putamen of the corpus striatum are most affected in early stages, but as the disease progresses, other areas of the brain also become affected. Within the striatum, medium spiny GABA neurons are severely affected, with up to 95% loss in advanced cases, whereas large interneurons are relatively spared. In addition, there are intranuclear inclusion bodies and perinuclear and neuritic aggregates of huntingtin in HD neurons.

The pathogenesis of HD is still incompletely understood and represents a challenge for neuroscience. The huntingtin protein is widely expressed throughout the brain and is expressed at lower levels in other regions of the body as well. HD, like other neurodegenerative diseases, involves abnormal protein folding and aggregation. The inclusions themselves appear not to be directly

toxic, but they likely represent a late stage of an abnormal process, whose earlier steps are pathogenic. The study of the disease has been facilitated by the generation of cell models, invertebrate models, and mouse models. Chaperone proteins can ameliorate the pathology, perhaps by refolding abnormally folded huntingtin. Huntingtin may normally be degraded by intracellular proteolytic machinery, termed the proteasome, and inhibition of the proteasome may be one of the toxic effects of the abnormally expanded polyglutamine.

A number of lines of evidence have pointed to a possible role for abnormal gene transcription in HD. Several studies have suggested that targeting of huntingtin to the nucleus enhances toxicity. Huntingtin may normally have a role in regulation of gene transcription, although this is poorly understood. Expression array studies show that mouse and cell models have an alteration of normal gene expression patterns. Abnormal interactions with coactivator and corepressor complexes may contribute.

Whatever the initial mechanisms, symptoms appear to be caused by both cell dysfunction and cell death, with cell death correlating best with functional disability. Thus, preventing cell death is a major goal of experimental therapeutics in HD and other neurodegenerative disorders. Cell death may partly involve apoptotic mechanisms with activation of caspases and may also involve mechanisms such as excitotoxicity, metabolic, or free radical stress. Therapeutic strategies under investigation include protection of neurons with neurotrophins, altering abnormal gene transcription patterns, and reducing cell death with inhibitors of caspase activation or blockers of excitotoxicity.

## OBSESSIVE-COMPULSIVE DISORDER

Obsessive-compulsive disorder (OCD) is a chronic disorder characterized by recurrent intrusive thoughts and ritualistic behaviors that consume much of the afflicted individual's attentional and goal-directed processes. Among the more agonizing illnesses in clinical medicine, OCD is classified as an anxiety disorder because of the marked tension and distress produced by resisting the obsessions and compulsions. Common obsessions involve thoughts of harming oneself or others, of being afflicted by various illnesses, or of being contaminated by germs. Compulsions may be a response to obsessive thoughts (e.g., repetitive hand-washing following skin contact with any object due to obsessive worries of having contacted germs) or may instead reflect cognitive-behavioral rituals performed according to stereotyped rules (e.g., counting one's footsteps to avoid ending on certain numbers). Although individuals with OCD recognize that such thoughts and behaviors are irrational, they feel irresistibly compelled to engage in them.

The onset of OCD usually occurs between late childhood and early adulthood. Without treatment, OCD is often disabling. However, chronic treatment with drugs that potentially inhibit serotonin reuptake can reduce the amount of time engaged in obsessions and compulsions and the magnitude of the associated anxiety. In addition, behavioral therapy involving repeated *in vivo* exposure and response prevention (e.g., having patients touch a toilet seat and subsequently preventing them from hand washing) may facilitate extinction of the anxiety responses generated by resisting obsessive thoughts and compulsive behaviors.

The etiology and pathophysiology of OCD are unknown. Converging evidence from analysis of the lesions that result in obsessive-compulsive symptoms, functional neuroimaging studies of OCD, and observations regarding the neurosurgical interventions that can ameliorate OCD implicate prefrontal cortical-striatal circuits in the pathogenesis of obsessions and compulsions. The neurological conditions associated with the development of secondary obsessions and compulsions include lesions of the globus pallidus and putamen, Sydenham chorea (a poststreptococcal autoimmune disorder associated with neuronal atrophy in the caudate and putamen), Tourette disorder (an idiopathic syndrome characterized by motoric and phonic tics that may have a genetic relationship with OCD, see Box 31.7), chronic motor tic disorder, and lesions of the ventromedial prefrontal cortex. Several of these conditions are associated with complex motor tics (repetitive, coordinated, involuntary movements occurring in patterned sequences in a spontaneous, unpredictable, and transient manner). Complex tics and obsessive thoughts may thus both reflect aberrant neural processes originating in distinct portions of the cortical-striatal-pallidal-thalamic circuitry that are manifested

within the motor and cognitive-behavioral domains, respectively. Compatible with this hypothesis, neurosurgical procedures that interrupt the white matter tracts carrying projections between the frontal lobe, basal ganglia, and thalamus are effective at reducing obsessive-compulsive symptoms in OCD cases that prove intractable to other treatments.

Functional neuroimaging studies have also implicated prefrontal cortical-striatal circuits in the pathophysiology of OCD. In primary OCD, "resting" cerebral blood flow and metabolism are increased abnormally in the orbitofrontal cortex and the caudate nucleus, and increase further during symptom provocation in these areas, as well as in the putamen, thalamus, and anterior cingulate cortex. During effective pharmacotherapy, orbital metabolism decreases toward normal, and both drug treatment and behavioral therapy are associated with a reduction of caudate metabolism. In contrast, imaging studies of obsessive-compulsive syndromes arising in the setting of Tourette syndrome or basal ganglia lesions have found reduced metabolism in the orbital cortex in such subjects relative to controls. Differences in the functional anatomical correlates of primary versus secondary OCD suggest that dysfunction arising at multiple points within the ventral prefrontal cortical-striatal-pallidal-thalamic circuitry may result in pathological obsessions and compulsions.

This circuitry in general appears to be involved in the organization of internally guided behavior toward a reward, switching of response strategies, habit formation, and stereotypic behavior. Electrophysiological and lesion analysis studies indicating that parts of the orbitofrontal cortex specifically are involved in the correction of behavioral responses that become inappropriate as reinforcement contingencies change. Such functions could potentially become disturbed at the level of this cortex itself or within the circuits conveying projections from the ventral PFC through the basal ganglia, conceivably giving rise to the perseverative patterns of nonreinforced thought and behavior that characterize the cognitive-behavioral state of OCD.

## BOX 31.7

## TOURETTE SYNDROME (TS)

A “tic” is a sudden, rapid, recurrent, nonrhythmic, stereotyped movement or sound. Individuals with TS exhibit prominent and persistent motor tics and at least one phonic tic, beginning in childhood. Current estimates of TS prevalence range between 0.1 and 1.0%, with a 3.51 male:female ratio. Symptoms wax and wane; roughly half of all TS patients experience a significant symptom decline in their early 20s, whereas others experience life-long symptoms.

Tics differ in complexity (simple, complex) and domain of expression (motor, phonic). In addition to their outward manifestations, a variety of sensory and mental states are associated with tics. “Simple” sensory tics are rapid, recurrent, and stereotyped, and are sensations at or near the skin. “Premonitory urges” are more complex phenomena, which often include both sensory and psychic discomfort that may be momentarily relieved by a tic. The full elaboration of tics, therefore, can include a sequence: (1) a sensory event or premonitory urge, (2) a complex state of inner conflict over if and when to yield to the urge, (3) the motor or phonic production, and (4) a transient sensation of relief.

Functional impairment in TS often results from comorbid conditions. More than 40% of individuals with TS experience symptoms of obsessive-compulsive disorder (OCD), and a comparable number have symptoms of attentional deficits and hyperactivity (ADHD).

Limited neuropathological evidence suggests four locations of potential pathology within cortico-striato-pallido-thalamic (CSPT) circuitry in TS: (1) intrinsic striatal neurons (increased neuronal packing density); (2) diminished striato-pallidal “direct” output (reduced dynorphin-like immunoreactivity in the lenticular nuclei); (3) increased dopaminergic innervation of the striatum (increased density of dopamine transporter sites); and (4) reduced glutamatergic output from the STN (reduced lenticular glutamate content).

Volumetric neuroimaging studies report an enlarged corpus callosum, reduced caudate volume, or diminished striatal and lenticular asymmetry; these changes are subtle and are not replicated uniformly. Metabolic neuroimaging studies in TS report a reduced glucose uptake in the orbitofrontal cortex, caudate, parahippocampus, and midbrain regions and reduced blood flow in the caudate nucleus, anterior cingulate cortex, and temporal lobes. Regional glucose uptake patterns suggest distributed CSPT dysfunction, based on covariate relationships

between reduced glucose uptake in striatal, pallidal, thalamic, and hippocampal regions. Tic suppression is associated with increased right caudate activation, measured by functional MRI, and by bilaterally diminished activity in the putamen, globus pallidus, and thalamus. Neurochemical imaging studies have reported relatively subtle abnormalities in the levels of dopamine receptors, dopamine release, DOPA decarboxylase, and dopamine transporter in the striatum of some individuals with TS. A report of greater caudate D2 receptor binding among more symptomatic TS identical twins may be relevant to factors contributing to heterogeneity of the TS phenotype.

There are a number of reported subtle abnormalities in the levels of major neurotransmitters, precursors, metabolites, biogenic amines, and hormones in blood, cerebrospinal fluid (CSF), and urine of TS subjects compared to controls. One qualitatively different finding is that of approximately 40% elevations of serum antiputamen antibodies in TS children. This finding may have particular importance, based on growing evidence for autoimmune contributions to at least some forms of TS.

Converging evidence for CSPT pathology in TS comes from neuropsychological and psychophysiological studies. Some forms of TS appear to be accompanied by abnormalities in sensorimotor gating, oculomotor functions, and visuospatial priming consistent with mild cortico-striatal dysfunction.

The mode of TS inheritance remains elusive. First-degree relatives of TS probands are 20–150 times more likely to develop TS compared to unrelated individuals. Concordance rates for TS among monozygotic twins approach 90%, if the phenotypic boundaries include chronic motor or vocal tics, versus 10–25% concordance for dizygotic twins across the same boundaries. One affected sibpair study with a total of 110 sibpairs yielded a multipoint maximum-likelihood scores (MLS) for two regions (4q and 8p) suggestive of high sharing (MLS > 2.0). Four additional regions also gave multipoint MLS scores between 1.0 and 2.0.

Treatments for TS focus on education, comorbid conditions, and direct tic suppression. Education is a critically important intervention for both family members and affected individuals. Treatments for comorbid conditions, particularly OCD and ADHD, are highly effective and can provide significant relief. Dopamine antagonists, particularly high potency, D2 preferential blockers, are the

## BOX 31.7 (cont'd)

most potent and rapid acting tic-suppressing agents, but have important, undesirable side effects. Newer, "atypical" antipsychotics are better tolerated, and some are effective in suppressing tics. The DA depletor tetrabenazine also offers significant tic suppression, but is not yet approved for use in the United States.  $\alpha_2$ -Adrenergic agonists are often used as antitictic agents; compared to dopamine antagonists, these drugs have relatively weaker antitictic abilities and their benefit generally evolves more gradually. New therapeutic avenues for TS are being explored in controlled studies, including dopamine agonists such as pergolide, nicotinic manipulations, and  $\Delta^9$ -tetrahydro-cannabinol. Intractable, localized tics also have been treated successfully with injections of botulinum toxic. An effective nonpharmacologic therapy, habit reversal therapy, involves the application of cognitive and behavioral therapy principles to TS, analogous to the

successful use of these therapies in the treatment of OCD.

## Cerebellum

The cerebellum is a softball-sized structure located at the base of the skull. Grab the back of your head just above where it meets your neck: your hand is now cupped around your cerebellum. As with most brain systems, much of what we know about the cerebellum stems from symptoms of damage or pathology and from its connectivity with the rest of the brain. From such evidence it has long been clear that the cerebellum is an important component of the motor system. Severe abnormalities of movement are produced by pathologies of the cerebellum. Cerebellar outputs influence systems that are unambiguously motor, such as the rubro-spinal tract, and inputs to the cerebellum convey information known to be essential for movement such as joint angles and loads on muscles. More recently it has become equally clear that the role of the cerebellum is not limited to movement. This is indicated by its interconnections with nonmotor structures, by the more subtle, nonmotor deficits seen with cerebellar lesions, and by functional imaging studies where regions of the cerebellum show activation during nonmotor tasks. In moving toward a stronger understanding of the cerebellum one obvious task will be to identify the common aspects or computational demands that these motor and nonmotor functions share.

Research on the anatomy, physiology, and function of the cerebellum has been complemented and enhanced by computational approaches that emphasize the rules for input/output transformation and how the cerebellar neurons and synapses implement this transformation. This interdisciplinary approach was made possible by the seminal work of Eccles, Ito, and Szentagothai, who in 1967 published "The cerebellum as a neuronal machine," which described most of the essential aspects of the cellular and synaptic orga-

nization of the cerebellum. Soon after, a remarkable paper was published in 1969 by David Marr who inferred some basic computational properties of the cerebellum solely on the basis of the wiring diagram that Eccles and associates had worked out. Since then, the numerous conceptual and practical advantages of working on the cerebellum have enabled a more detailed understanding of what the cerebellum computes and how its neurons and synapses produce this computation.

### ANATOMY AND PHYLOGENETIC DEVELOPMENT OF THE CEREBELLUM

The cerebellum is present in all vertebrates and in the most primitive prevertebrates (myxinooids) up through primates (Jansen and Brodal, 1954; Larsell, 1967, 1970, 1972). In agnathans (lampreys and hagfish), it is a rudimentary structure that assists the functions of the well-developed vestibulo-ocular, vestibulospinal, and reticulospinal systems. The cerebellum is somewhat larger in fishes where, on the input side, it processes sensory information from the vestibular, lateral line, and to a lesser extent proprioceptive and somatosensory systems. On the output side it is connected to the vestibular and reticular nuclei (Box 32.1). In amphibians the region of the cerebellum that receives proprioceptive and other sensory information is expanded. This region, called the corpus cerebella, increases further in reptiles, birds, and mammals. In these vertebrate classes, it constitutes the largest portion of the cerebellum, receiving proprioceptive, somatosensory, visual, and auditory information and projecting to the tectum, the red nucleus, and the

## BOX 32.1

## THE GIGANTOCEREBELLUM

The weakly electric fish (family Mormyridae) have an enormous cerebellar structure called the gigantocerebellum. On a per body-weight basis, the gigantocerebellum is comparable in weight to the human cerebellum. The largest portion of the gigantocerebellum, called the valvula, has a Purkinje cell layer that would stretch to

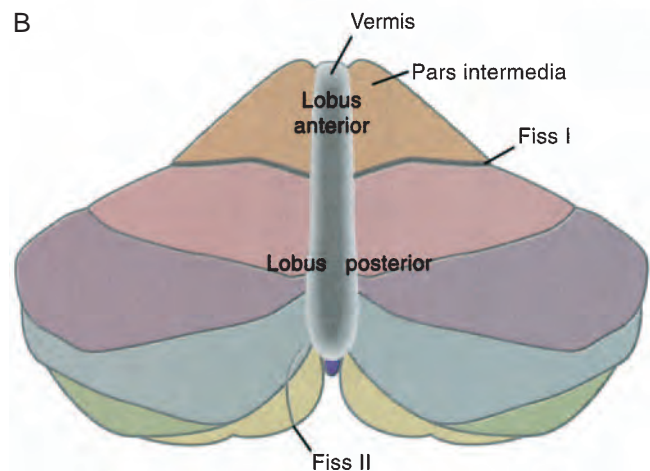

approximately 1 m if unfolded. That length is similar to the length of the Purkinje cell layer in the entire human cerebellum. The valvula receives inputs from the electro-sensory organs, the lateral line, and possibly the visual system. The functional significance of this massive expansion of the cerebellum is a mystery.

cerebral cortex via the thalamus. In primates, the hugely expanded lateral hemispheres of the corpus cerebella are connected with the enlarged cerebral cortex (Fig. 32.1). The hemispheres receive information from the frontal parietal, and visual cortices by way of pontine nuclei and project to the motor and premotor cortices as well as to more anterior portions of the frontal lobe (Fig. 32.2). (Asanuma *et al.*, 1983a, 1983b, 1983c, 1983d; Middleton and Strick, 1994; Orioli and Strick, 1989; Sasaki *et al.*, 1976; Schell and Strick, 1984)

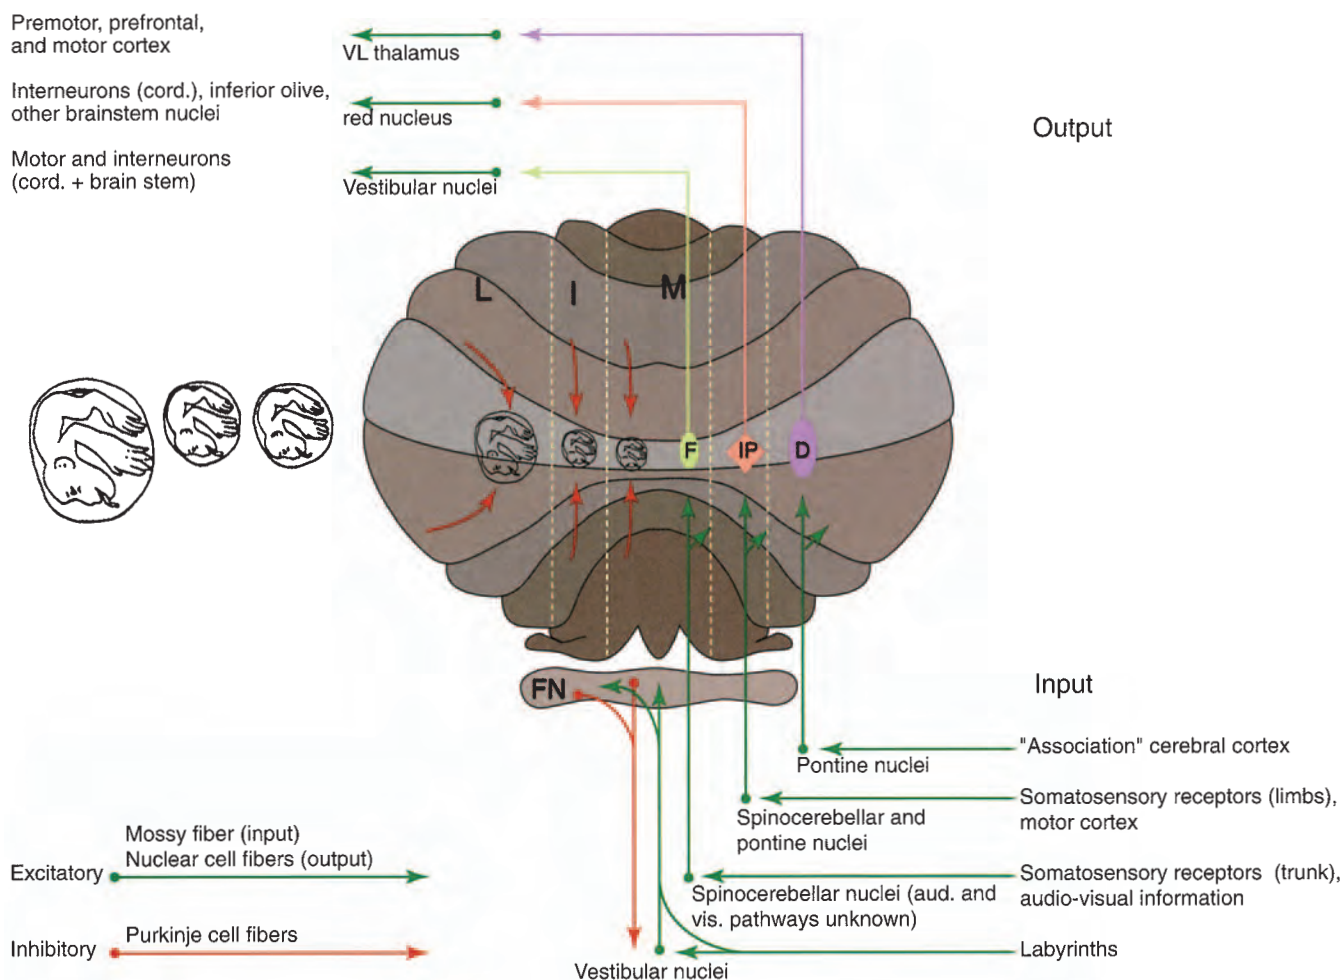

### The Cerebellum Can Be Subdivided on the Basis of Phylogeny, Anatomy, and the Effect of Lesions

Superficially, the cerebellum consists of a three-layered cortex folded in thin, parallel strips called folia (leaves), which in most species run roughly transverse to the long axis of the body (Fig. 32.2). The cerebellar cortex surrounds three pairs of deep cerebellar nuclei. From medial to lateral, the deep cerebellar nuclei are the fastigius, the interpositus (which is further divided into the globose and emboliform nuclei in humans), and the dentate. The deep cerebellar nuclei and the vestibular nuclei constitute the output structures of the cerebellum. An inner mass of white matter contains axons that run between the cerebellar cortex and the deep cerebellar nuclei.

The cerebellum is divided into three lobes (Jansen and Brodal, 1954). The flocculonodular lobe (vestibulocerebellum) is located on the inferior surface and is separated from the posterior lobe via the posterolateral fissure. Superior to the posterior lobe is the anterior lobe: these two lobes are separated by the primary fissure. The lobes are divided further into lobules (Larsell, 1967, 1970, 1972) (Fig. 32.2), which are numbered I–X beginning at the dorsal anterior vermis and ending at the inferior posterior vermis. Each lobule contains a number of folia. Lobulation is fairly consis-

**FIGURE 32.1** Cerebellar structure and functional subdivisions. (A) Dorsal view of the human cerebellum. (B) Functional subdivisions. Adapted from Nieuwenhuys, Voogd, and van Huijzen (1979).

**FIGURE 32.2** Cerebellar inputs and outputs. The cerebellum is shown schematically with the flocculonodular (FN) lobe unfolded and represented at the inferior surface. Green arrows indicate excitatory projections into and out of the cerebellum; red arrows indicate the inhibitory projections from cerebellar cortex to the deep cerebellar nuclei and the vestibular nuclei. Adapted from Thach, Fig. 31-3. In: Mountcastle, J. B. (1980). *Medical Physiology*, Volume I. 14 Ed. C. V. Mosby Co., St. Louis.

tent across individuals of the same species and extends with few exceptions across species, despite great variation in hemispheric development.

The corpus cerebella can be divided into three longitudinal zones (medial, intermediate, and lateral) based on the projection of the cortex onto the three deep nuclei (Jansen and Brodal, 1954). These zones differ in the type of information that comes into them over mossy fibers. The medial zone is dominated by information from vestibular, somatosensory, visual, and auditory regions. The intermediate zone receives proprioceptive and somatosensory information from the spinal cord, as well as information from the motor cortex via the pontocerebellar nuclei (Allen *et al.*, 1977). The lateral zone receives information via the pontine nuclei from the motor cortex, the premotor cortex (area 6), and perhaps all the rest of the cerebral cortex, with the possible exception of portions of the temporal lobes

(Allen *et al.*, 1978). It was once thought that the outputs of the zones (and nuclei) were also segregated—flocculonodular lobe to vestibular nuclei, fastigius to the vestibular and reticulospinal systems, interpositus to red nucleus, and dentate (via thalamus) to motor cortex—but we now know that this picture is greatly oversimplified. Although there may be a predominance to projection along these lines, there is also a great deal of overlap. Thus, vestibular, fastigial, interposed, and dentate nuclei all project via the thalamus to the motor cortex, and vestibular, fastigial, and interposed nuclei all project directly to the spinal cord (Asanuma *et al.*, 1983a, 1983b, 1983c, 1983d).

Staining for acetylcholinesterase, zebrin, and other markers reveals strips running sagittally within the longitudinal zone (Bloedel and Courville, 1981; Groenewegen and Voogd, 1977; Groenewegen *et al.*, 1979; Voogd and Bigare, 1980). The strips, which have

been given names (c1, c2, etc.), are constant in their presence and location within a species and to some extent across species. They have been used chiefly as anatomical markers for physiological experiments, although whether they represent afferent mossy and climbing fibers, efferent Purkinje fibers, or boundaries between them is not clear.

Various attempts have been made to divide the cerebellum according to its functional organization. Fulton and Dow (Botterell and Fulton, 1938a, 1938b; Dow, 1938) described three divisions in the monkey based on different behavioral abnormalities that resulted when each was damaged. Lesion of the vestibulocerebellum (flocculonodular lobe) caused ipsilateral jerk nystagmus, head tilt (occiput to the side of the lesion), and circling gait (Dow, 1938). These deficits were interpreted as consistent with disturbed vestibular function. Lesion of the spinocerebellum (anterior lobe and lobulus simplex) impaired gait without impairing reaching, deficits interpreted as consistent with abnormal spinal control of walking (Botterell and Fulton, 1938b). Lesions of the cerebrocerebellum (pontocerebellum) caused inaccuracy in reaching and clumsiness of hand movements, suggesting impaired voluntary control of body parts (Botterell and Fulton, 1938a). These results were confirmed and extended with lesions of the deep nuclei in the cat (Chambers and Sprague, 1955a, 1955b; Sprague and Chambers, 1953).

Another scheme based on functional organization arose from cerebellar input mapping studies that revealed a somatotopic map in the anterior lobe of the cerebellum, with trunk in the midline, limbs lateral, tail anterior, and head posterior (Adrian, 1943; Snider and Eldred, 1952; Snider and Stowell, 1944). Each paramedian lobule also has a small ipsilateral map whose head region is contiguous with that of the anterior lobe map. It has been argued from these maps that the midline cerebellum controls the trunk, the lateral cerebellum controls distal limb parts, and the intermediate zone controls proximal limb parts. This scheme differs from that of Fulton and Dow, which holds that each major subdivision controls all parts of the body for a specific range of behaviors (e.g., behaviors under vestibular control, reflex control, and voluntary control).

### The Cerebellar Cortex Contains Seven Types of Neurons

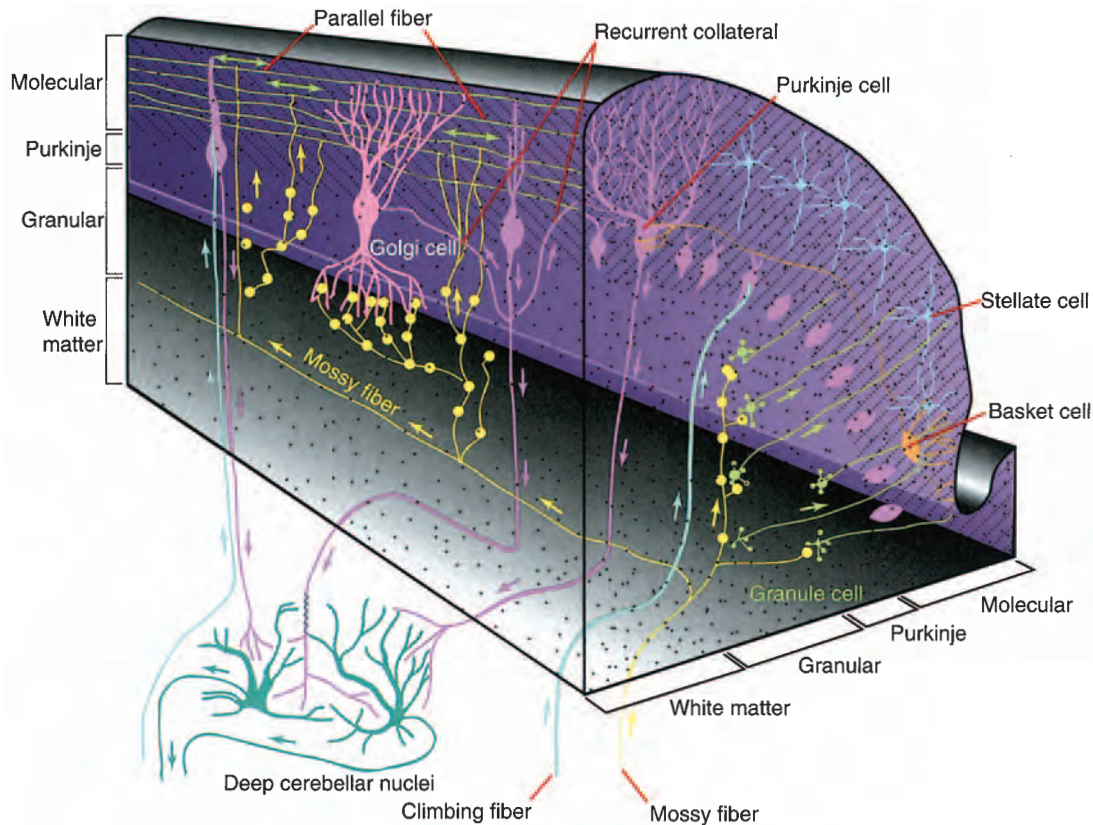

The three-layered cerebellar cortex contains a highly regular arrangement of seven distinct cell types (Eccles *et al.*, 1967; Llinas, 1981; Ramon y Cajal, 1911) (Fig. 32.3). The innermost layer, the granule cell layer, is home to an enormous number of small granule cells,

as well as other inhibitory neurons called Golgi and Lugaro cells. Granule cells have compact dendritic arbors consisting of three to five arms, each of which terminates in a glomerulus, a specialized synaptic cluster containing synaptic terminals from mossy fibers (the major input to the cerebellum), granule cell dendrites, and Golgi cell axons and dendrites. Each mossy fiber excites up to 30 granule cells, and each granule cell receives input from about four mossy fibers. Despite the compact electrotonic structure of granule cells, their excitability is lowered by tonic GABAergic currents such that a granule cell must receive three to four near-simultaneous inputs to produce an action potential. Golgi neurons, also located in the granule layer, receive excitatory input from both mossy fibers and granule cell axons, so that they provide both feed-forward and feedback inhibition to granule cells. Nearby Lugaro cells form inhibitory synaptic contacts onto Golgi, stellate, and basket neurons; a distinguishing characteristic is that Lugaro cells, unlike Golgi neurons, are sensitive to serotonin. Both Golgi and Lugaro cells can be found at the outermost edge of the granule cell layer.

Granule cell axons ascend radially through the next layer of the cerebellum, the Purkinje cell layer, where the large Purkinje cell somata are located. The ascending granule cell axons make a few synaptic contacts onto Purkinje cells before bifurcating in the outermost molecular layer to form the parallel fibers (so named because they run parallel to the folia), each of which extends 5 to 10 mm through the cortex and releases glutamate onto the dendritic spines of 2000 to 3000 Purkinje cells (Mugnaini, 1983). The parallel fibers in any one region of the cortex may come from granule cells in the medial, intermediate, and lateral zones of the cerebellum. Thus, each Purkinje cell may receive information about sensory conditions, internal states, external states, and the plans of the organism.

The outer molecular layer contains two additional types of inhibitory interneurons, called stellate and basket cells. Both interneuron types are excited by parallel fibers and form a feed-forward inhibitory circuit by synapsing onto Purkinje cells, whose dendritic arbors extend into the outer molecular layer. Relatively little is known about how the recruitment of these interneurons influences Purkinje cell firing.

The unipolar brush cell is a more recently characterized cerebellar neuron that is found mostly in vestibular regions of the cerebellum (Nunzi *et al.*, 2001). It interacts with the mossy fiber/granule cell system with an unusual connectivity. Unipolar brush cells receive excitatory input from mossy fibers, as granule cells do, but their axons branch like mossy fibers and form synapses onto granule cells. *In vitro* studies have

**FIGURE 32.3** Schematic view of cerebellar cortex. This section shows the three-dimensional relationship between the different cell types—specifically, the medullary layer or white matter, granular layer, basket cells, stellate cells, Purkinje cells, Golgi cells, granular cells, parallel fibers, climbing fibers, mossy fibers, deep cerebellar nuclei, and recurrent collaterals. Adapted from Fox, C. A. (1962). The structure of the cerebellar cortex. In *Correlative Anatomy of the Nervous System*. New York, MacMillan [Fig. 16.10A].

shown that unipolar brush cells respond to brief bursts of excitatory input with prolonged bursts of output that far outlast the input (Diño *et al.*, 2000). The influences of these properties on coding in the mossy fiber/granule cell system are still being investigated.

### Most Cerebellar Input Arrives over Mossy Fibers and Climbing Fibers

The mossy fiber is the main operational input to the cerebellum, carrying afferent information both from the periphery and from other brain centers (Ramon y Cajal, 1911). Mossy fibers that project to the vestibulocerebellum originate predominantly in neurons in the vestibular nuclei, whereas those that project to vermal cerebellar cortical regions and the fastigius nucleus come from the spinocerebellar pathway, the vestibular nuclei, and the reticular nuclei. The intermediate zone of the cerebellar cortex and the interpositus nuclei receive mossy fibers from the periphery via the spinocerebellar tracts and from the motor cortex via the pons (Eccles *et al.*, 1967; Llinas,

1981). Finally, mossy fibers that project to the lateral zone of the cerebellar cortex and the dentate nucleus arise from the basal pontine nuclei. The basal pontine nuclei receive information from virtually the entire cerebral cortex but primarily from the premotor, supplementary motor area, sensorimotor, parietal association, and visual cortices (Allen and Tsukahara, 1974; Brodal, 1978; Brooks and Thach, 1981; Glickstein *et al.*, 1985).

Because mossy fibers originate from second-order sensory neurons, some processing of even the most direct afferent information occurs before that information is sent to the cerebellum. All mossy fiber input into the cerebellum is excitatory (glutamatergic) (Eccles *et al.*, 1967; Llinas, 1981), and many mossy fibers send a branch to excite the deep nucleus cells before the main trunk ascends to the cortex. Mossy fiber excitation of granule cells causes them to fire, leading to transmitter release from parallel fiber synapses onto Purkinje cells (Figs. 32.3 and 32.4). Each parallel fiber synapse has a small unitary conductance ( $\sim 1$  nS), which alone is insufficient to influence Purkinje cell firing.

**FIGURE 32.4** Maintained discharge of a Purkinje cell recorded extracellularly from an awake, behaving monkey. The “simple” and “complex” spikes are shown. The top trace shows the relationship between simple and complex spikes over a few seconds. The bottom traces show simple and complex spikes individually and together over smaller periods of time to demonstrate the different waveform patterns. Adapted from Thach.

However, because Purkinje cells receive approximately 150,000 parallel fiber synapses on their large dendritic arbors, the concurrent arrival of many such inputs will affect Purkinje activity. Purkinje cells fire “simple spikes” spontaneously at rates of about 30 to 50 Hz, even in the absence of excitatory input; therefore, parallel fiber synaptic currents likely affect the precise timing of these simple spikes.

The second major type of input to the cerebellum is the climbing fiber, which arises from the inferior olivary complex located in the brainstem (Eccles *et al.*, 1967). Climbing fibers branch in the sagittal plane and make contact with up to 10 Purkinje cells in the molecular layer of the cortex. Each Purkinje cell receives input from only one climbing fiber, which makes about 300 synaptic contacts on the soma and proximal dendrites. The simultaneous release of multiple vesicles of glutamate from each of these synapses results in a powerful postsynaptic excitatory current that drives an unusual action potential termed a “complex spike” because of its multiple components, including several spikelets riding on the back of a larger depolarization. Olivary neurons fire at about 1 Hz (Keating and Thach, 1995; Thach, 1968) and increase firing as an animal encounters novel conditions or tries to adapt its movement (Gellman *et al.*, 1985; Gilbert and Thach, 1977; Ojakangas and Ebner, 1992; Simpson and Alley, 1974).

### Neuromodulatory Brain Stem Afferents Are a Third Type of Cerebellar Inputs

A class of cerebellar afferents with nonlaminar distribution originates in the locus ceruleus, raphe nuclei, and other undefined brainstem nuclei. These afferents

innervate the deep cerebellar nuclei and all cortical layers, with some preference for the molecular layer. Afferent fibers from the locus ceruleus release norepinephrine (Hoffer *et al.*, 1972, 1973; Mugnaini, 1972), fibers from the raphe nuclei release serotonin, and fibers from undefined brain stem nuclei release acetylcholine. All three nonlaminar fiber systems synapse on Purkinje cells, although they also target cortical neurons in all layers.

Synapses of nonlaminar afferents have been difficult to define at the electron microscopic level for several reasons (Mugnaini, 1972; Palay and Chan-Palay, 1974). The afferents are rather sparse and form terminal branches that mimic those of other cerebellar fibers. They may ascend radially from the granular layer and divide into two branches that run longitudinally in the folia, where they resemble parallel fibers; they may ascend into the molecular layer and branch along the dendritic arbors of Purkinje cells, resembling stunted climbing fibers; or they may form ascending and descending collaterals in the molecular layer, resembling stellate cell axons. In the granular layer, the branches of nonlaminar afferents intermingle with the axonal plexus of Golgi cells. With standard preparation methods the synaptic vesicles contained in the varicosities of nonlaminar afferents are difficult to distinguish from the vesicles of granule cell axons. Some confusion also arises because certain mossy fiber endings in the caudal cerebellum have serotonin uptake properties similar to those of nonlaminar afferents from the raphe nuclei (Mugnaini, 1972; Palay and Chan-Palay, 1974). Distinct active zones and postsynaptic densities have been identified for all three nonlaminar afferent systems, although one cannot exclude that these afferents may also release their transmitters at nonspecialized regions of their terminal branches.

### Purkinje Cells Inhibit Deep Nuclear and Vestibular Neurons and Exhibit Plasticity

Purkinje cell output exclusively targets deep cerebellar and vestibular nucleus neurons. Their GABAergic synapses are specialized for faithful high-frequency response, with large boutons that each contain multiple vesicle release sites, ensuring successful transmission (Telgkamp *et al.*, 2004). Deep nuclear and vestibular neurons, like Purkinje cells, also fire spontaneous action potentials even in the absence of glutamatergic excitation. Therefore, modulations of Purkinje cell activity sculpt the firing rates of their targets via powerful inhibition. Many deep nuclear neurons recorded respond to prolonged intracellular hyperpolarization by firing at exceptionally high rates afterward, providing a potential mechanism for the coordination of

target neuronal firing by synchronous activity of multiple Purkinje cells.

When a Purkinje cell fires a complex spike in close temporal register with parallel fiber input, the strength of the parallel fiber contact onto the Purkinje cell is reduced (Ekerot and Kano, 1985; Ito *et al.*, 1982; Kano and Kato, 1987; Strata, 1985). This phenomenon, which is an example of long-term depression (Chapter 49), is thought to be an important mechanism in cerebellar learning. Conversely, when parallel fibers are stimulated without matched complex spikes, their strength is increased in a form of long-term potentiation (LTP). In contrast to hippocampus and cortex, where high postsynaptic calcium levels can induce LTP and low levels LTD, Purkinje neurons appear to have an inverted relationship, such that low calcium levels (from concurrent parallel fiber activation alone) cause LTP, and high calcium levels (from climbing fiber activation) yield LTD. NMDA receptors, a primary requirement for cerebral cortical synaptic plasticity, are absent from Purkinje cells, which instead rely on metabotropic glutamate receptors to induce LTD. Interestingly, not all parallel fiber synapses are equally plastic. In recordings *in vitro*, zebrin II positive Purkinje cells appear less susceptible to LTD induction than those in zebrin negative areas (Wadiche and Jahr, 2005). Several studies have shown that abolishing parallel fiber LTD leads to impairments in short-term motor learning, but the role of LTD in long-term memory storage, as well as the implications of disinhibition of deep nuclear neurons for cerebellar function and plasticity, remain to be elucidated (DeZeeuw and Yeo 2005).

### Cerebellar Development Proceeds from Output Structures to Input Structures

Cerebellar cell types develop at different times and at different places (Jacobson, 1985; Rakic, 1982; Verbitskaya, 1969). The first cells to be formed are the neurons of the deep cerebellar nuclei. They are followed soon after by Purkinje cells, which originate in the ventricular epithelium and migrate to their ultimate location in the cortex. Golgi cells, basket cells, stellate cells, astrocytes, and Bergmann glia also originate at the ventricular epithelium and migrate to their final positions after the migration of the Purkinje cells. The Bergmann glia later guide the descent of the granule cells from the external granule cell layer.

Once Purkinje, Golgi, basket, and stellate cells have formed, climbing fibers enter the cerebellum from the inferior olive and begin to innervate the Purkinje cells. Much later, after the Purkinje cells have begun to receive synapses from parallel fibers, most of the climbing fiber contacts with Purkinje cells are elimi-

nated. Mossy fibers also enter the cerebellum and grow to the level just below the Purkinje cell layer. They will ultimately synapse on granule cells, which have yet to arrive.

The granule cells first develop at a very distant site, posterior and lateral in the anlagen at the rhombic lip. They then crawl over the Purkinje cells to form an external granule cell layer. Some granule cells may cross the midline to the other side of the cerebellum as they make this migration. The granule cells extend their axons, which branch to form parallel fibers that run as coronal beams through the dendrites of the Purkinje cells. Only then do the granule cells descend, guided by the Bergmann glia, to form the internal granule cell layer. Each granule cell is connected by the proximal portion of its axon to the branch point of its parallel fibers, which remain in the external granule cell layer. In the internal granule cell layer, the cell's two to seven dendrites meet the terminals of the mossy fibers and gradually make connections with them. Connections also are made between granule cells and the intrinsic cortical inhibitory neurons—the Golgi, stellate, and basket cells. It is interesting that the output side of the cerebellar circuit (the deep nuclear I cells and Purkinje cells) forms first, the input side (mossy fibers) then arrives, and the “matrix” that connects the two (the granule cells and intrinsic inhibitory neurons) is the last to develop.

### Human Cerebellar Development Is Not Complete at Birth

In humans, the first cerebellar structures develop at approximately 32 days after fertilization, and development is not completed until after birth. The cerebellar cortex of the early embryo has six distinct layers, but this number ultimately is reduced to three. The cortex begins to differentiate slightly earlier in the vermis, flocculus, and median sections of the hemispheres than in the lateral hemispheres. By seven months after fertilization, the deep cerebellar nuclei have attained the shape and location they will have in the adult. At birth, the cerebellar cortex consists of four uneven layers, and the Purkinje cells and basket cells are weakly developed. The fourth layer (the external granule cell layer) disappears within the first postnatal year. In humans, full myelination of cerebellar connections is not complete until the second year of life (Brody *et al.*, 1987).

### Summary

The cerebellum is a prominent structure in the nervous systems of all vertebrates. The cerebellum

receives input from many parts of the nervous system but projects mainly to motor and frontal lobe cognitive areas. This suggests that many different kinds of information are brought together to help control movement and certain cognitive functions. The intrinsic structure is relatively simple and stereotyped throughout the cerebellum, very different from that of the cerebrum. The ontogenetic development is conspicuously late: cell migrations and fiber connections continue to occur after birth and the development of the rest of the motor nervous system.

## ASSESSING CEREBELLAR FUNCTION

### The Deep Nuclei Generate the Output of the Cerebellum

All the cerebellum's output is produced by the deep cerebellar nuclei and vestibular nuclei. Each deep nucleus has a separate somatotopic representation of the body in which the head, tail, trunk, and extremities are represented in the caudal, rostral, lateral, and medial regions of the nucleus, respectively (Allen *et al.*, 1977, 1978; Asanuma *et al.*, 1983a, 1983b, 1983c, 1983d; Ramon y Cajal, 1911; Rispal-Padel *et al.*, 1982; Thach *et al.*, 1992b, 1993). The deep nuclei exert control over movement of ipsilateral parts of the body. Nearly every motor center of the CNS receives input from the deep nuclei, including the spinal cord, the vestibular, reticular, and red nuclei, the superior colliculus, and (via the thalamus) the primary motor and premotor cortices, the primary and secondary frontal eye fields, and even the prefrontal cortex. The projections from the deep nuclei to these centers are thought to be glutamatergic and excitatory. However, a set of small GABAergic neurons in the deep nuclei makes inhibitory projections to the inferior olivary complex (Mugnaini, 1972). These inhibitory projections may be important for maintaining balanced induction of plasticity in the cerebellar cortex and thus for preventing spontaneous drift of synaptic strengths (Kenyon *et al.*, 1998; Medina *et al.*, 2002).

All cerebellar target structures receive other excitatory inputs in addition to those from the cerebellum. There are no direct projections from the deep nuclei to the basal ganglia (Table 32.1). The deep nuclei differentially control the medial and lateral motor systems and their respective functions. The vestibular nucleus and the fastigius control eye and head movements, equilibrium, upright stance, and gait; the interpositus controls the stretch, contact, placing, and other reflexes; and the dentate controls voluntary movements of the

extremities, such as those involved in reaching and grasping for objects (Fig. 32.5).

In the absence of movement, deep nuclear cells fire at maintained rates of approximately 40 to 50 Hz (Fortier *et al.*, 1989; Thach, 1968, 1970a, 1970b, 1978). During movement, their firing rates increase and decrease above and below their baseline. Through these variations in firing rate, the cerebellum modulates the activity of motor pattern generators (MPGs). In addition, increases in cerebellar nuclear firing rate precede and help increase the discharge frequency in MPGs, thus facilitating the initiation of movement (Lamarre *et al.*, 1983; Meyer-Lohmann *et al.*, 1975; Spidalieri *et al.*, 1983; Strick, 1983; Thach, 1978). Deep cerebellar nuclear cells may also combine the functions resident in MPGs into new or novel combinations (Babinski, 1899, 1906; Flourens, 1824; Thach *et al.*, 1992a). Thus, an MPG by itself could initiate movements that are within its repertoire, but only the cerebellum could initiate movements that are combinations of components within and across movement patterns.

### Activity in Individual Deep Cerebellar Nuclei Correlates with Behavior

The fastigius controls all musculature involved in stance and gait. It receives input from the vermal cortex, vestibular complex, lateral reticular nucleus, and (indirectly) spinocerebellar pathways. Single-unit recordings in the fastigius and vermal cortex of decerebrate cats have shown neural discharge that is correlated with both walking and scratching movements (Andersson and Armstrong, 1987; Antziferova *et al.*, 1980). Discharge in the interpositus and dentate is not correlated with these behaviors (Arshavsky *et al.*, 1980). Fastigial neurons also are involved in the generation of saccadic eye movements (Chapter 33).

Interpositus neurons fire when the holding position of a limb is perturbed. In doing so, these neurons appear to control antagonist muscles that check the reflex movement of the limb to its prior hold position (Flament and Hore, 1986; Strick, 1983; Thach, 1978; Vilis and Hore, 1977, 1980). Interpositus neurons also modulate their activity in relation to sensory feedback, including that from tremor accompanying movement (Schieber and Thach, 1985; Soechting *et al.*, 1978; Thach, 1978). This finding is consistent with the idea that the interpositus is involved in somesthetic reflex behaviors, controlling the antagonist muscle to dampen the tremor (Elble *et al.*, 1984; Flament and Hore, 1986; Mauritz *et al.*, 1981; Vilis and Hore, 1977, 1980). Other evidence suggests that the interpositus is important in deter-

**FIGURE 32.5** Major deficits produced by microinjection of muscimol and kainic acid into different regions of the cerebellum. F indicates the standing and walking deficit seen after muscimol injections into the fastigius. I indicates arm position (tremor) during reaching after muscimol injection into the interpositus. D indicates the deficits in reaching and pinching after muscimol injection into the dentate. Adapted from Thach *et al.*

mining whether the pattern of activity in muscles acting at a joint represents reciprocal activation or cocontraction (Frysinger *et al.*, 1984; Smith and Bourbonnais, 1981; Wetts *et al.*, 1985). During behaviors that involve cocontraction, interpositus cells fire as if activating both agonist and antagonist muscles, and Purkinje cells are silent. In behaviors where agonists and antagonists are reciprocally active, both interpositus cells and Purkinje cells fire in similar patterns.

One interpretation of these results is that alternating firing in Purkinje cells creates (through inhibition) a similar pattern of activity the interpositus cells, which in turn produces the alternation between agonist and antagonist muscles. Other work suggests that the interpositus contributes to stretch reflex excitability by controlling the discharge of gamma motor neurons (Soechting *et al.*, 1978) (Fig. 32.6).

Neuronal activity in the dentate precedes the onset of movement and may also precede firing in the motor cortex (Lamarre *et al.*, 1983; Thach, 1978). Dentate cells fire preferentially at the onset of movements that are triggered by mental associations, with either visual or

auditory stimuli. Single-unit recordings in the motor cortex, dentate, and interpositus were correlated with electromyograms as monkeys made wrist movements in response to stimuli. In tasks where movements were triggered by light, the order of activity is dentate, motor cortex, interpositus, and muscles. When a transient force perturbs the wrist, however, the firing order is muscles, interpositus, motor cortex, and dentate. These results suggest that the dentate helps initiate movements triggered by stimuli that are mentally associated with the movement, whereas the interpositus is more involved in compensatory or corrective movements initiated via feedback from the movement itself. In other studies, the dentate responded strongly when movements were triggered by either visual or auditory signals but not somesthetic signals (Lamarre *et al.*, 1983). Activity in both the dentate and the interpositus is thought to relate more to movements involving multiple joints than to those involving single joints. Neither nucleus codes for any specific parameter (e.g., velocity, amplitude, or duration) during single jointed movements (Elble *et al.*, 1984;

Mauritz *et al.*, 1981; Schieber and Thach, 1985; Thach *et al.*, 1992a; van Kan *et al.*, 1993). In sum, the dentate plays a role in initiating movements that require a mental interpretation of the visual or auditory signal, and both the dentate and the interpositus are increasingly active during multijointed movements.

### Damage to the Cerebellar Nuclei Causes Unique Behavioral Deficits

Ablations of the fastigius in cat and monkey dramatically impair movements requiring control of equilibrium, such as unsupported sitting, stance, and gait (Botterell and Fulton, 1938b; Sprague and Chambers, 1953; Thach *et al.*, 1992b). Longitudinal splitting of the cerebellum along the midline also produces very significant and long lasting disturbances of equilibrium. In humans, lesions in the vermal and intermediate zones of the anterior cerebellar lobe preferentially impair movements requiring equilibrium control (Horak and Diener, 1994; Mauritz *et al.*, 1979). These data suggest that the fastigius may be preferentially involved in movements like gait and stance.

Ablations of the interpositus in monkeys primarily cause tremor (Dow, 1938). Temporary inactivation of both the interpositus and the dentate with cooling probes elicits tremor that is dependent on proprioceptive feedback but is influenced by vision (Vilis and Hore, 1977). In monkeys, interpositus inactivation disturbs gait minimally but causes a large-amplitude, 3- to 5-Hz action tremor as the animals reach for food (Dow, 1938). These studies support the idea that the interpositus in monkeys is most concerned with balancing the agonist-antagonist muscle activity of a limb as it moves. The interpositus may use the abundant afferent input it receives from the periphery to generate predictive signals that decrease alternating stretch reflexes capable of causing limb oscillation.

Ablations of the dentate nucleus in monkeys produce slight reaction time delays, poor endpoint control, and impaired multijointed movements far beyond any deficits found in single-jointed movements. In several studies, lesions of the dentate produced very slight delays in the onset of motor cortex cell activity (Beaubaton and Trouche, 1982; Meyer-Lohmann *et al.*, 1975; Spidalieri *et al.*, 1983; Thach *et al.*, 1992b). These delays were due to the loss of phasic dentate activity rather than tonic support, because

**FIGURE 32.6** Simple and complex spikes recorded during motor learning task. Adapted from Ito; original reference Gibert and Thach.

there was no change in the resting firing rate of motor cortical cells after dentate cooling (Meyer-Lohmann *et al.*, 1975). Lesions of the dentate also produce a slight delay in the reaction time of movements triggered by light or sound (Beaubaton and Trouche, 1982; Spidalieri *et al.*, 1983). In single-jointed movements, dentate ablation causes monkeys to overshoot very slightly (Thach *et al.*, 1992b) or moderately (Flament and Hore, 1986), whereas in multijointed movements, it results in profoundly impaired reaching patterns with abnormally increased angulation of the shoulder and elbow and excessive overshoot of the target (Thach *et al.*, 1992b). Dentate inactivation also causes monkeys to have difficulty pinching small bits of food out of a narrow well; instead, the animals use one finger as a scoop to retrieve the food (Fig. 32.5). In sum, dentate ablation profoundly impairs movements requiring coordination of multiple joints but affects single-jointed movements only slightly. Dentate inactivation also slightly impairs the initiation of movements that are triggered by vision or mental percepts.

Damage to the cerebellar cortex causes disability similar to but less severe than that resulting from damage to the deep nuclei. Damage to the cortex and the inferior olive also prevents many kinds of motor adaptation, including the acquisition of new and novel muscle synergies.

### Parallel Fibers and Purkinje Cell Beams Act in the Coordination of Linked Nuclear Cells

The relationship between cerebellar somatotopic maps and parallel fiber morphology is consistent with a cerebellar role in movement coordination. In Figure 32.2, in each body representation in the deep nuclei, the rostrocaudal axis of the body is mapped onto the sagittal axis of the nucleus. The hindlimbs are represented anteriorly, the head posteriorly, distal parts medially, and proximal parts laterally. This orientation would suggest that the myotomes, which are arranged orthogonal to the rostrocaudal axis of the body, are represented primarily in the coronal dimension of the cerebellum and thus roughly parallel to the trajectory of the parallel fibers. Because the parallel fibers are connected to the deep nuclear cells by Purkinje cells, a coronal "beam" of parallel fibers would control the nuclear cells that influence the synergistic muscles in a myotome. In this way, the parallel fiber would be a single neural element spanning and coordinating the activities of multiple synergistic muscles and joints.

Anatomical studies indicate that parallel fibers in the monkey are about 6 mm long (Mugnaini, 1983), spanning stretch of cerebellar cortex that projects across the width of one deep nucleus. Thus, a strip of

Purkinje cells under the influence of a set of parallel fibers of the same origin and length will control a strip of nuclear cells across an entire nucleus. Depending on which portion of the somatotopic map is involved, that nuclear strip may influence synergistic muscles across several joints in a limb or the muscles of the eyes, head, neck, and arm, for example.

Parallel fiber beams can also serve to link activity in different deep cerebellar nuclei. A link occurring across the two fastigial nuclei would effectively couple the two sides of the body in stance and gait. A link across the fastigius and interpositus would couple locomotion and reflex sensitivity. A link across the interpositus and dentate would couple reach and reflex sensitivity. In a recent study in trained reaching rats (Heck *et al.*, 2007), simple spikes of pairs of Purkinje cells were recorded that, with respect to each other, either were aligned on a beam of shared parallel fibers or instead were located off beam. Firing rates of simple spikes firing in both on-beam and off-beam Purkinje cell pairs commonly showed large variation during reaching behavior. But with respect to timing, on-beam Purkinje cell pairs had simple spikes that were tightly time-locked to each other and to movement, despite the variability in rate. By contrast, off-beam Purkinje cell pairs had simple spikes that were not time-locked to each other.

What is the consequence of the on-beam synchronicity? Parallel fibers in the cerebellar cortex run roughly parallel to the myotomes of the body maps in the deep nuclei. On-beam parallel fiber activity may thus recruit Purkinje cell inhibition to modulate coordination and timing of the natural myomeric synergists mapped within the deep nuclei. In addition, parallel fibers would be long enough to span (via Purkinje cell projections) two or more adjacent nuclei, fastigius controlling stance and gait, interpositus agonist/antagonist coordination at a single joint, and dentate eye-limb coordination in reaching and of digits in multidigit movements (Heck *et al.*, 2007). Bastian *et al.* reported how this might explain the inability to coordinate bilateral body movements in gait and balance after vermal section in humans (Bastian *et al.*, 1998). In five children who had surgical midline division of the posterior cerebellar vermis to remove fourth ventricular tumors, individuals could hop on one leg as well as normal controls. Yet these same individuals could not do tandem heel-to-toe walking along a straight line without falling to one side or the other. Fortunately, regular gait was little impaired. These observations suggested that vestibular information could be used to control one leg, but that the two legs could not be so coordinated. The division of parallel fibers crossing the midline seemed best able to explain this dissociation.

## Several Models Attempt to Explain the Operation of the Cerebellum

### *Tonic Reinforcer Model*

Given its tonic excitatory effect on motor pattern generators in the vestibular nuclei, reticular nuclei, and the motor cortex, the cerebellum may be responsible for tuning these structures so that they respond optimally to noncerebellar inputs. Luciani championed the idea of a reinforcing tone with his interpretation of the behavioral deficits produced by cerebellar ablation in animals, a principal component of which was atonia. Holmes endorsed this interpretation based on his own analysis of behavioral deficits in human subjects with cerebellar lesions (Dow, 1987; Dow and Moruzzi, 1958; Homes, 1939). We now know that the predominant output of the cerebellum is excitatory and that the cerebellum is tonically active even in the absence of movement (Eccles *et al.*, 1967; Thach, 1968). Granit *et al.*, (1955) and Gilman (1969) emphasized how tone could be controlled by the cerebellum's excitation of gamma motor neurons, which modulate stretch reflexes. However, because the cerebellum also projects to alpha motor neurons (Dow, 1938) and because cerebellar nuclear discharge changes tonically in relation to different held postures and phasically in relation to different movements, basic cerebellar function must be more complex than this model supposes.

### *Timer Model*

Numerous investigators have proposed that the cerebellum performs a pure timing function. Braitenberg and colleagues (Braitenberg, 1967) proposed that a wave of activity propagated along a parallel fiber could be "tapped off" by successive Purkinje cells, each tap occurring at an incremental delay after the onset of the wave. This delay could be used to time movements for up to 50 ms or so. Llinas and Lamarre (Lamarre, 1984; Lamarre and Mercier, 1971; Llinas and Yarom, 1986) independently proposed motor clock functions for the cerebellum on the basis of presumed periodic discharge the inferior olive. This proposal was founded on the effects of the drug harmaline, which induced a whole-body, 10-Hz tremor in experimental animals (Lamarre and Mercier, 1971) and a correlated synchronous discharge in inferior olive cells in slice preparations (Llinas and Yarom, 1986). It was also supported by the tendency for olivary neurons to fire periodically and in synchrony, and on the electronic coupling between olivary neurons, which might synchronize their discharge. However, this interpretation is contradicted by the finding that olivary discharge in the awake, performing monkey is not only

nonperiodic but indeed random (Keating and Thach, 1995).

Ivry *et al.* (1988) proposed, based on different evidence, that the cerebellum functions as a general purpose timer. Patients with lateral cerebellar injury are impaired in their ability to perceive differences in intervals between tone pairs of the order of half a second. This observation has been interpreted as indicative of a general clock not only for movement but also for perception. These timer/clock models maintain that the cerebellum (or the inferior olive) controls only the timing of muscle activity. Arguing against these ideas is the absence of any demonstrated clocklike periodicity of cerebellar nuclear cell discharge. Instead, these cells produce a graded, tonic discharge that correlates with muscle pattern and force, limb position, and movement direction (Keating and Thach, 1995, 1997).

### *Command-Feedback Comparator Model*

Several models of cerebellar function incorporate linear systems principles (Allen and Tsukahara, 1974; Brooks and Thach, 1981; Evarts and Thach, 1969). According to these models the lateral cerebellum receives commands from the association cortex and feedback from the motor cortex, and it projects back to the motor cortex to help initiate and correct the commands. The intermediate cerebellum receives commands from the motor cortex and feedback from the spinal cord, and it projects to the red nucleus to help execute and correct errors in ongoing movements. These models are consistent with the early discharge of dentate neurons in the initiation of movement and the later discharge of interpositus neurons. However, the models do not specify how relatively slow neural feedback signals could make the same kind of error corrections that electronic feedback can.

### *Combiner-Coordinator Model*

The combiner-coordinator model proposes that the role of the cerebellum is to coordinate movements (Flourens, 1824). This model is supported by the finding in cerebellar patients of a loss of coordination of compound movements without any impairment of force in simpler movements (Babinski, 1899, 1906). Mathematical descriptions of the model have been developed for translating one reference frame (such as body musculature) to another (such as movements in space), for both static and dynamic aspects of motor control (Fujita, 1982; Pellionisz and Llinas, 1980). The model has been modified to explain how parallel fibers might function in combining the activities of lower MPGs, motor neurons, and muscles to provide many unique patterns of coordinated movement (Thach

*et al.*, 1992a). A learning capability, as developed in the Marr-Albus-Ito hypothesis (discussed next), is another feature of the model.

### **Motor Learning Model**

According to the Marr-Ito motor learning hypothesis (Albus, 1971; Ito, 1972, 1984, 1989; Marr, 1969; Thach *et al.*, 1992a; Thompson, 1990), the climbing fiber input to the cerebellum controls the induction of synaptic plasticity in the cerebellar cortex. This plasticity mediates the unconscious correction or expression of movements through trial-and-error linking of a certain behavioral context to the movement response. The cerebellar circuitry seems well suited to interpret the various aspects of the context, to implement the many components in a response, to formulate the context-response linkages that constitute our learned movement repertoire, and to carry out the process of learning them. Damage to the cerebellum abolishes the ability to make automatic, rapid, smoothly coordinated movements and to learn new complex movements. Patients with cerebellar damage can still move, by virtue of the activity of the frontal cerebral cortex and the actions of sensory inputs on each of the MPGs, but each component of a movement must be thought out; movements are slow and irregular, because the agonist, antagonist, synergist, and fixator muscles cannot be linked together in time, amplitude, and combination.

### **The Cerebellum Contributes to Cognitive Processes**

For many years the cerebellum was thought to be involved only or mostly in the control and adaptability of movement. This notion was based on the profound motor deficits seen in cerebellar patients and on the fact that cerebellar projections had been traced only to motor areas. Recently, however, this view of the cerebellum has changed (Leiner *et al.*, 1993; Thach, 1996). Sophisticated anatomical and brain imaging techniques, including positron emission tomography (PET) and magnetic resonance imaging (MRI), have provided evidence for cerebellar contributions to cognition (Dum *et al.*, 2002; Dum and Strick, 2003; Kelly and Strick, 2003; Middleton and Strick, 2001).

Initial suggestions that the cerebellum participates in cognition arose from anatomic connections that were thought to exist due to the parallel expansion of the frontal lobe, lateral cerebellum, and dentate (Leiner *et al.*, 1993). Transneuronal transport of herpes simplex virus type 1 (HSV1) has revealed these connections: injection of HSV1 into the principle sulcus (area 46) of the cerebral cortex in cebus monkeys retro-

gradely labels neurons in the dentate (Middleton and Strick, 1994). Area 46 lies in the prefrontal cortex, which is not thought to be directly involved in motor performance.

Human brain imaging studies indicate that the cerebellum participates in some types of cognitive functions. One study revealed cerebellar activation when subjects imagined or passively observed movement without moving themselves (Decety *et al.*, 1990). In another study, the lateral cerebellum was activated in a language task in which subjects were asked to generate appropriate verbs for visually presented nouns (Petersen *et al.*, 1989). The cerebellum was not activated when the nouns were simply read, indicating that the cerebellum somehow contributed to the generation of the appropriate verb. Interestingly, once the verb generation task had been well practiced, cerebellar activation diminished (Raichle *et al.*, 1994). A third study showed that the dentate was activated bilaterally when subjects worked to solve a pegboard puzzle, and this activation was three to four times greater in magnitude than during simple peg movements (Kim *et al.*, 1994). Overall, these findings indicate that the lateral cerebellum and dentate are activated in ways that would not be expected to account for movement alone.

Behavioral observations of humans with cerebellar damage have also provided evidence that the cerebellum participates in nonmotor aspects of cognition. In one case study, a cerebellar patient was unable to detect errors in a verb-generating task and did not exhibit normal practice-related learning, although the patient performed normally on standard intelligence and memory tests (Fiez *et al.*, 1992). In another study, cerebellar patients were deficient in both the production and the perception of a timing task. Lateral cerebellar lesions interfered with the perception of time intervals, whereas medial cerebellar lesions affected the timing of implemented responses.

Clinical investigations of adults and children with diseases confined to the cerebellum have defined a cerebellar cognitive affective syndrome characterized by impairments of executive processing, working memory, visual spatial reasoning, language disturbances (ranging from autism to agrammatism), and a flattened or inappropriate affect. The net effect of these deficits is a lowering of overall intellectual ability. The posterior lobe of the cerebellum appears particularly important in generating the deficits, and the vermis is consistently involved when the affective component is pronounced. Elements of this clinical syndrome have also been noted in patients with developmental cerebellar anomalies, cerebellar degeneration, autism, and fragile X syndrome. In addition, cerebellar

abnormalities, particularly in the vermis, have been observed in patients with schizophrenia.

### Curmudgeonly Caveats

There is now little question that the cerebellum projects to many areas of cerebral cortex outside of primary motor cortex, and that many of these areas are known to have cognitive as well as motor functions, however it remains to be seen whether the cerebellum targets the “cognitive” functions of these areas and not the “motor.” The studies of Schmahman and Sherman (1998), for example, include a wide variety of types of mental disturbance and of cerebellar location. In proposing that there is indeed a “cognitive affective cerebellar syndrome,” one would like to be assured that there is indeed a “syndrome”—that is, a constellation of behavioral and anatomic features that consistently and reliably “run together.” The studies of Courchesne and associates, which document the attention deficits and the focal cerebellar atrophy in autism, do seem to constitute a syndrome (Courchesne *et al.*, 1975). Nevertheless, subjects with autism have abnormalities of movement in addition to abnormalities of mentation.

Since there is no consensus that focal cerebellar lesions in previously normal individuals consistently produce such a syndrome, one may be skeptical that the atrophy in autism produces the disorder of mentation as well as that of movement. Similarly for work on schizophrenia, which has documented a common association of focal cerebellar atrophy (Okugawa *et al.*, (2002). Yet schizophrenic patients commonly also demonstrate disorders of movement. Thus, it remains to be seen whether a focal cerebellar lesion in a previously normal individual consistently produces the mental defects as well as the motor. Finally, there have been many studies as discussed earlier that have implicated a fundamental role of the cerebellum in governing abstract timing. The work of Ivry documents that patients with lateral cerebellar lesions do indeed have deficits in estimating differing time intervals and the speed of moving objects. Yet other studies of Decety and Ingvar and others show that the cerebellum is active in imagined movement as well as in overt movement. It also has been pointed out that one of the ways of estimating and comparing time intervals is to create a mental motor replica, as in the silent speech mechanism of estimating seconds by silently counting “one thousand one, one thousand two, one thousand three. . . .” It remains to be seen therefore whether this is the timing mechanism within the cerebellum rather than or in addition to something more abstract and fundamental.

### The Cerebellum Exerts Oculomotor Control

Eye movements are also differentially controlled by specific parts of the cerebellum (Chapter 33). The vestibular nuclei and the vestibulocerebellum control the vestibulo-ocular and optokinetic reflexes (VOR and OKR, respectively) and participate in smooth pursuit eye movements. The cerebellar cortex is necessary for visual smooth-pursuit tracking, which requires VOR cancellation. The interpositus and intermediate cerebellar cortex participate in conditioned eye-blink. The dentate and lateral cerebellar cortex are involved in voluntary gaze, saccades, and eye-hand coordination (see Fig. 32.7 for a test).

### Clinical Testing Can Reveal Cerebellar Damage

In the early 1900s, Gordon Holmes carefully described the movement deficits associated with discrete cerebellar lesions caused by gunshot wounds (Dow, 1987; Dow and Moruzzi, 1958; Homes, 1939). His descriptions provide the fundamental basis for our understanding of clinical cerebellar syndromes and a rationale for classifying the manifestations of cerebellar disease according to seven basic deficits. These deficits may be attributed to cerebellar disease only in patients who have normal strength and somesthesia, because similar symptoms may arise from damage of peripheral nerves, the corticospinal tract, and lemniscalthalamocortical sensory systems (Fig. 32.8).

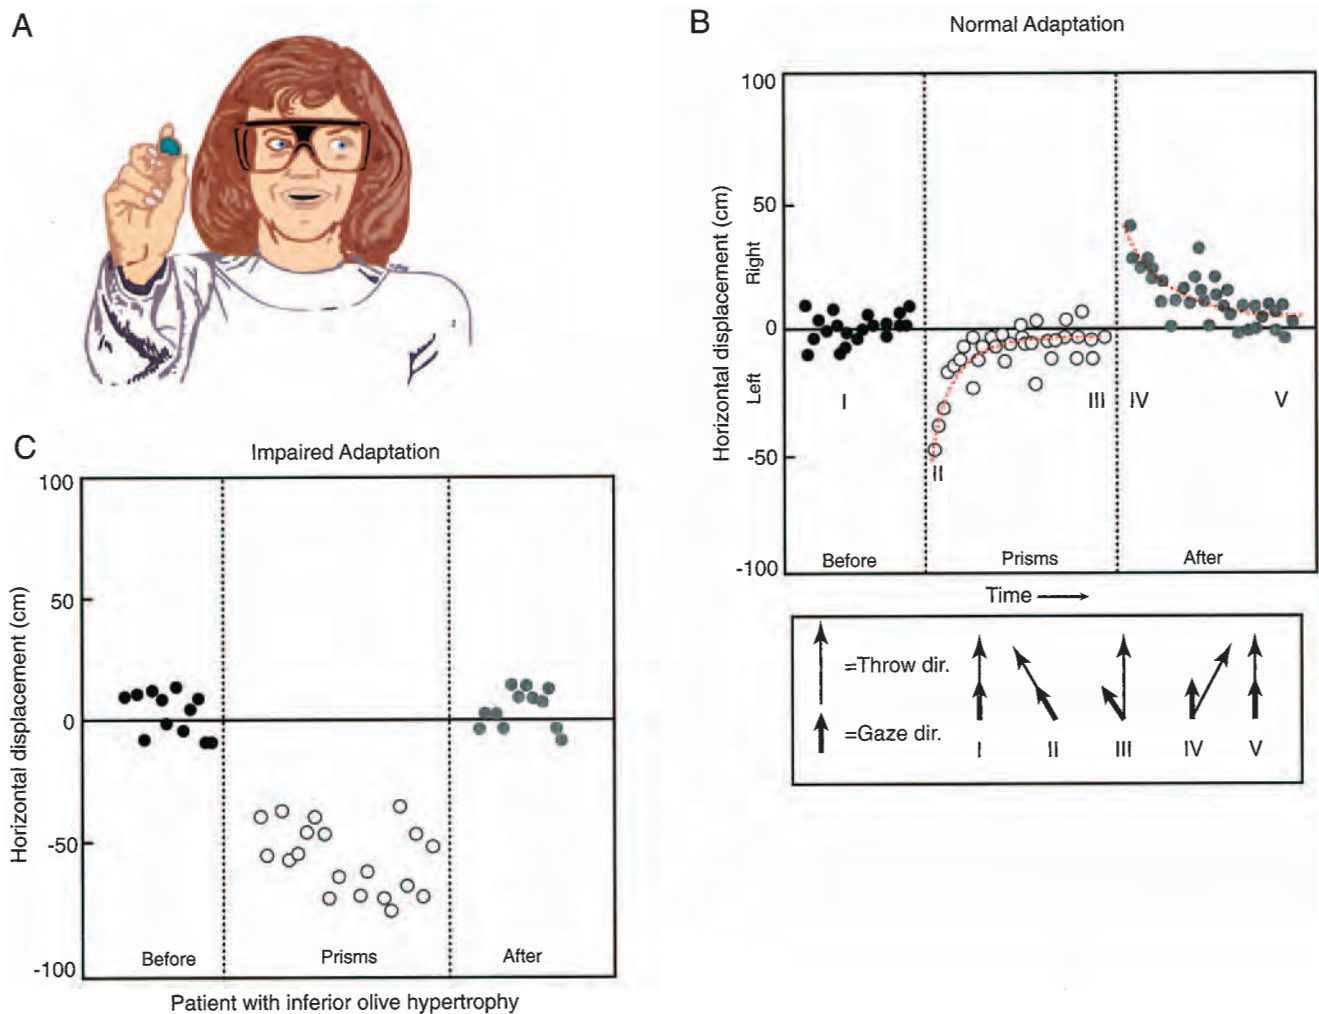

**Ataxia** is a condition that involves lack of coordination between movements of body parts. The term often is used in reference to gait or movement of a specific body part, as in “ataxic arm movements.”

**Dysmetria** is an inability to make a movement of the appropriate distance. Hypometria is undershooting a target, and hypermetria is overshooting a target. Patients with cerebellar damage tend to make hypermetric movements when they move rapidly and hypometric movements when they move more slowly and wish to be accurate.

**Dysdiadochokinesia** is an inability to make rapidly alternating movements of a limb. It appears to reflect abnormal agonist-antagonist control.

**Asynergia** is an inability to combine the movements of individual limb segments into a coordinated, multisegmental movement.

**Hypotonia** is an abnormally decreased muscle tone. It is manifest as a decreased resistance to passive movement, so that a limb swings freely upon external perturbation. Hypotonia often is limited to the acute phase of cerebellar disease.

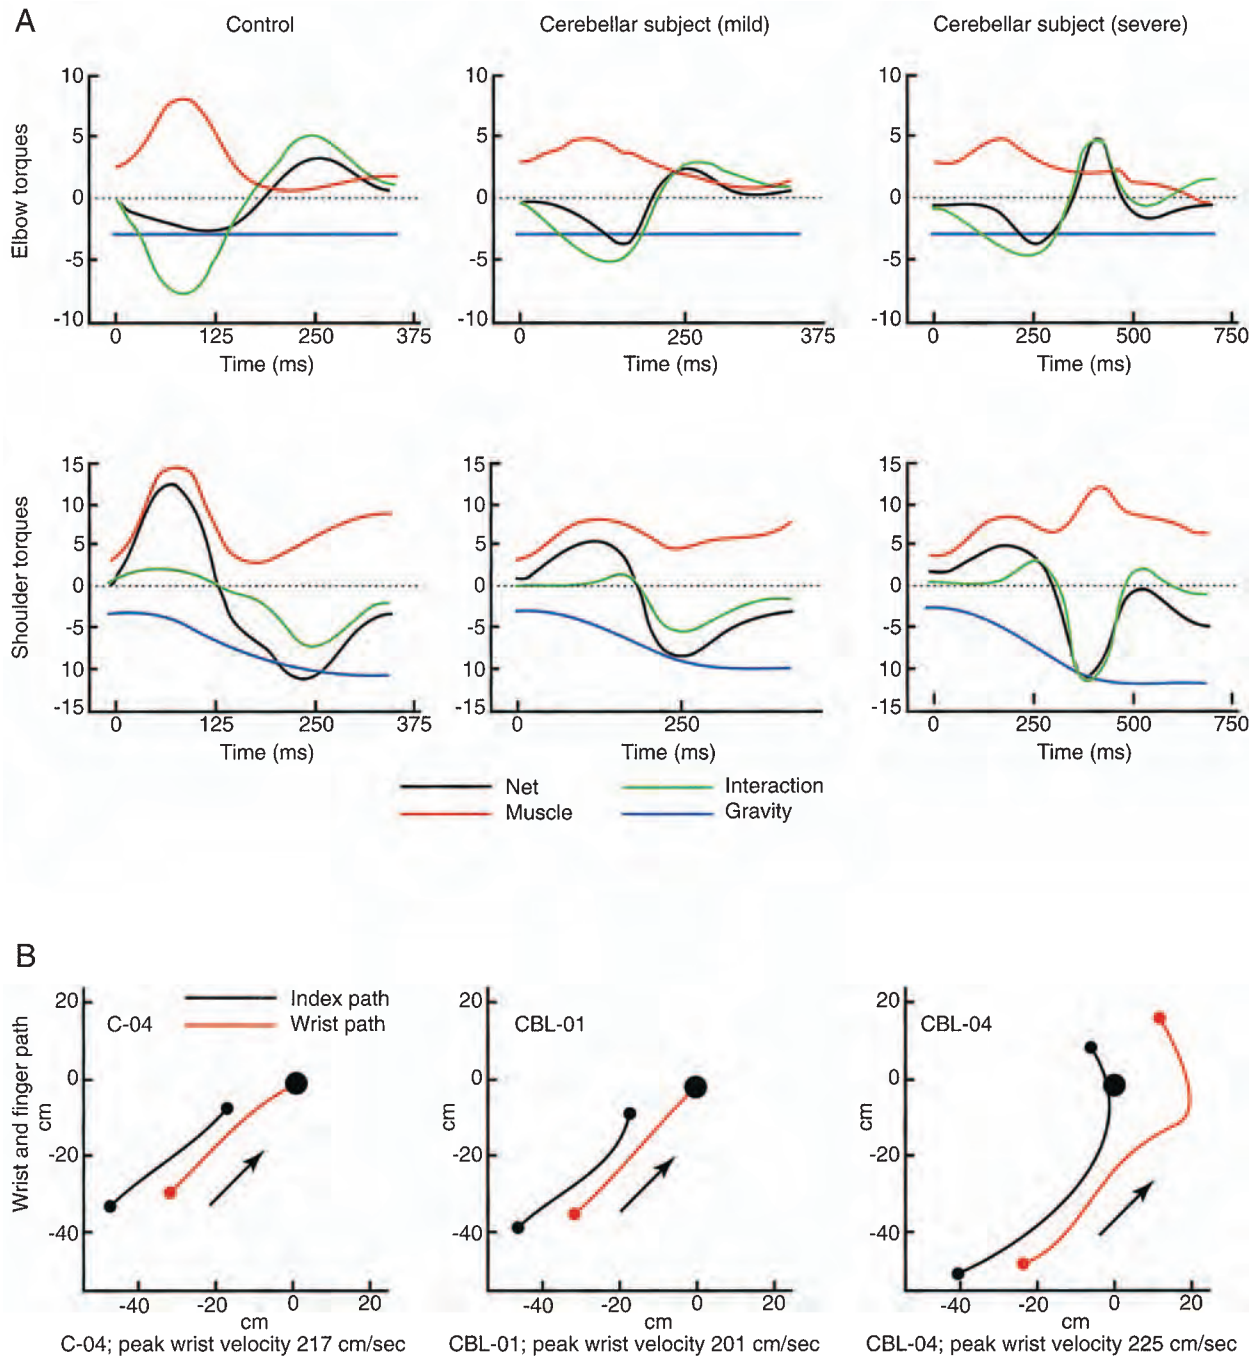

**FIGURE 32.7** Prism adaptation test, control subject. (A) Eye-hand positions after adaptation to base right prisms. The optic path is bent to the subject's right, giving a larger view of right side of her face. Her gaze is shifted left along the bent light path to foveate the target in front of her. Her hand position is ready for a throw at the target in front of her. (B) Horizontal locations of throw hits displayed sequentially by trial number. Deviations to the left are negative values; deviations to the right, positive. While the subject is wearing the prisms (gaze shifted to the left), the first hit is displaced 60cm left of center. Thereafter, hits trend toward 0. After the prisms are removed, the first hit is 50cm right of center. Thereafter, hits trend toward 0. Data during and after prism use have been fitted with exponential curves. The decay constant is a measure of the rate of adaptation. The standard deviation of the last eight preprism throws is a measure of performance. Gaze and throw directions are schematized with arrows. Inferred gaze (eye and head) direction assumes the subject is foveating the target. Roman numerals beneath the arrows indicate times during the prism adaptation experiment (see B). (C) Failure of adaptation in a patient with bilateral infarctions in the territory of the posterior inferior cerebellar artery. Adapted from Martin *et al.*

**Nystagmus** is an involuntary and rhythmic eye movement that usually consists of a slow and a fast phase. In an unilateral cerebellar lesion, the fast phase of nystagmus is toward the side of the lesion.

**Action tremor, or intention tremor**, is an involuntary oscillation that occurs during limb movement and disappears when the limb is at rest. Cerebellar action tremor is generally of high amplitude and low frequency (3–5Hz). **Titubation** is a tremor of the entire trunk during stance and gait. Lesions of

cerebellar target structures (e.g., the red nucleus and the thalamus) often result in cerebellar outflow tremor, or postural tremor. Most prominent when a limb is actively held in a static posture, postural tremor attenuates during limb movement and disappears when the limb is at rest.

Ataxia of stance and gait can result from a loss of equilibrium and vestibular reflexes produced by lesions of the vestibular nuclei and vestibulocerebellum. Abnormal synergies during standing and walking

**FIGURE 32.8** (A) Single trials of the torques produced by one control subject and two cerebellar subjects, all moving in the fast-accurate condition. One cerebellar subject (mild) produced mildly abnormal reaches by kinematic measures. The other cerebellar subject (severe) produced reaches that were profoundly abnormal by kinematic measures. The torques produced by the control subject and the mildly impaired cerebellar subject were similar, although the mildly impaired cerebellar subject's elbow and shoulder net torques (bold lines) more closely followed the dynamic interaction torque (small dotted lines). The severely impaired cerebellar subject produced torques that were abnormal, with the net elbow and shoulder torques (bold line) closely following the dynamic interaction torque at the respective joints (small dotted line). (B) The wrist and index finger paths are shown moving toward the target (large dot) for the same trials as in A. The control subject makes straight line wrist and index paths and stops right on the target (bold circle). One cerebellar subject (mild) produced slightly curved wrist and index paths and stopped on target. The other cerebellar subject (severe) produced curved wrist and index paths and overshoot the target by a great extent. Adapted from Bastian *et al.*

can also be produced by lesions of the fastigius and vermal cerebellar cortex. The fastigius ultimately influences muscles associated with posture and gait through the vestibulospinal and reticulospinal pathways. Finally, degeneration of the medial anterior lobe of the cerebellar cortex, which often results from thiamin deficiency in alcoholism (Victor *et al.*, 1959), can cause ataxic gait patterns.

Action tremor probably is caused by instability of stretch reflexes, due to an inability to adjust the gain and sensitivity of the reflexes. Dysdiadochokinesis may be due to a failure to coordinate the activation of a muscle with the inhibition of its antagonists and antagonistic stretch reflexes. Damage to the interpositus, alone or in combination with damage to the dentate, is speculated to cause this deficit.

Asynergy of voluntary movements is thought to result mostly from damage to the dentate and the lateral cerebellar cortex, because loss of the dentate significantly impairs the coordination of multijointed movements but has much less effect on single-jointed movements (Gilman *et al.*, 1976; Goodkin *et al.*, 1993). The increased number of degrees of freedom in multijointed movements adds greatly to the mechanical complexity of these movements. When multiple joints are moved together, the motor system must compensate for interaction torques, forces that are generated at one joint when a segment that is directly or indirectly linked to it moves. Cerebellar patients are unable to correct for interaction torques generated during multijointed movements (Bastian *et al.*, 1996) (Fig. 32.8), such that their movements can become dominated by interaction torques, appearing ataxic and inaccurate.

It has been proposed that a major function of the lateral cerebellum is to generate predictive and feedback corrections that are used to compensate for extraneous forces generated by one's own body movements. Lesions of the lateral cerebellum also produce modest increases in voluntary reaction time. This defect may reflect the loss of the early cerebellar signals that generate movements. Cerebellar damage can also result in the loss of adjustability of movement. Studies of prism adaptation have shown that some patients with cerebellar damage are unable to adjust their hand-eye coordination appropriately (Martin *et al.*, 1996; Weiner *et al.*, 1983) (Fig. 32.7).

### A Cerebellar Role in Rehabilitation? Functional Recovery through Relearning after Damage of Other Parts of the Nervous System

A series of patients sustained infarct of the left cerebral cortical frontal speech area with immediate onset

of aphasia. After time and speech training, they recovered the ability to speak. FMRI study showed that upon speaking, symmetrically opposite portions of the opposite right cerebral hemisphere were active. Further, the regions of the cerebellum now active in speech had shifted to the left cerebellar hemisphere. This suggests that (1) the primary property of the cerebellar hemispheres is not speech (right) or spatial operations (left), but rather (2) their cooperation/training of the opposite cerebral hemisphere cortex, whatever activities it is engaged in (Connor *et al.*, 2006).

An ongoing series of studies is exploring this potential role in neurorehabilitation of gait after hemiplegia due to cerebral hemispheric cortical infarcts or hemispherectomy for seizure control. Subjects repeatedly walk on a split treadmill. The belt on the defective side can be made to move faster to bring gait in the impaired leg up to match that on the normal side. This training appears to carry over to over ground gait for a period of time. Further studies will determine whether additional intensive training can induce a permanent learning effect, as in the prism gaze-arm throwing experiments.

### Computation in the Cerebellum

The preceding sections illustrate that the contributions of the cerebellum are diverse and that there are a variety of ideas about the function of the cerebellum that at the surface appear somewhat mutually exclusive. Presumably however, what these contributions share is the computation that the cerebellum accomplishes—that is, the rules that describe the transformation of inputs to outputs. Like all brain systems, the cerebellum receives inputs from other parts of the brain, acts on these inputs with rules determined by its connectivity and synaptic/cellular properties, and produces output to other brain systems. Understanding the cerebellum, or any brain system, thus involves accomplishing three interrelated goals:

1. **What the cerebellum computes**, which involves a thorough characterization of the rules for input/output transformation. In essence, this goal states that we understand the cerebellum when given an input to it (and information about past history) we can reliably predict the output.
2. **How the cerebellum computes**, which means to understand the interactions between synaptic organization and synaptic physiology that mediates the input/output transformations.
3. **Why the cerebellum is involved in various aspects of behavior** should then be derivable from their common need for the computation that the cerebellum accomplishes.

In this section we outline progress toward these goals. We will limit discussion to research related to the motor function of the cerebellum, mainly because movement is inherently more experimentally tractable than cognition. Thus, much more is known about the cerebellar computations that are applied to motor coordination. Given that the synaptic organization of the cerebellum is relatively uniform it is likely that the same computational principles apply qualitatively for cerebellar regions involved in cognitive functions.

### Motor Coordination, Motor Learning or Timing?

For cerebellar contributions to the motor system, three functions generally dominate discussion: (1) motor coordination, which is an obvious inference given the severe motor deficits described earlier; (2) motor learning, which is inferred from cerebellar involvement in several experimentally tractable forms of motor learning (Pavlovian eyelid conditioning, adaption of the VOR, adaptation of saccades and learning of smooth pursuit eye movements to name four); and (3) timing, which is suggested by timing-related deficits in cerebellar patients, functional imaging in humans, and by certain rhythmic properties of cerebellar neurons. This list is not complete, but it can serve as an illustration of how a focus on cerebellar computation can tie together many, if not all of the functions that have been proposed for the cerebellum. From analysis of the input/output transformations of the

cerebellum enabled largely by analysis of eyelid conditioning, this computation appears to be feed-forward prediction. Thus, motor coordination is enhanced by cerebellar feed-forward prediction, which requires associative learning with timing (Ohya *et al.*, 2003).

In principle there are two ways to make use of sensory input to make decisions about output: feedback and feed-forward. Feedback is familiar and simple—a thermostat is an example of feedback. The measured temperature (sensory input) is compared to a target and differences are translated into turning on the heater or cooler. Feedback systems of this sort can be accurate and reliable, but they cannot be fast. Attempts to make a feedback system fast result in oscillations as, in the thermostat example, small deviations from the target produce alternating activations of the heater and cooler as each output causes overshoot of the target temperature (Fig. 32.9). Feed-forward control can be faster because it involves anticipation of errors from previous experience. A hypothetical feed-forward thermostat would be outfitted with a variety of sensory for temperature, humidity, number of people in the room, position of the sun, number of windows open, and so on. When a rapid change in room temperature is required, this hypothetical feed-forward thermostat would predict, from previous experience, the burst of hot or cold air required to produce the rapid change.

If, after producing its response, the wrong outcome is detected, then the feed-forward thermostat should learn from this mistake so that subsequent predictions

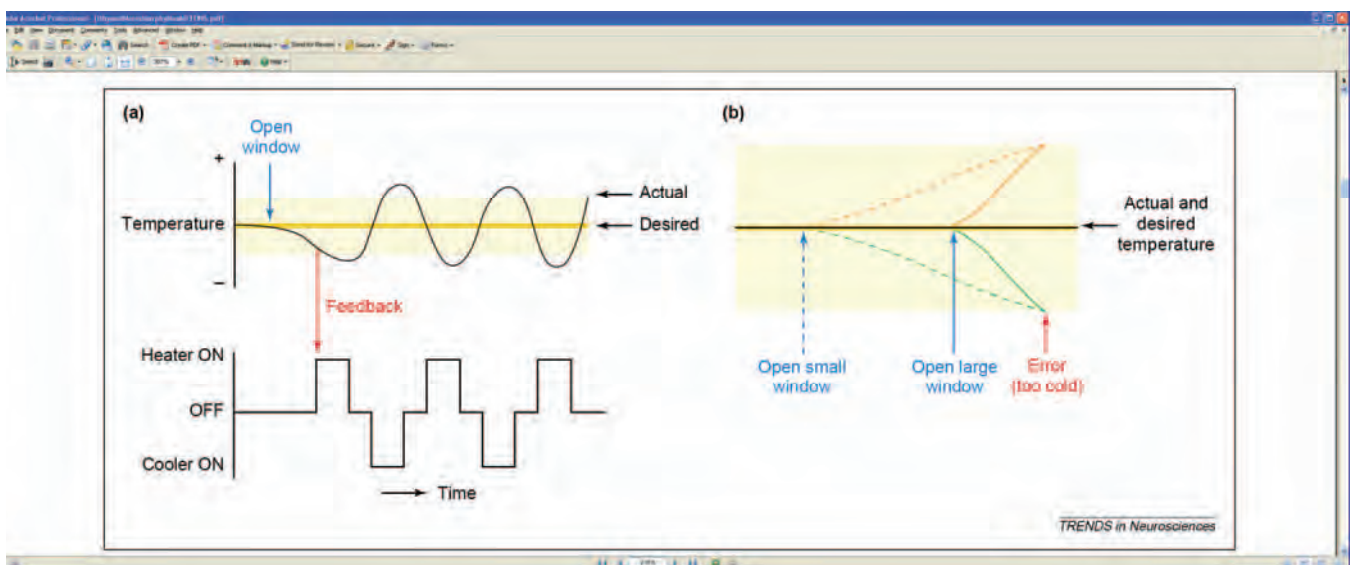

FIGURE 32.9 This is from Ohya *et al.* 2003 (TINS).

in similar circumstances are better. The properties required of this learning are fairly specific. Since different mossy fiber inputs may have preceded the error signal by different temporal intervals, learning should not produce changes in output time locked to any particular mossy fiber input, but should instead produce changes that are timed to occur just before the error occurred (since that was the errant output). This hypothetical example reveals the need for specific learning features:

1. The learning should be associative: it should modify only the future output of the system for inputs that are similar to the ones that were present just before the error.
2. The learning should show temporal flexibility: the learned changes in output should not be time locked to the onset of any given mossy fiber input, but should be delayed after their onset so that the changed responses fix the errant prediction—namely, the one that occurred just before the arrival of the error signal. In other words, the error signal should fix the output that just occurred, not the output present at the onset of the mossy fiber inputs that preceded and predicted the error.

Eyelid conditioning studies reveal precisely these properties in cerebellar learning. It is associative in that it takes mossy fiber inputs predicting climbing fiber inputs to occur. Moreover, the timing of the responses is precisely as described earlier. Pairing a mossy fiber input with a climbing fiber input produces a change in cerebellar output that is not time locked to the onset of the mossy fiber input, but is instead timed to peak just before

the time when the climbing fiber input arrives. This shows that cerebellar learning can develop predictions, through trial and error learning with climbing fiber error signals, that improve the prediction about the proper cerebellar output for a given mossy fiber input.

This may tie together many key ideas about cerebellar function. Motor coordination is improved by feed-forward learning feed-forward predictions. This learning requires associative learning with quite specific temporal properties. It requires motor learning with timing. An interesting challenge for the future will be to determine how feed-forward prediction can contribute to the various cognitive processes that appear to engage the cerebellum. The most important information that currently is lacking is what activates the climbing fiber (error) inputs for regions of the cerebellum involved in cognition and how do learned changes in output contribute to or improve cognitive processes?

### Summary

Ideas about cerebellar function have been driven largely by the effects of lesion or dysfunction of the cerebellum and by the anatomical and physiological properties of cerebellar inputs, outputs, and intrinsic circuitry. This has led to a wide variety of models of cerebellar function and to debates about whether it is a motor structure, a sensory structure, or a cognitive structure. A view of cerebellar function that incorporates cerebellar computations may be more informative and may also help us understand how the various theories of cerebellum function are interrelated.

#### BOX 32.2

### ANIMAL MODELS OF CEREBELLAR DEVELOPMENT

Several genetic mutations in mice perturb the normal development of the cerebellum. In the *weaver* mutation, granule cells (and thus parallel fibers) are absent, causing Purkinje cells to develop abnormally organized dendrites with an excessive number of spines. The *reeler* mutation causes Purkinje cells to migrate abnormally, resulting in a large displacement of Purkinje cells within the central cerebellar mass. In the *staggerer* mutation, most Purkinje

cells are absent before granule cell migration, while in the *nervous* mutation, Purkinje cells begin to develop normally but then degenerate after most synaptic connections with parallel fibers have been formed. Studies of these and other mutations that cause specific cellular components to be deleted at different developmental stages are furthering our understanding of the complex cellular interactions that take place during normal synaptogenesis.

## BOX 32.3

## CEREBELLUM—THE TRUE THINKING MACHINE

It no longer seems reasonable to consider the function of the cerebellum as being confined to the control of voluntary movement, speech, and equilibrium. Considerable evidence suggests that the cerebellum is critical also for thought, behavior, and emotion. Anatomical studies demonstrate that the cerebellum is an important part of the distributed neural circuitry that subserves cognitive processing. The association and paralimbic cerebral cortices known to subserve higher order functions are linked with the cerebellum in a precisely organized system of feedforward and feedback loops, and physiological studies indicate that these pathways are functionally relevant. Cerebellar ablation and stimulation experiments in animals have demonstrated cerebellar influences on many nonmotor functions, including classical conditioning, navigational skills, cognitive flexibility, sham rage, predatory attack, and aggression. Functional neuroimaging investigations of the morphologic correlates of cognitive processing using PET and fMRI in humans have revealed sites of activation in the cerebellum in a number of cognitive tasks. These include linguistic processing, verbal working memory, shifting attention, mental imagery, classical conditioning, motor learning, sensory processing, and modulation of emotion. Furthermore, there appears to be a topographic organization of the sites within the cerebellum activated by these different cognitive processes.

Clinical investigations of adults and children with diseases confined to the cerebellum have defined a cerebellar cognitive affective syndrome characterized by impairments of executive processing, working memory, visual spatial reasoning, language disturbances (ranging from mutism to agrammatism), and a flattened or inappropriate affect. The net effect of these deficits is a lowering of overall intellectual ability. The posterior lobe of the cerebellum appears particularly important in the generation of this syndrome, and the vermis is consistently involved when the affective component is pronounced. Elements of this clinical syndrome have also been noted in pa-

tients with developmental cerebellar anomalies, cerebellar degeneration, autism, and fragile X syndrome. In addition, cerebellar abnormalities, particularly in the vermis, have been observed in patients with schizophrenia.

The mechanisms whereby the cerebellum influences higher function are still debated. The organization of the cerebellar corticonuclear microcomplex and the interactions between the mossy and climbing fiber systems prompted the hypothesis that the cerebellum provides an error detection mechanism for the motor system. This mechanism may also be relevant for mental operations.

The relationship between the cerebellum and nonmotor function has been conceptualized as follows.

1. The cerebellum is able to subserve cognitive functions because it is anatomically interconnected with the associative and paralimbic cortices.
2. Cognitive and behavioral functions are organized topographically within the cerebellum.
3. The convergence of inputs from multiple associative cerebral regions to adjacent areas within the cerebellum facilitates cerebellar regulation of supramodal functions.
4. The cerebellar contribution to cognition is one of modulation rather than generation.
5. The cerebellum performs computations for cognitive functions similar to those for the sensorimotor system—but the information being modulated is different.
6. The disruption of the cerebellar influences on higher functions leads to dysmetria of thought, impairment of mental agility that manifests, at least in part, as the cerebellar cognitive affective syndrome.

The potential for further discovery in this field places the cerebellum, previously thought of as a motor control device, in the forefront of current behavioral neuroscience research.

## Eye Movements

As we learned in Chapter 27, the photoreceptor mosaic of the vertebrate retina transduces light energy in the form of photons into neural activity, ultimately in the form of action potentials. The spatial resolution of this transduction system is limited by the mosaic of photoreceptors and the optics of the eye, but only if the eye is held stationary with respect to the objects of interest in the external world. Thus, stabilizing the eyes with regard to the outside world and aiming the eyes toward moving or stationary targets are critical challenges to effective vision. Evolutionary pressures have shaped the eye movement systems of animals to meet this challenge in ways that are tailored to the visual structures and behavioral needs of each species. In this chapter we examine the behavioral and neural systems used by vertebrates to control eye movements in the support of vision.

As we shall see, the control of eye movements provides a window into several fundamental aspects of neuroscience. Because the eyes are a relatively simple mechanical system, eye movements provide an excellent system for investigating the neural mechanisms of motor control, and also offer some of the clearest views of other complex processes, such as neural plasticity, sensory-motor interactions, and the higher-order control of behavior.

### EYE MOVEMENTS ARE USED TO STABILIZE GAZE OR TO SHIFT GAZE

Similar to the handling of a camera, the images that fall on the retina depend on how the eyes are held and moved. The orientation of the eyes in the head and the orientation and position of the head in space together determine the gaze direction (i.e., gaze = eye + head) and, consequently, control the retinal image. These

spatial arrangements underlie the two general classes of eye movements in vertebrates. One class is responsible for *gaze stabilization*. When animals move with respect to their surroundings, they risk degrading their visual acuity, because moving the head necessarily moves the eyes, and can cause images to streak across the retina. Gaze stabilization mechanisms have evolved to solve this problem. They maintain visual acuity during self-motion by stabilizing the retinal image of the world with rotations of the eyes that exactly compensate for head and body movements. The neural mechanisms for gaze stabilization are highly conserved across vertebrates, reflecting the widespread need to stabilize visual inputs despite other sensory and motor differences between species.

The second class is responsible for *gaze shifting*. When animals visually inspect their surroundings, they may use these eye movements to direct the line of sight to objects or features of particular interest, even when those items move. In contrast to stabilization mechanisms, gaze shifting mechanisms involve selectively sampling the animal's visual environment, because tracking one visual object often causes the retinal images of other objects to become blurred. Accordingly, the mechanisms for gaze shifting are found only in animals that have retinal specializations, such as the primate fovea, that can be used to examine a limited region of visual space at a higher spatial resolution.

### Gaze Stabilization

There are two types of mechanisms for stabilizing gaze (Fig. 33.1): the vestibulo-ocular reflex (VOR) and the optokinetic response (OKR). The VOR uses signals from the vestibular labyrinth to counter-rotate the eye-balls to keep retinal images stable during head move-

FIGURE 33.1 Eye movements that stabilize gaze. The vestibulo-ocular reflex keeps the line of sight fixed in the world by counter-rotating the eyes during movements of the head. Here, the eyes rotate rightward at a short latency after the beginning of the leftward head movement. The optokinetic response stabilizes the line of sight with respect to the moving visual surround, but does so after a longer latency.

ments. The *rotational VOR* is driven by head-rotation signals from the semicircular canals and represents a phylogenetically old reflex present in all vertebrate species. The fast transduction properties of the vestibular periphery, combined with a direct 3-neuron pathway, give the rotational VOR a very short latency ( $<10\text{ ms}$ ). However, because the canals do not accurately transduce constant velocity head rotations, the output of the VOR decays over several seconds. Some vertebrates also possess a *translational VOR*, which is driven by head-movement signals from the otoliths. Unlike the image motion caused by head rotations, which is uniform across the visual field and can be fully compensated for by counter-rotating the eyes, the image motion caused by translations are complex and can only partly be eliminated by eye movements. This explains why the translational VOR is found only in animals with central retinal specializations (e.g., foveal vision).

The optokinetic response (OKR) is driven by visual signals about the en masse movement of images across the retina. Because of the slow transduction of visual signals, the OKR has a longer latency (50–100 ms) than the VOR, but the use of visual motion signals makes it able to compensate for the constant motions and low speeds that the VOR cannot. The properties of the OKR therefore complement those of the VOR in maintaining stable gaze during movements, and the visual signals used by the OKR play a major role in guiding adaptive changes in the VOR. Animals with foveal vision also possess an ocular following response that is driven at very short latencies ( $\sim 50\text{ ms}$ ) by shifts in

the retinal image, and that serves as the visual complement to the translational VOR (Miles, 1997).

### Gaze Shifting

Animals with foveal vision also possess several mechanisms for shifting gaze (Fig. 33.2). Saccadic eye movements act to quickly move the image of a visual target from an eccentric retinal location to the center of the retina where it can be seen best. Saccades are very fast movements, reaching peak speeds greater than  $500\text{ deg/s}$  and lasting only tens of milliseconds. Consequently, although saccades often are triggered by visual stimuli (at typical latencies of 150–250 ms), the trajectory of saccades is not guided by visual feedback, but instead follows a stereotyped profile that is largely determined by the size of the movement. Saccades do not require a visual stimulus, but can be guided by other modalities, and can even be directed toward the location of imagined or remembered targets.

Smooth pursuit eye movements slowly rotate the eyes to compensate for any motion of the visual target, and thus act to minimize the blurring of the target's retinal image that would otherwise occur. Smooth pursuit is a relatively slow movement whose trajectory is determined by the moving stimulus. Pursuit is triggered by visual stimuli at latencies similar to, but somewhat shorter than, the latencies of saccades (typically 100–200 ms), and generates eye velocities up to  $\sim 50\text{ deg/s}$ , continuously adjusted by visual feedback about the target's retinal image. Unlike saccades,

**FIGURE 33.2** Eye movements that shift gaze. Saccades shift the line of sight to place the retinal image of visual targets onto the fovea. They are characterized by rapid changes in eye position (upward deflection in eye position trace) involving very high eye velocities (brief pulse in eye velocity trace). Smooth pursuit continuously changes the line of sight to minimize blurring of the target's retinal image. These movements are characterized by smooth and continuous changes in eye position (ramp in eye position trace) involving lower eye velocities (smooth step in eye velocity trace).

pursuit cannot be generated in the absence of a stimulus, although moving targets that are sensed through modalities other than vision can also guide pursuit.

Saccades and smooth pursuit produce conjugate, or yoked, movements of the two eyes. These are also referred to as *versional* eye movements. In contrast, a third type of mechanism for shifting gaze, called *vergence* eye movements, produces disconjugate movements—the two eyes move in opposite directions or by different amounts. Vergence eye movements act to change the depth at which the eyes' lines of sight meet. When we look at a near object our eyes converge (rotate inward), and when we look at a far object our eyes diverge (rotate outward). Before shifting our gaze to an object at a different distance, the pair of images produced by that object will be spatially mismatched between the two eyes, causing binocular disparity. Also, because the curvature of the two eyes' lenses are set to focus the currently viewed object, the image of the new object will also be blurred. These two signals, binocular disparity and blur, drive the combination of vergence eye movements and *accommodation* (which changes the dioptric power of the lenses by contracting or relaxing the ciliary muscle) that bring the new object into focus on the fovea of both eyes. Vergence and accommodation are tightly linked and often are referred together as the *near response*. When evoked by themselves (e.g., by binocular disparity), vergence movements are very slow, taking up to 1 second to

converge or diverge the eyes. However, when they occur in combination with faster versional eye movements such as saccades, vergence movements speed up, and interestingly, so does accommodation.

### Fixation and Fixational Eye Movements

In between gaze shifts, the eyes are actively held steady by a fixation mechanism. By preventing the eyes from shifting gaze to another visual target, fixation makes it possible to visually inspect a particular object at length. Periods of fixation typically last about 200ms, but vary depending on what the animal is doing. Fixation does not necessarily act to keep the eyes from moving, but to hold the eyes steady with respect to the environment. For example, gaze stabilization mechanisms such as the VOR are active during periods of fixation.

Even during periods of steady fixation of a stationary object, the eyes are not completely still. The eyes typically make tiny movements during fixation in seemingly random directions that cause very slight changes in how images fall on the retinal mosaic but without displacing images from the fovea. *Microsaccades* are very small saccades with amplitudes typically less than 0.1 degree of visual angle, and often are interspersed with slow drifts (speeds less than  $\frac{1}{4}$  degree per second) of similar amplitude. The function of these movements remains unclear. They may

prevent the adaptation of retinal signals that would occur with perfectly stabilized images, but the frequency of these small movements is in fact reduced during tasks that place high demands on foveal vision, such as threading a needle.

## THE MECHANICS OF MOVING THE EYES

### Each Eye Is Controlled by Three Pairs of Muscles

Moving the eye involves rotating the globe of the eye in the orbital socket of the skull. Because the eye undergoes minimal translation during movement, it can be viewed as a spherical joint with an orientation defined by three axes of rotation (horizontal, vertical, and torsional). Correspondingly, the orientation and movement of each eye is accomplished by three complementary pairs of extraocular muscles (Fig. 33.3). The lateral and medial rectus muscles form an antagonistic pair that controls the horizontal position of the eye. Contraction of the lateral rectus (and commensurate relaxation of the medial rectus) causes the eye to abduct, or rotate outward. Conversely, contraction of the medial rectus (and relaxation of the lateral rectus) causes the eye to adduct, or rotate inward. The actions of the other two pairs of muscles are more complex. When the eye is centered in the orbit, the primary

effect of the superior and inferior recti is to elevate (rotate up) or depress (rotate down) the eye. However, when the eye is deviated horizontally in the orbit, these muscles also contribute to torsion, the rotation of the eye around the line of sight that determines the orientation of images on the retina. The primary effect of the superior and inferior obliques is intorsion (the top of the eye rotates toward the nose) or extorsion (the top of the eye rotates away from the nose), but depending on the horizontal deviation of the eye, these muscles may also help determine the vertical orientation of the eye. Eye movements therefore involve redefining the three-dimensional orientation of the eye by changing the balance of forces applied to the globe by all three pairs of extraocular muscles.

The mechanics of moving the eye may seem simple, but the details are quite complicated. Because the eye is free to rotate in three dimensions, the final orientation of the eye depends on the order in which the rotations are carried out; for example, “turn-then-spin” gives a different outcome than “spin-then-turn.” This property is referred to as *noncommutativity*. In fact, when the eye moves, the final three-dimensional orientation of the eye and the axis of rotation used to get there are not arbitrary, but form an orderly set. *Donders’s law* states that the orientation of the eye is always the same when the eye is aimed in a particular direction. *Lister’s law* specifies these orientations by stating that the axes used to rotate the eye are confined to a single plane, referred to as Lister’s plane. These orderly relationships are achieved, at least in part, by a mechanism that involves the muscles themselves. The extraocular muscles consist of two distinct layers: global fibers, which attach directly to the globe of the eye, and orbital fibers, which terminate in connective tissue that ensheathes the body of the muscle and acts like a moveable pulley for the global fibers. Because the pulleys themselves move when the muscle is contracted or relaxed, the pulling direction of the extraocular muscles changes with eye position. These gaze-dependent mechanical changes in muscle action largely account for Lister’s law (Demer, 2006).

Interestingly, Lister’s law is obeyed during saccades and smooth pursuit, but is violated during the VOR and the OKR. This difference presumably stems from the different inputs for these movements. Saccades and smooth pursuit may follow Lister’s law because they involve local two-dimensional retinal inputs that do not uniquely specify the orientation of the eye. In contrast, the VOR is driven by three-dimensional inputs from the semicircular canals for which the extra degree of freedom is not redundant. Thus, the mechanics of the eye muscles impose kinematic constraints that are helpful during visually guided eye movements, but

**FIGURE 33.3** Muscles of the eye. Six muscles, arranged in three pairs, control the movements of the eye as shown here in a cutaway view of the eye in its socket, or orbit.

these constraints can be altered or lifted by neural control signals during gaze stabilization.

### Central Control of the Extraocular Muscles

The six extraocular muscles are innervated by three of the bilaterally paired cranial nerves (Fig. 33.4). The oculomotor nerve (cranial nerve III) innervates the medial rectus, the superior and inferior rectus, and the inferior oblique on one side of the head. The cell bodies for these motor neurons thus lie in the third cranial nerve nucleus. The oculomotor nerve also contains the fibers that control accommodation of the lens. The trochlear nerve (cranial nerve IV) innervates the superior oblique muscle, and the abducens nerve (cranial nerve VI) innervates the lateral rectus. These three pairs of nuclei, distributed through the brain stem, contain all the oculomotor motor neurons and are heavily interconnected by a pathway called the medial longitudinal fasciculus. This interconnection is crucial for the precise coordination of the extraocular muscles that is necessary for the control of eye movements.

The firing rates of the oculomotor motor neurons determine the forces applied by the extraocular muscles and, consequently, whether the eye moves or is held in place (Fuchs and Luschei, 1970). When the eye is

stationary, the firing rate of oculomotor motor neurons is proportional to eye position, because under static conditions the balance of forces exerted on the globe determines the orientation of the eye (Fig. 33.5). Each motor neuron has a recruitment point (an eye position at which the motor neuron begins to fire) and a characteristic slope (the change in firing rate as the eye rotates in the pulling direction of the relevant muscle). Thus, as in the skeletal system, oculomotor motor neurons have a fixed recruitment order. When the eye moves in the pulling direction of the motor unit, oculomotor motor neurons exhibit a high-frequency pulse of activity that drives the high-velocity phase of the eye movement. The high-frequency pulse is followed by a sustained step-like increase in firing rate appropriate for the new static position of the eye. When the eye moves in the opposite direction, the motor neurons pause their firing during the movement and then resume their activity at a lower sustained level.

The neural commands from these motor neurons therefore take the form of a pulse-step during rapid eye movements such as saccades. The amplitude and duration of the pulse determine the speed and duration of the movement, and the amplitude of the step determines the final static eye position. The need for the pulse derives from the sluggish dynamics of the

**FIGURE 33.4** Oculomotor nuclei in the brainstem. Parasagittal section through the brainstem, cerebellum, and thalamus of a rhesus monkey, showing the location of the major brainstem nuclei involved in the control of eye movements. Motor neurons for the eye muscles are located in the oculomotor nucleus (III), trochlear nucleus (IV), and abducens nucleus (VI), and reach the extraocular muscles via the corresponding nerves (n. III, n. IV, n. VI). Premotor neurons for controlling eye movements are located in the paramedian pontine reticular formation (PPRF), the mesencephalic reticular formation (MRF), rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), the interstitial nucleus of Cajal (IC), the vestibular nuclei (VN), and the nucleus prepositus hypoglossi (NPH). The medial longitudinal fasciculus (mlf) is a major fiber tract containing the axons of these neurons. Other abbreviation: MB, mammillary body of the hypothalamus.

**FIGURE 33.5** The firing rate patterns of eye movement motor neurons during horizontal eye movements. The rapid rightward change in eye position, indicated by the upward deflection in the eye position trace, involves contraction of the right lateral rectus and relaxation of the right medial rectus. This is accomplished by a pulse-step increase in activity of the agonist motor neurons in the abducens nucleus, and a pause-step decrease in activity of the antagonist motor neurons in the oculomotor nucleus.

eye and orbital tissues, which is dominated by the viscosity of the extraocular muscles. If the eye were moved by only a step change in force, it would take nearly a second for the eye to settle at its new orientation, which would obviously be incompatible with the goal of supporting vision. Similarly, during slow eye movements such as smooth pursuit, the neural commands from the motor neurons consist of a ramp-like change in activity to drive the smooth changes in eye position, plus an additional increment to overcome the sluggish dynamics of the eye. These patterns of activity are adjusted precisely by central mechanisms involving the brain stem and cerebellum, and illustrate a general problem in motor control—the need to convert desired actions into appropriately formed motor commands. The solution appears to involve the use of internal models that allow central mechanisms to take into account the dynamic properties of the body part or object to be moved.

Oculomotor motor units are also unusual in several ways (Buttner-Ennever, 2007). Unlike skeletal motor units, eye motor neurons participate equally in all types of eye movements, regardless of the speed involved. The extraocular muscles contain muscle spindles, but no Golgi tendon organs, and there are no ocular stretch reflexes. Instead, eye proprioception appears to come mainly from palisade endings on the eye muscle tendons. The function of this input is unclear, but it is distributed via the trigeminal nucleus to many key structures in the oculomotor system (including the vestibular nuclei, cerebellum, superior

colliculus, and frontal eye fields) and may play a role in the long-term adaptive control of eye movements.

## THE FUNDAMENTAL CIRCUITS FOR STABILIZING GAZE

### The Vestibulo-Ocular Reflex (VOR) Stabilizes Gaze during Head Movements

The function of the VOR is to stabilize retinal images during head movements by using head-motion signals from the vestibular organs. A purely rotational VOR can be elicited in complete darkness by rotating the head roughly about its center (e.g., the interaural axis). Head rotations stimulate the semicircular canals of the inner ear, which provide the sensory signals about head motion that drive this highly conserved mechanism for counter-rotating the eyes. During sustained rotations of the head, the eyes cannot continue to counter-rotate endlessly in the orbit, but are intermittently and rapidly reset to a central position during the ongoing compensatory eye rotation. The profile of eye position over time during the VOR therefore exhibits a characteristic saw-tooth pattern consisting of the slow-phase counter-rotations and quick-phase resetting eye movements. This pattern is called *nystagmus*, and is described by the direction of the quick phases (Fig. 33.6 is an example of right-beat nystagmus).

The speed of the slow phases during nystagmus indicates how effectively the VOR is compensating for

**FIGURE 33.6** The eye movements and neural circuits for the VOR. During a sustained rotation of the head (here, rightward), the eyes rotate slowly to the left (downward deflections in eye position trace labeled “slow phases”), and then abruptly shift rightward to reset the eyes toward a central position (upward deflections in eye position trace labeled “quick phases”). This is an example of right-beat nystagmus. The diagram of the basic VOR circuit shows the push-pull organization of the horizontal VOR. When the head rotates rightward, activity increases in the right semicircular canal, right vestibular nucleus (VN), and left abducens nucleus (VI). This leads to increased activation of the left eye lateral rectus and, through a crossed projection to the oculomotor nucleus (III), increased activation of the right eye medial rectus. The complementary set of pathways (colored in gray) show decreases in activity.

the head rotation. The degree of compensation often is characterized by the VOR gain, which is defined as the ratio of slow-phase eye speed over the speed of head rotation. Perfect compensation occurs when the eye rotates in the opposite direction at exactly the same speed as the head rotation, which corresponds to a gain of 1. The ability of the VOR to compensate for head motion is limited by the dynamics of the signals from the semicircular canals, which act as “high-pass” sensors of head velocity. Thus, the VOR is very effective (its gain is near 1) for fast back-and-forth head rotations that take a second or less to complete (i.e., frequencies over 1 Hz), but it is much less effective for slow head rotations that continue over many seconds (e.g., 0.1 Hz). Under natural conditions, this limitation of the VOR does not pose a problem for vision, because at these lower speeds visual signals can be used to stabilize gaze very effectively through the optokinetic response.

The fundamental neural mechanism for the VOR consists of brain stem circuits linking the vestibular afferents to the extraocular muscles, including a direct 3-neuron arc pathway (Fig. 33.6). For example, during a rightward head rotation, vestibular afferents from the horizontal semicircular canal on the right side increase their firing rates, and this increase is passed on to neurons in the vestibular nucleus on the same side. These vestibular nucleus neurons, in turn, increase the activity of motor neurons and interneurons in the abducens nucleus on the opposite (left) side. Motor neurons

in the abducens innervate the lateral rectus of the left eye, completing the three-neuron arc. Interneurons in the abducens provide a crossed projection back to the right oculomotor nucleus, where motor neurons innervate the medial rectus of the right eye. By contracting both the left lateral rectus and the right medial rectus, the two eyes rotate leftward together in response to the rightward head rotation. In addition, because the vestibular afferents on the left side decrease their activity during a rightward rotation, a complementary circuit causes relaxation of the right lateral rectus and the left medial rectus. The VOR therefore is controlled in a push-pull fashion that yokes the movements of the two eyes through the bilateral symmetry of these basic circuits.

These direct pathways are key components of the VOR mechanism, but the VOR also requires indirect pathways to function correctly. As discussed in the previous section, the firing rate of oculomotor motor neurons is related primarily to eye position, but the afferent signals from the semicircular canals are related primarily to the head velocity. In order to construct the motor commands needed to hold, as well as move, the eyes during the VOR, the brain needs to transform the dynamic signals provided by the vestibular afferents into the combination of dynamic and static commands found on motor neurons. Similar to the operation of mathematical integration in calculus, this process involves the temporal integration of velocity inputs into position signals.

The neural integrator for eye movements is accomplished by neurons in the vestibular nuclei and two other brain stem nuclei—the nucleus prepositus hypoglossi (for horizontal components) and the interstitial nucleus of Cajal (for vertical)—and is fine-tuned by connections between these brain stem nuclei and the vestibulocerebellum (Cannon and Robinson, 1987). The output from the neural integrator pathway sums with the signals from the direct pathway to provide the motor neurons with the complete set of velocity and position commands needed to accomplish the VOR. Importantly, all conjugate eye movements also use this same indirect integrator pathway. Thus, although the source of the velocity signals for the VOR, OKR, saccades, and pursuit are quite different, they appear to share a common brain stem mechanism for transforming these signals into the final motor commands.

### The Optokinetic Response (OKR) Uses Visual Inputs to Stabilize Gaze

The OKR also functions to stabilize retinal images during head movements, but uses visual inputs to infer the direction and speed of head motion rather than responding directly to head-velocity signals. The optimal stimulus for the OKR is full-field motion of the visual environment that, like head rotations, causes a saw-tooth pattern of eye movements referred to as *optokinetic nystagmus*. Like the VOR, the slow phase movements during nystagmus compensate for the head rotation that presumably caused the full-field motion. However, because the OKR is driven by visual signals, which are processed much more slowly than vestibular signals, the range of motions that are effectively compensated by the OKR is quite different from the VOR. The OKR is very effective (its gain is near 1) for slow rotations that continue over many seconds, but it is much less effective for very fast back-and-forth rotations. These properties of the OKR therefore complement those of the VOR and together, the two types of mechanisms can effectively stabilize gaze over a much wider range of speeds and behavioral conditions than either could achieve alone.

The interlocking nature of the two systems is also evident in the neural pathways for the OKR, despite the difference in their input signals. In vertebrate species without foveal vision, such as the rabbit, the visual processing for the OKR is accomplished entirely within the brain stem. Direction-selective retinal ganglion cells project directly to a set of visual nuclei in the midbrain called the pretectum and accessory optic nuclei. In species with foveal vision, the visual properties of these nuclei are determined not only by inputs from the retina, but also are shaped by inputs from visual areas

of the cerebral cortex. Neurons in the accessory optic nuclei have very large receptive fields and respond selectively to global visual motion that would result from rotating the head about a particular spatial axis. Remarkably, the selectivity of individual neurons is restricted to one of the three axes of rotation that are also detected by the semicircular canals. This common rotational coordinate system makes it easier to combine visual *reafferent* signals about head motion from the accessory optic nuclei with the vestibular *afferent* signals provided by the labyrinths. Accordingly, neurons in the pretectum and accessory optic nuclei project to the vestibular nuclei and nucleus prepositus hypoglossi, where these visual signals join the same final pathways used by the VOR. These nuclei also project to the vestibulocerebellum, where the visual signals contribute to the velocity commands for the OKR and other smooth eye movements, and also act as feedback signals that play a critical role in the long-term adjustment of the VOR.

### THE COMMANDS FOR SHIFTING GAZE ARE FORMED IN THE BRAIN STEM

The commands for shifting gaze use the same final motor pathways that are used for stabilizing gaze, but the signals and mechanisms giving rise to the gaze-shifting commands are quite different. For smooth pursuit, they are based on motion signals about the visual target that are first extracted in specialized areas of the cerebral cortex and then used to commandeer the brain stem and cerebellar pathways for the OKR. For saccades, which are not guided by visual feedback, a specialized circuit in the brain stem reticular formation produces the stereotyped velocity command that determines the trajectory of the saccade.

### The Motor Commands for Saccades Are Constructed in the Brain Stem Reticular Formation

The control signals for saccades descending from higher centers specify the location of the target, which is then transformed by circuits in the brain stem reticular formation into the motor commands for saccades (Fig. 33.7). The horizontal and vertical components of saccades are formed by separate but interconnected circuits—the horizontal commands are formed in the paramedian pontine reticular formation (PPRF), and the vertical commands are formed in a part of the mesencephalic reticular formation called the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF).

Within these brain stem circuits, often referred to as the *saccadic burst generator*, several different classes of neurons work together to construct the saccade motor

**FIGURE 33.7** The brainstem circuits for controlling saccadic eye movements. This diagram of the saccade burst generator outlines the major classes of neurons involved in constructing the motor command for horizontal saccades. Omnipause neurons (OPN) located near the midline in the nucleus raphe interpositus (RIP) tonically inhibit excitatory burst neurons (EBN) located in the paramedian pontine reticular formation (PPRF). When OPNs pause, the EBNs emit a burst of spikes, which activate motor neurons (MN) in the abducens nucleus (VI) innervating the lateral rectus muscle. The burst also activates interneurons (IN) which, in turn, activate motor neurons on the oculomotor nucleus (III) on the opposite side, innervating the medial rectus. Inhibitory burst neurons (IBN) show a pattern of activity similar to EBNs, but provide inhibitory inputs to decrease activation in the complementary circuits and antagonist muscles. Long-lead burst neurons (LLBN) show activity long before movement onset, and provide an excitatory input to EBNs.

command (Keller, 1974). *Burst neurons* fire a high-frequency volley of action potentials that begins ~10 ms before the onset of the saccade and ends slightly before the saccade lands on the target. The firing rate during the burst is related to the instantaneous velocity of the saccade, and the number of spikes in the burst is related to the amplitude of the saccade. There are several types of burst neurons. Excitatory burst neurons (EBNs), sometimes called “medium-lead burst neurons,” provide the velocity signal for the eye muscles that will contract during the saccade, and specify the “pulse” portion of the saccade motor command. The EBNs provide a copy of this velocity signal to the brain stem nuclei of the neural integrator, which then generate the “step” portion of the motor command, just like they do for other eye movements. EBNs also contact inhibitory burst neurons (IBNs), which provide a crossed projection that inhibits motor neurons for the antagonist eye muscles that will relax during the saccade. Finally, long-lead burst neurons show changes in their activity well in advance of the saccade, presumably reflecting inputs received from higher centers, and provide an excitatory input to the EBNs.

The other major class of neurons in the saccadic burst generator are the *omnipause neurons* (OPNs). These neurons fire at a constant high rate (~100 spikes/s) during fixation, but completely pause their activity just before and during saccades in all directions. Because the OPNs directly inhibit both EBNs and IBNs, their

tonic activity prevents unwanted saccades during fixation, and the pause in their activity unleashes the synchronized bursts of action potentials that initiate and drive the saccade. The onset of the pause in OPN activity appears to be triggered by inhibitory signals originating from higher brain centers, but the duration of the pause does not determine when the saccade ends. Instead, stopping saccades involves another inhibitory influence on burst neurons. One likely candidate is the oculomotor cerebellum (lobules VI and VII of the vermis and the caudal fastigial nucleus). The oculomotor vermis is interconnected with the saccadic burst generator and plays a crucial role in adjusting the metrics of saccades so that the eyes land accurately on the target at the end of the gaze shift.

### The Motor Commands for Pursuit Are Formed in the Brain Stem and Cerebellum

The control signals for pursuit descending from higher centers continuously specify the motion of the target to be followed with the eyes. Thus, in contrast to saccades, pursuit does not require motor circuitry to construct the velocity command from scratch. Instead, the pursuit pathways in the brain stem and cerebellum sculpt the descending control signals to form an appropriately shaped velocity command, and provide a copy of this velocity signal to the neural integrator to generate the position component of the motor command.

**FIGURE 33.8** The brainstem and cerebellar circuits for controlling pursuit eye movements. During pursuit, the line of sight changes smoothly to follow the motion of the target. The smooth changes in eye velocity are often accompanied by small “corrective” saccades, indicated by the upward deflection in the eye velocity trace (dotted lines). The diagram outlines the circuits involved in constructing the motor command for horizontal pursuit. The major pathways involve projections from areas of the cerebral cortex via the pontine nuclei to the cerebellum (CBLM), which then modulates activity in nuclei associated with the VOR – namely, the vestibular nuclei (VN) and nucleus prepositus hypoglossi (NPH) – and also modulates activity in nuclei associated with saccades, such as the paramedian pontine reticular formation (PPRF). A second pathway involves projections from the pretectum to the pontine nuclei, as well as a direct projection to the vestibular nuclei and prepositus hypoglossi.

The velocity commands for pursuit arise in areas of the cerebral cortex and reach the final motor circuits through several routes (Fig. 33.8). One pair of pathways involves projections from the cerebral cortex to the cerebellum via a large set of relay neurons on the floor of the brain stem called the basal pontine nuclei. Areas in extrastriate visual cortex provide signals related to visual motion through the dorsolateral pontine nuclei to a portion of the vestibulocerebellum called the ventral paraflocculus. The frontal cortex provides signals related to target and eye velocity through the dorsomedial pontine nuclei, and the adjacent nucleus reticularis tegmenti pontis, to the oculomotor cerebellum (vermis), the same portion of the cerebellum involved in adjusting the metrics of saccades. Both of these cerebellar regions provide inputs to parts of the brain stem motor pathways that we already have discussed. The output of the ventral paraflocculus is closely related to eye velocity and terminates in the vestibular nuclei, where it contributes to the velocity command for pursuit, and also provides an input to the neural integrator. The output of the oculomotor vermis is less well defined, but appears to be related to eye acceleration as well as eye velocity. The outputs of the vermis and the associated deep cerebellar nucleus (the caudal fastigial nucleus) are sent to neurons in the brain stem reticular formation, and may play a role in shaping the velocity command appropriately when the target motion changes.

Another route for conveying motion signals for pursuit involves the pretectum. As described earlier, the pretectum plays a key role in the OKR, but in primates the pretectum receives inputs from areas of the cerebral cortex that are important for pursuit. Accordingly, some neurons in the primate pretectum have smaller receptive fields and respond well to the small moving stimuli typically used to elicit pursuit. The pretectum provides an input to the cerebellum through the basal pontine nuclei, but also projects directly to the vestibular nuclei and nucleus prepositus hypoglossi, offering a relatively direct route to the final motor pathways.

The brain stem control of pursuit also appears to involve some of the same neurons that are part of the saccadic burst generator. The EBNs and IBNs are not involved in forming the pursuit motor command, but some of the long-lead burst neurons in the brain stem reticular formation increase their tonic firing during pursuit, and show a build-up of activity before the onset of pursuit and saccades. Even more surprisingly, OPNs—the “gatekeepers” for saccades—are also modulated during pursuit. They do not completely pause their activity as they do during saccades, but decrease their activity by about one-third. Moreover, electrical stimulation applied to the OPNs slows down pursuit eye movements, in addition to stopping saccades (Missal and Keller, 2002). The function of this overlap between saccades and pursuit in these premotor circuits is not yet fully understood, but one possibility is that descending

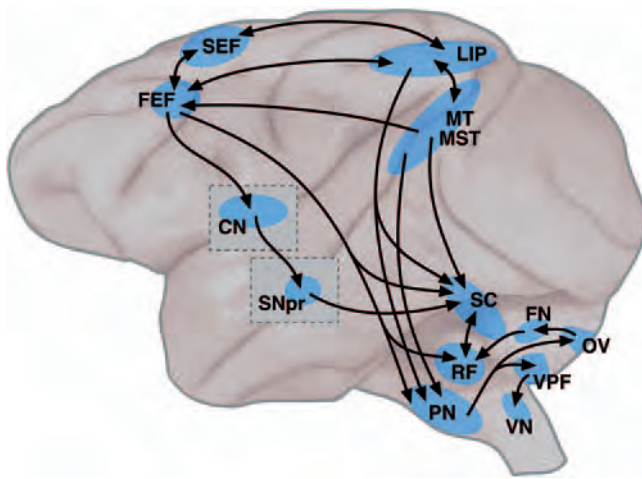

information about the target does not directly trigger saccades and pursuit, but instead a motor decision process at the level of the brain stem and cerebellum determines which type or combination of movements is most appropriate under the particular circumstances.

## GAZE SHIFTS ARE CONTROLLED BY THE MIDBRAIN AND FOREBRAIN

The motor commands for gaze shifts formed in the brain stem depend on control signals descending from higher centers, in particular, from the superior colliculus (SC) and several eye-movement related areas of the cerebral cortex (Fig. 33.9). These brain regions make it possible to bring the well-honed motor circuits in the brain stem under the control of higher-order processes such as attention, perception, and cognition.

### The Superior Colliculus Contains a Retinotopic Map for Controlling Gaze

The superior colliculus (SC) is a multilayered structure lying on the roof of the midbrain. In nonmammals, the homologous structure is called the optic tectum, which serves as the primary center for processing retinal inputs and for transforming sensory inputs into

**FIGURE 33.9** The descending pathways for controlling gaze shifts, depicted schematically on a lateral view of the monkey brain. The superior colliculus (SC), located on the roof of the midbrain, is a major source of descending control signals. In the cerebral cortex, the major areas involved are the frontal eye fields (FEF), supplementary eye fields (SEF), lateral intraparietal area (LIP), middle temporal area (MT), and medial superior temporal area (MST). In the basal ganglia, a cascade through the caudate nucleus (CN) and substantia nigra pars reticulata (SNpr) provides inhibitory control over activity in the superior colliculus. These descending control signals are then converted into motor commands by circuits involving regions such as the reticular formation (RF), pontine nuclei (PN), vestibular nuclei (VN), and parts of the cerebellum such as the ventral paraflocculus (VPF), oculomotor vermis (OV) and fastigial nucleus (FN).

commands for orienting movements. In mammals, the SC has a similar functional role, and consists of superficial layers that receive direct inputs from the retina and striate cortex, and intermediate and deep layers that receive inputs from extrastriate, parietal, and frontal cortex, and the basal ganglia. Neurons in the superficial layers have responses to visual stimuli that are enhanced when the stimulus is the target of a saccade. Neurons in the intermediate and deep layers may also respond to visual stimuli, and also to auditory stimuli from corresponding locations, so that the visual and auditory maps of the animal's surroundings are in register. It is these intermediate and deep layers that also possess the movement-related activity that plays a crucial role in the control of gaze shifts (Wurtz and Goldberg, 1972). These movement-related layers provide a major descending projection to the oculomotor nuclei in the brain stem reticular formation, and also a major ascending projection to the frontal cortex through the medial dorsal nucleus of the thalamus.

The most distinctive feature of the superior colliculus is that it contains a retinotopic map of contralateral visual space and this topography applies to the movement-related activity in the deeper layers as well as to the visual activity in the superficial layers (Fig. 33.10). The significance of this retinotopic map becomes evident when neural activity is artificially manipulated by passing small amounts of electrical current through the tip of an electrode placed in the intermediate layers (Robinson, 1972). Such stimulation elicits a saccadic eye movement with an amplitude and direction that depends on the placement of the electrode in the map. If the stimulation is applied as a long train, rather than as a brief pulse, a series of saccades is elicited, forming a "staircase" of eye movements, each with the same characteristic amplitude and direction. Thus, activity in the superior colliculus map is related to changes in eye position and not with absolute eye position, consistent with the organization of the superior colliculus in retinotopic (or oculocentric) coordinates.

During naturally occurring eye movements, activity in the superior colliculus is not restricted to just the few neurons that best match the endpoint of the saccade, but is distributed across a large number of neurons across the retinotopic map. This point was elegantly demonstrated by testing what happens to saccades when the injection of chemical agents into the superior colliculus temporarily inactivates neurons at a particular location in the map (Lee *et al.*, 1988). Remarkably, it is still possible to make saccades directed to the center of the inactivated region, because the broad distribution of activity across the map leaves a halo of neurons that can still accurately guide the saccade. Moreover, saccades directed to locations slightly beyond the inactivated site

**FIGURE 33.10** The superior colliculus and its retinotopic (or oculocentric) map of saccades and target positions. The left plot shows that electrical stimulation in the superior colliculus causes eye movements whose direction and amplitude depends on the location. Each arrow corresponds to a stimulation site in the left superior colliculus, and the length and direction of the arrow indicate the metrics of the evoked saccade. The evoked saccades are all directed rightward, but rostral sites are associated with smaller movements than caudal sites, and medial sites are associated with upward movements whereas lateral sites are associated with downward movements. The right plot summarizes these results in the form of a continuous map of saccades and target positions. As in the visual cortex, the representation of the center of the visual field is amplified. Adapted from Robinson (1972).

become hypermetric (bigger than normal), because the inactivation removes the contribution from neurons that code for more proximal locations and smaller saccades. These results show that saccades are guided by the vector average of population activity in the superior colliculus, and were the first demonstration of vector averaging in a mammalian motor system.

The intermediate layers of the superior colliculus contain two main classes of neurons related to the control of gaze (Munoz and Wurtz, 1995). Burst neurons in the superior colliculus fire a volley of action potentials that begins ~20ms before the onset of saccades, somewhat earlier than the burst neurons located downstream in the reticular formation, and often also have a visual response to the onset of visual targets. Unlike the burst neurons in the reticular formation, those in the superior colliculus fire for saccades directed to a portion of the visual field referred to as the neuron's movement field, and the size of the burst depends on where the target falls with respect to the neuron's movement field. Buildup neurons also have visual responses and saccade-related activity, but they are distinguished by the presence of sustained activity when the subject is required to delay eye movement response after the presentation of a visual stimulus. This sustained activity typically increases over time as the time of the saccade draws near, and is believed to be important for the preparation of saccades, perhaps by facilitating the occurrence of the saccade-related burst. Recent results show that the activity of neurons in these layers of the

superior colliculus not only is involved in motor preparation, but also is involved in the antecedent step of selecting the visual target, and may be part of the neural circuits that control visual attention.

In the part of the superior colliculus map that represents the central visual field, the neuronal activity is somewhat different. Like the rest of the map, this part also contains burst neurons that fire during saccades, although the preferred saccades are smaller, as would be expected. In place of buildup activity, however, there are neurons that show tonic activity during fixation and decrease their activity during most saccades (Munoz and Wurtz, 1993). Because of this fixation-related activity, and a prominent projection to the omnipause neurons, this region has been referred to as a fixation zone. However, these same neurons increase their activity during small contralateral saccades and are also modulated during pursuit eye movements, which, like fixation, also involve foveal target positions (Krauzlis *et al.*, 1997). Although the issue is not yet settled, this argues that these neurons do not provide a separate motor command for fixation, but instead represent the foveal region of a single target position map extending across the superior colliculus.

### The Frontal Eye Field Is the Primary Cortical Area for Controlling Gaze Shifts

The frontal eye field (FEF) exerts its control on gaze shifts through several descending pathways, including

a direct projection to the intermediate layers of the superior colliculus, an indirect projection to the superior colliculus via the basal ganglia, and also projections to the cerebellum and the brain stem reticular formation. The FEF is best known for its role in the generation of saccades, but it also contains zones that are involved in the control of pursuit and vergence eye movements. Like the superior colliculus, electrical stimulation of the FEF causes saccades to a particular location in the contralateral visual hemifield, although the topography in the FEF is less orderly than in the superior colliculus. Electrical stimulation of the pursuit zone of the FEF causes smooth eye movements toward the ipsilateral side, and is the only cortical area where stimulation can directly evoke smooth eye movements (Gottlieb *et al.*, 1993). Damage to the FEF produces deficits in saccades, and the impairments are most noticeable when the target stimulus is accompanied by irrelevant distracter stimuli. For pursuit, disruption of the FEF reduces pursuit eye velocity and, in particular, affects the ability of pursuit to follow targets using prediction. The impairments after FEF damage are usually temporary, but combined damage to the FEF and SC results in a permanent deficit in the ability to generate voluntary gaze shifts (Schiller *et al.*, 1980).

The FEF contains neurons with different combinations of motor and visual activity. Movement-related neurons have movement fields like those found in the superior colliculus—they are active for saccades within a particular range of directions and amplitudes. Movement-related neurons project to the superior colliculus and show changes in activity that are related with when and if voluntary gaze shifts will be initiated. In particular, the variability in the timing of saccade initiation is closely correlated with when the firing rates of these neurons reach a fairly constant “threshold” value (Hanes and Schall, 1996). Fixation neurons show the opposite pattern, decreasing their activity for saccades in all directions. In the pursuit zone of the FEF, neurons exhibit directionally selective responses to moving visual stimuli that are appropriate for determining the velocity command for pursuit eye movements.

Most neurons in the FEF also have visual responses, including a large class of visuo-movement neurons that show activity for both visual stimuli and the eye movements that follow. These visually responsive neurons often show activity related to the selection of the target. Prior to the gaze shift, the activity evoked by the non-selected stimulus is rapidly suppressed, whereas the activity for the selected stimulus remains conspicuous. Some FEF neurons discriminate visual targets even in the complete absence of an eye movement response, indicating that their activity is related to the allocation of visual attention rather than to the preparation of eye

movements. Indeed, stimulation within the FEF with currents too weak to directly cause eye movements can nonetheless enhance the visual responses of neurons located in other visual areas of cortex, and can improve the behavioral performance on visual discrimination tasks (Moore and Fallah, 2004).

Another region of frontal cortex, the supplementary eye field (SEF), plays a less direct role in the control of saccades but is important for movements that are guided by cognitive factors. Neurons in the SEF are preferentially modulated in tasks that involve more abstract instructions, such as when saccades are directed to a particular side of an object rather than to a spatial location, or when saccades are directed to the location opposite the visual stimulus (the “anti-saccade” task). During pursuit eye movements, SEF neurons are especially active when the target moves along a predictable trajectory.

### The Parietal Cortex Contributes to Eye Movements by Controlling Visual Attention

The lateral intraparietal area (LIP) plays a major role in the process of visual selection that precedes the generation of gaze shifts. Reversible inactivation of neurons in area LIP does not cause large deficits in the timing or accuracy of gaze shifts, but it dramatically reduces the frequency of movements toward the affected portions of the visual field, especially when competing stimuli are present elsewhere (Wardak *et al.*, 2002). These deficits suggest a visual neglect of stimuli in the affected region, rather than a motor deficit in the generation of eye movements. Damage to the parietal cortex in humans, especially to the right hemisphere, also produces a neglect syndrome with similar deficits in attention.

Neurons in LIP show activity related to visual attention and to the intention to make gaze shifts to particular locations in visual space. When an attention-grabbing, but irrelevant, distracter stimulus appears while the animal is preparing a saccade directed elsewhere, the activity of LIP neurons closely tracks the short-lived shift of attention to the distracter and its subsequent return to the intended location of the saccade (Bisley and Goldberg, 2003). Activity in LIP therefore often is described as a salience map that helps to determine the location of spatial attention, as well as the endpoint of gaze shifts.

### Motion-Processing Areas of Cortex Provide Crucial Signals for Pursuit Eye Movements

The middle temporal area (MT) and the medial superior temporal area (MST) are the primary sources of visual motion information that are used to construct the motor commands for pursuit. This motion information

also is used to adjust the size of saccades made to moving visual targets. These cortical areas provide these inputs through several pathways, including projections to other cortical areas involved in controlling gaze shifts (in particular, the FEF), descending projections to the vestibulocerebellum via the basal pontine nuclei, and projections to the pretectum, which contains neurons with activity related to the OKR and pursuit.

Neurons in MT and MST have activity related to the velocity of visual stimuli. In MT, neurons have smaller receptive fields and activity that depends on the presence of a visual stimulus. Lesions in MT produce blind spots for seeing motion that affect the motor commands for pursuit and saccades, and the perception of motion as well. In MST, neurons have larger receptive fields and prefer more complex patterns of visual motion. Lesions in MST also produce blind spots for motion, but in addition, cause a directional deficit in pursuit for movements directed to the ipsilateral side (Dürsteler and Wurtz, 1988). Stimulation of MT and MST can affect pursuit eye movements, but only if pursuit is already ongoing, unlike the effects of stimulation in the FEF. Thus, MT and MST are crucial sources of the motion signals needed to drive pursuit eye movements, but other areas appear necessary to determine when and if the movement should be started.

### **The Basal Ganglia Regulate Saccades by Inhibiting the Superior Colliculus**

The caudate nucleus (CN) and the substantia nigra pars reticulata (SNpr) are parts of the basal ganglia that form an important circuit for controlling when gaze shifts are initiated. The SNpr applies tonic inhibition to the superior colliculus using GABA-ergic synapses, suppressing the response to the many excitatory inputs to the superior colliculus that might otherwise evoke gaze shifts. When SNpr neurons reduce or pause their activity, there is a disinhibition of activity in the superior colliculus, which then permits gaze shifts to be initiated. The SNpr itself is under inhibitory control from the CN, which contains neurons that increase their activity with gaze shifts. Together, this series of inhibitory connections through the basal ganglia act to gate the generation of gaze shifts by the superior colliculus.

The basal ganglia appear to be especially important for gaze shifts involving reward and motivation. For example, the visual responses of CN neurons is larger for stimuli that are associated with larger rewards (Lauwereyns *et al.*, 2002). This modulation in excitability may be caused by dopaminergic inputs from neurons in the substantia nigra pars compacta (SNpc), the same neurons whose degeneration is implicated in Parkinson's disease.

### **The Thalamus Provides Feedback about the Control of Gaze Shifts**

In addition to these descending pathways, there are also ascending pathways to eye movement-related areas of cortex from nuclei in the central thalamus. These nuclei receive inputs from a wide range of oculomotor structures, including the superior colliculus, substantia nigra pars reticulata, cerebellum, the nucleus prepositus hypoglossi, and the brain stem reticular formation. Feedback through the thalamus appears to convey corollary discharge signals about the gaze shifts that are executed by downstream motor structures, and is used to update the control signals formed in the cortex. Thus, when the central thalamus is inactivated by chemical agents, single saccades can still be made accurately, even in the dark, but subsequent saccades are spatially inaccurate, as though the intervening movement had not been taken into account (Sommer and Wurtz, 2002).

### **THE CONTROL OF GAZE SHIFTS INVOLVES HIGHER-ORDER PROCESSES**

#### **Saccades and Pursuit Are Coordinated during Gaze Shifts**

The functions of saccades and pursuit are distinct, and yet during normal gaze shifts the two types of movements are tightly coordinated and almost always select the same visual target. How is this coordination achieved? One possibility is that target selection for pursuit is determined by the generation of saccades. When subjects are presented with two moving stimuli simultaneously, they almost always begin smooth pursuit in a direction that is the average of the two motions. After a brief period of this "vector average" pursuit, subjects make a saccade toward one stimulus or the other and then pursue that one selectively. These observations suggest that pursuit target selection is serially linked to saccade execution (Gardner and Lisberger, 2002). On the other hand, pursuit can selectively follow one stimulus in the presence of distracters without a targeting saccade, showing that saccades are not strictly necessary for pursuit target selection.

Another possibility is that targets are selected in common for pursuit and saccades. Pursuit typically starts earlier than saccades, and the stimulus selected by pursuit usually predicts the target of the saccade choice by ~50 ms. This suggests that the two choices are guided by the same decision signals, but saccades might use a somewhat more stringent decision criterion. Consistent with this view, pursuit and saccades exhibit nearly the same tradeoff between speed and

accuracy, but saccades tend to be delayed and somewhat more accurate (Liston and Krauzlis, 2005). The exact mechanism for this putative shared decision process is not yet known, but one possibility is that it is related to visual attention.

### Voluntary Gaze Shifts Are Tightly Linked to Shifts of Visual Attention

A crucial aspect of voluntary gaze shifts is that they are selectively guided by objects of interest to the observer, despite the fact that our surroundings usually contain many other distracting signals. This selectivity is achieved by a tight functional link between the control of gaze shifts and the mechanisms of visual attention. When gaze shifts, the movement of the eyes always is preceded by a shift of visual attention to the new location. For example, when subjects are asked to detect visual targets that appear just before a saccade is made, performance is much better when the target and saccade locations coincide than when they do not (Deubel and Schneider, 1996). Similarly during pursuit, subjects make more accurate perceptual judgments about the stimulus they are smoothly tracking with their eyes than about other, nontracked stimuli in the visual display. However, judgments about nontracked stimuli are still better than chance, showing that the selection of targets for gaze shifts can occur in parallel with the perceptual processing of other visual stimuli. Also, although gaze shifts typically require visual attention, the converse is not true—visual attention can shift to new locations in the absence of gaze shifts; these are referred to as covert shifts of attention.

The tight linkage between visual attention and the planning of eye movements provides support for the premotor theory of attention, which posits that the mechanisms for spatial attention and eye motor programming are essentially the same. The theory is controversial, because the degree of overlap between attention and eye movements depends on which level of brain organization is considered relevant. As described in the previous section, there is substantial overlap between the areas of the brain involved in the control of attention and eye movements, consistent with the theory. On the other hand, the activity of single neurons in these areas can often be attributed to either visual attention or motor planning, but not both. Resolving these issues will require understanding how the properties of individual neurons are brought together into the larger functional circuits that span brain areas.

### Visual Perception and Cognition Contribute to the Control of Gaze Shifts

Much of what we know about the neural control of gaze shifts was learned using very simple visual, often small bright spots in an otherwise dark room. These studies made it possible to test and identify the basic feedback mechanisms and motor circuits that control gaze shifts. However, it is now generally recognized that under more natural conditions, eye movements show properties that are more complex and flexible. One striking set of examples is provided by the work of Yarbus (Yarbus, 1967), who showed that the pattern of saccades made while looking at a visual scene depends heavily on the instructions given to the observer (Fig. 33.11). These results illustrate that gaze shifts are normally not just reactions to retinal events, but instead are guided by longer-term goals and serve to collect relevant visual information from the environment.

Gaze shifts also reveal properties of the visual processing steps required to segment and interpret the visual scene. In one demonstration, a few lights are attached to the rim of a wagon wheel, which is then rolled along in an otherwise dark display. Although the retinal stimulus consists of several spots, each undergoing cycloidal motion, subjects perceive the horizontal motion of the wheel and are able to easily track this motion with their eyes (Steinbach, 1976). More recent studies have examined how these processes evolve over time. For many moving objects, the true trajectory of the object cannot be calculated locally in the retinal image, but requires integrating information over regions of visual space. This integration evidently takes some time (for example, ~100 ms), and the transition from local-motion signals to object-motion signals can be found in both the eye motor output and perceptual judgments.

Visual perception also is changed by eye movements. In particular, the world is not perceived as moving during saccadic eye movements, despite the rapid motion of the retinal image. You can demonstrate this to yourself by watching yourself make saccades in a mirror—you can see that your eyes change position, but you cannot see them actually move. This phenomenon is referred to as saccadic suppression, and it refers to the observation that the ability to detect visual stimuli is reduced dramatically during saccadic eye movements, especially for visual stimuli with low spatial frequencies (Burr *et al.*, 1994). The mechanism of saccadic suppression is not fully understood, but its effect is to help the visual system reduce its sensitivity to the unreliable visual signals that occur during gaze shifts.

**FIGURE 33.11** The scan path depends on the goals of the observer. Among other experiments, Yarbus (1967) monitored the eye movements of subjects as they viewed Repin's painting "An Unexpected Visitor" and found that the pattern of eye movements depended on the task. When subjects were instructed to give the ages of the people, the scan path mostly settled on the faces, whereas when subjects were instructed to surmise what the family had been doing, the scan path included many more objects in the room. Adapted from Figure 109 of Yarbus (1967) with kind permission of Springer Science and Business Media.

## THE CONTROL OF EYE MOVEMENTS CHANGES OVER TIME

### Different Eye Movements Develop over Different Timescales

Studying the development of eye movements is especially challenging, because infants are not always cooperative subjects, and the observed changes in eye movements are due to developmental changes that occur at sensory as well as motor stages of processing. Nonetheless, in humans, all eye movements appear to be different in infants than they are in adults, and the development of eye movements that stabilize gaze (e.g., VOR and OKR) follow a faster time course than those that act to shift gaze (e.g., saccades and pursuit).

Human infants are born with an excellent VOR. In fact, the gain of the VOR (the ratio of eye velocity to head velocity) in infants is approximately 1, which is better than that typically found in adults. The temporal dynamics of the VOR are somewhat different at birth, possibly reflecting an immature neural integrator, but these achieve near-adult values within the first six months of life. The strong VOR at birth compensates for the fact that the OKR is not fully developed until age 5–6 months. The OKR in infants is symmetric for rightward and leftward motion, but only when viewed binocularly (i.e., with both eyes). With monocular

viewing, the amplitude of the OKR is markedly larger for horizontal motion directed toward the nose than for motion directed away from the nose. This directional asymmetry is like that found in the adult OKR of "lower" mammals such as the rabbit, and in cats that have been reared with disrupted visual inputs from one eye. The asymmetry in infants is believed to be due to the delayed maturation of the cortical inputs to the visual nuclei in the brain stem, which confer binocularity and other visual properties to the neurons in the pretectum important for generating the OKR.

As might be expected given the relative immaturity of the visual system at birth, saccades and pursuit take many months to approach adult-like characteristics. Newborns can generate saccades in response to a visual target, but the latencies are long and the movements fall well short of the target. In fact, 1-month old infants typically acquire the target by making a series of three to five saccades, each of which is approximately the same size and which scales with the initial eccentricity of the visual target. Over time during the first year, the number of sequential saccades decreases and their amplitude increases. Similarly, newborns have a limited ability to generate pursuit eye movements, and the responses are better for larger stimuli that likely also activate the OKR. The gain of pursuit to small target spots is very low (0.5 or less) in the first few postnatal months, and saccades often are used to

keep up with the target. Interestingly, the pursuit velocity generated at these young ages is not only low, but does not scale with the velocity of the visual target, presumably due to the delayed maturation of the cortical circuits involved in motion processing. The ability to match target speed improves markedly by the end of the first year, as does the ability to use prediction to guided pursuit. However, for both saccades and pursuit, the exact age at which the movements become adult-like is difficult to determine.

### Eye Movements Continuously Undergo Plastic Changes

Even in adulthood, the circuits for controlling gaze movements are continually adjusted to compensate for changes in the motor output and the sensory inputs. As many of us have experienced after getting a new pair of eye glasses, which changes the VOR output needed to stabilize the visual world, the inaccuracies in the programming of eye movements usually are corrected automatically and fairly rapidly. This type of adaptive control is especially important for rapid movements like the VOR and saccades, because the movements occur too rapidly to be corrected mid-flight by visual feedback.

For saccades, the adaptation is guided by visual signals about whether the eyes have landed on the target. This feedback is used by structures such as the oculomotor vermis in the cerebellum to adjust the “pulse” component of the command for saccades. Saccadic adaptation also depends on visual signals about whether the eye stays on target after the saccade or drifts off. This visual motion feedback is used by the vestibulocerebellum to adjust the size of the “step” component of the saccade command. Adaptive changes in saccades also tend to be spatially specific rather than parametric—the changes affect a limited range of saccade amplitudes and directions near the adapted saccade, rather than simply scaling all saccades. This property illustrates the great flexibility and precision of the output motor pathways in fine-tuning the control of saccades.

Adaptive changes to the VOR have been extensively studied and provide a general model for understanding the neural basis of motor learning. It is well established that the vestibulocerebellum plays a fundamental role in motor learning for the VOR, but the exact role of the cerebellum remains controversial. Early studies emphasized the role of the cerebellar cortex as the principal site of learning. Theories put forward by Marr and Albus, and elaborated by Ito, drew attention to the crystalline structure of the cerebellar cortex and highlighted the synaptic interactions that might take place on the output neurons from the cerebellar cortex, the Purkinje cells. In particular, they proposed that climbing fiber inputs to

the cerebellar cortex provide visual “error signals” that modify the strength of parallel fiber synapses providing vestibular information to Purkinje cells. Subsequent studies have supported this proposal by showing that paired stimulation of the climbing fibers and parallel fibers induces a long-term depression (LTD) of the parallel fiber synapse. However, other studies have shown that although the cerebellum is critical for VOR adaptation, it could be removed after the adaptation was complete without changing the state of the VOR. This led later researchers to propose that the cerebellum does not store the motor memory needed for VOR plasticity but instead computes an instructive signal that induces changes elsewhere, such as in the vestibular nuclei that receive the cerebellar output. These careful studies of the VOR circuit have made it possible now to begin probing the cellular and molecular mechanisms that underlie this basic form of learning.

---

## CONCLUSIONS

---

Eye movements serve two different functions. First, eye movements stabilize gaze when animals move about in their environment. Unpredictable high-speed rotations of the head, which are produced whenever an animal moves, shift the line of gaze and, by smearing the optical image, reduce the resolution of the visual system. These high-velocity movements are compensated for by counter-rotations of the eyes generated by the VOR. Working in tandem with the VOR is the optokinetic system. The optokinetic system compensates for the slower movements of the head, which happen so gradually that the vestibular system cannot accurately detect them. Second, in animals with retinas that have a small region of high resolution, eye movements shift gaze to redirect the line of sight to objects or features in the visual scene that are of particular interest. Saccades are fast, discrete movements that quickly move the image of a visual target to the center of the retina where acuity is best. Pursuit is a slow, continuous movement that compensates for the motion of the visual target, minimizing the blurring that would otherwise limit acuity. Although the properties of saccades and pursuit are distinct, the two types of movements are closely coordinated during visual search of the environment and both are tightly linked to visual attention. Together, the different types of eye movements make it possible to efficiently gather the visual information that is important for achieving other, longer-term behavioral goals.

Eye movements are controlled by circuits that span the brain. The eyes themselves are a relatively simple motor apparatus, and they are controlled by a final

motor pathway in the brain stem that is shared by all classes of eye movements. The construction of the motor commands involves generating an eye velocity command to move the eyes, and an integrated version of this command to hold the eyes at their new position. These motor commands are constructed by circuits in the brain stem reticular formation, and fine-tuned by additional circuits involving several parts of the cerebellum. The descending control signals that drive these motor commands are provided by multiple brain regions, but the superior colliculus in the midbrain and the frontal eye fields in the cortex are especially important. These brain regions help integrate sensory inputs with a variety of higher-order influences so that eye movements are directed to the appropriate visual stimuli.

Overall, eye movements provide a window into the brain mechanisms that accomplish motor control, but also the mechanisms of neural plasticity, sensory-motor interactions, and higher-order process like attention and perception.

# The Hypothalamus: An Overview of Regulatory Systems

The hypothalamus is an integrative center essential for survival of an organism and reproduction of its species. Regulatory systems emerged as each organism adapted to its environment and have evolved to control the complex interactions of physiology and behavior.

The diversity in regulatory function of the hypothalamus is reflected in its structure, neurochemistry, and connections. Almost every major subdivision of the central nervous system (CNS) communicates with the hypothalamus and is subject to its influence. In addition, the hypothalamus communicates with peripheral organ systems by converting synaptic information to blood-borne hormonal signals. In turn, the hypothalamus responds to feedback from the peripheral systems that it regulates. The chapters in this section discuss the processes by which the hypothalamus influences physiology and behavior, and the purpose of this chapter is to provide an introductory context for those presentations. We begin by providing a historical perspective on research that has defined the hypothalamus as an important regulatory center, continue with an overview of its structural and functional organization, and conclude with a discussion of how this region of the diencephalon functions within brain circuitry devoted to the control of motivated behaviors.

## HISTORICAL PERSPECTIVE

Research on the hypothalamus has a rich and storied history. Although depicted in early brain atlases, the hypothalamus was not recognized as a distinct divi-

sion of the diencephalon until the work of Wilhelm His (1893). Our understanding of the structure and function of the hypothalamus developed as basic and clinical neurosciences were integrated. Harvey Cushing, a neurosurgeon who studied endocrine disorders from a neuroscience perspective provided important and influential early insights into hypothalamic function. He described diabetes insipidus, a neuroendocrine dysfunction of uncontrolled urinary water excretion and thirst, and identified the importance of injury to the pituitary stalk in the condition. Cushing also described the syndrome that bears his name, Cushing's syndrome, a disorder characterized by excessive secretion of adrenal corticoids, and he was among the first to recognize that the hypothalamus and pituitary form a functional unit. He was a pioneer in the development of pituitary surgery and is viewed as a founder of the fields of neurosurgery and endocrinology. In 1929, summing up his work in this area shortly before his retirement, Cushing wrote of the hypothalamus, "*Here in this well concealed spot, almost to be covered with a thumb nail, lies the very mainspring of primitive existence—vegetative, emotional, reproductive—on which, with more or less success, man has come to superimpose a cortex of inhibitions.*"

Gurdjian (1927), Kreig (1932), and Le Gros Clark *et al.* (1938) build upon the clinical observations of Cushing and others, using histological procedures to describe the cytoarchitecture of hypothalamic nuclei. Their observations proved to be remarkably predictive of functional specializations revealed by the work of Ranson, Hess, and others during the same period. These investigators demonstrated that lesions and localized stimulation of the hypothalamus could selectively affect appetite, weight control, water balance,

autonomic control, reproductive function, and emotional behavior. This work progressed so well that in 1940 it could be summarized only in a large volume of the annual series of the "Association for Research in Nervous and Mental Disease." In that volume, Ernst and Berta Scharrer (1940) presented evidence for "neurosecretory neurons," providing the foundation for a fundamental tenet of hypothalamic function. That is, there are neurons—in the brain—that secrete hormones directly into the bloodstream. In 1949, Wolfgang Bargmann published his studies documenting neurosecretory neurons with cell bodies in the hypothalamus and axons projecting to the posterior lobe of the pituitary gland. Bargmann's work provided a framework for our current understanding of neuroendocrine regulation, that is, that release of peptides into the peripheral circulation allows the hypothalamus to exert a profound influence on the physiology of peripheral organs.

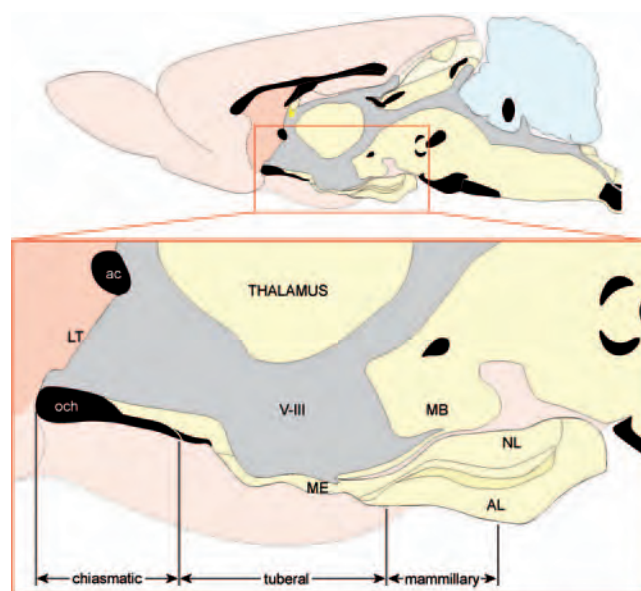

In the 1950s Harris and Green defined the means through which the hypothalamus regulates the anterior lobe of the pituitary. Their identification of a neurovascular link, the portal plexus, through which the hypothalamus regulates the anterior pituitary, fundamentally altered concepts of hypothalamic function and neuroendocrine regulation. The neurochemical basis of anterior pituitary regulation was revealed in the 1970s when Guillemin and Schally independently isolated and characterized peptide hormones that acted on the anterior pituitary. In subsequent years the field of neuroendocrinology built enormously on these observations, and the resulting literature documents a diverse family of hypothalamic peptides that are transported through the portal plexus to stimulate or inhibit the release of other hormones from the anterior lobe of the pituitary gland.

We have made great progress in improving our understanding of Cushing's "mainspring of primitive existence." Tremendous insights into CNS function have emerged from the analysis of hypothalamic structure and function, underscoring the importance of this small, complex region of the diencephalon in the regulation of homeostasis and behavioral functions essential for survival.

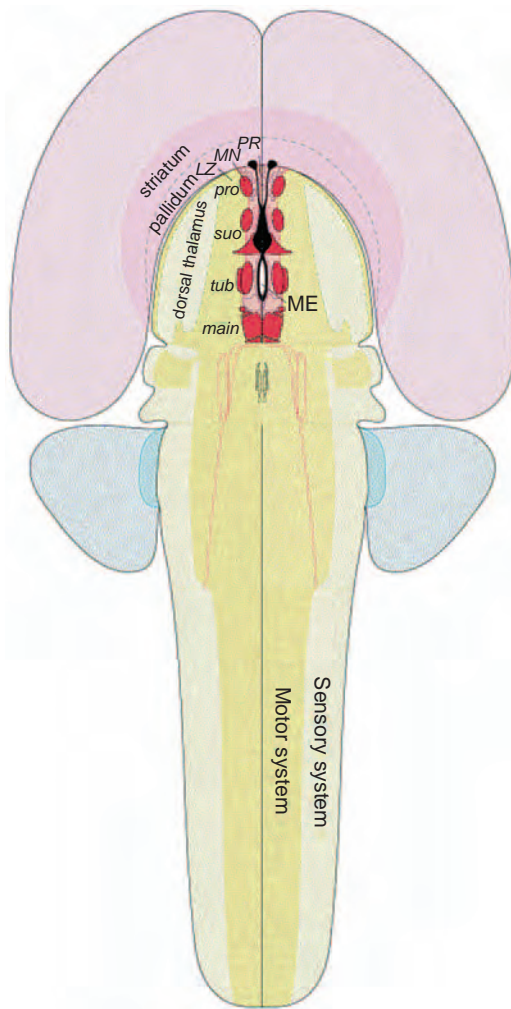

### HYPOTHALAMIC CYTOARCHITECTURE

Early studies of hypothalamic organization defined subdivisions that were largely based upon landmarks visible on the ventral surface of the brain. On this basis, three major subdivisions were defined based upon

their associations with the optic chiasm (chiasmatic), the tuberal eminence containing the pituitary stalk (tuberal), and the mammillary bodies (mammillary) (Fig. 34.1). Contemporary research indicates that the hypothalamus is organized into three longitudinal columns on either side of the third ventricle (Fig. 34.2). These columns are largely consistent with the initial descriptions of Gurdjian (1927) and Krieg (1932) and consist of *periventricular*, *medial*, and *lateral* zones that extend through the entire rostrocaudal extent of the hypothalamus. The periventricular zone, as the name implies, lies adjacent to the ependymal lining of the third ventricle. Its constituent neurons are densely packed within a narrow zone adjacent to the ependyma and occasionally expand into cytoarchitecturally distinct nuclear groups such as the suprachiasmatic

**FIGURE 34.1** Boundaries of the rat hypothalamus viewed in midsagittal section. The ventricular system is shaded gray. The boxed area shows the approximate location of the hypothalamus in the ventral quadrant of the diencephalon, below the thalamus. The floor of the third ventricle (V-III), formed by the optic chiasm (och), median eminence (ME), and rostral portion of the mammillary body (MB), defines a large portion of the rostrocaudal extent of the hypothalamus. These landmarks also define the major subdivisions (chiasmatic, tuberal, and mammillary) classically used to subdivide the hypothalamus. The tuberal hypothalamus is distinguished by the infundibular stalk, which connects the ventral diencephalon to the pituitary. The rostral limit of the hypothalamus is the lamina terminalis (LT), a thin strip of tissue extending between the optic chiasm and anterior commissure (ac) that also forms the rostral wall of the third ventricle. NL, neural lobe of posterior pituitary; AL, anterior lobe of pituitary.

**FIGURE 34.2** The columnar organization of hypothalamic cell groups is illustrated on a flat map of the rat central nervous system. Three longitudinal zones form columns that extend through the rostrocaudal extent of the hypothalamus. The periventricular region (PR; light red) lies immediately adjacent to the third ventricle and contains cell groups responsible for neuroendocrine control of the pituitary gland (black). The medial nuclei consist of cytoarchitecturally distinct cell groups (dark red) between the periventricular and lateral zones. The diffusely organized but phenotypically distinct neurons of the lateral zone (LZ) are shown in yellow. Contemporary research also recognizes four transverse subdivisions of hypothalamus (pro, preoptic; supraoptic or anterior, SUO; tuberal, tub; mammillary, mam). Reprinted with permission from Swanson (2000).

and arcuate nuclei. The medial zone lies adjacent to the periventricular zone and contains cell groups that vary in size and cell morphology, but are organized into cytoarchitecturally distinct nuclei. This contrasts with the diffusely distributed neurons of the lateral zone, which is the least distinct of the three columns. Neurons in all three regions have been further subdivided on

the basis of cellular phenotype, connectivity, and cellular markers of cellular activation that allow investigators to impose functional definitions.

## FUNCTIONAL ORGANIZATION OF THE HYPOTHALAMUS

To effectively integrate diverse physiological processes and behaviors, the hypothalamus must communicate with systems in both the brain and periphery. More than any other region of the nervous system, the hypothalamus depends on conversion of synaptic information to hormonal signals. In addition, the hypothalamus is subject to feedback regulation by the physiological processes that it controls. The following sections describe basic organization principles that govern hypothalamic function.

### Integrative Processing in the Hypothalamus

Projections from all major subdivisions of the nervous system terminate within the hypothalamus. In many instances, such as vision, monosynaptic projections bring first-order sensory information from the periphery directly to hypothalamic nuclei. In other cases, such as limbic projections, multisynaptic cerebral pathways relay processed information to the hypothalamus. Integration of this sensory information is an essential function of the hypothalamus and has profound influence on the regulatory outputs of hypothalamic nuclei. These diverse systems are best understood by looking at the functions that they modulate.

### Olfaction

Multisynaptic pathways allow the olfactory system to influence neurons in many parts of the hypothalamus. Olfactory information passes directly to the olfactory tubercle, piriform cortex, and amygdala, which in turn relay it to the hypothalamus through the medial forebrain bundle (corticohypothalamic projections), stria terminalis, ventral amygdalofugal pathway, and fornix. In many vertebrates, olfaction is integral to behaviors involved in reproduction, defense, and feeding, and this is reflected in the large amount of forebrain dedicated to the processing of olfactory stimuli. Insight into the complexity of these circuits is apparent in recent rodent studies employing transneuronal tracing technology to define polysynaptic olfactory circuits that innervate hypothalamic neurons involved in the regulation of reproduction and fertility (Boehm *et al.*, 2005; Yoon *et al.*, 2005). These and other

findings illustrate the importance of hypothalamic integration of olfactory information in functions essential to reproduction and survival.

### Visual Projections

A principal function of the hypothalamus is to impose temporal organization on hormonal and behavioral processes through the timekeeping properties of the biological clock in the rostral hypothalamus. The neurons that constitute this clock are found within the suprachiasmatic nuclei (SCN). The genetically determined circadian rhythmicity of SCN neurons provides a timekeeping capacity that is essential to successful adaptation to the environment and, in many instances, reproduction of organisms. Importantly, the rhythmic activity of the biological clock is responsive to environmental cues, which is accomplished through central visual projections of the retina. A unique population of ganglion cells that contain light sensitive melatonin transduces light in the retina. The central projections of these ganglion cells through the retino-hypothalamic projection synchronize the circadian activity of SCN neurons with the daily cycle of light and dark. Polysynaptic connections from the clock that influence melatonin secretion from the pineal gland also provide a feedback mechanism for measuring day length that is important for the timing of reproduction in photoperiodic species. The responsiveness of this regulatory system to variations in photoperiod is also responsible for the “jet lag” that humans suffer when traveling across time zones.

Surprisingly, the neural projections of the SCN are largely confined to the hypothalamus. Therefore, the SCN is dependent upon relays that integrate a variety of sensory information important for the temporal organization of diverse functions regulated by the hypothalamus. A more detailed description of this “circadian timing system” is presented in Chapter 41.

### Visceral Sensation

Sensory information also reaches the hypothalamus through ascending projections arising from neurons in the nucleus of the solitary tract (NTS) of the caudal brain stem. The NTS is the principal visceral sensory nucleus that receives topographically organized input from the major organ systems of the body by way of cranial nerves X and IX, the vagus and glossopharyngeal nerves. As such, it is the first region in the CNS to process information about visceral, cardiovascular, and respiratory functions, as well as taste. The NTS coordinates reflex modulation of peripheral organ function and sends processed sensory information

to forebrain nuclei, where it is integrated in the control of more complex physiological processes and behaviors.

Neurons in the paraventricular hypothalamic nucleus (PVH) and the lateral hypothalamic area (LHA) are prominent among a subset of hypothalamic nuclei that receive direct projections from the NTS and indirect projections reach the hypothalamus through the ventrolateral medulla and parabrachial nucleus in the pons. Many of these projections are bidirectional and are part of a larger system that includes the central nucleus of the amygdala, bed nuclei of the stria terminalis, and insular cortex. In addition, the NTS and parabrachial nuclei relay splanchnic visceral and nociceptive sensory information from the spinal cord. This “interoceptive” sensory feedback has an important influence upon autonomic and endocrine outputs of the hypothalamus essential for regulation of homeostasis, and recent evidence suggests that it also influences mood. Evidence for the latter is particularly prevalent in literature examining sensory integration related to stress induced activation of the endocrine and autonomic axes.

### Multimodal Brainstem Afferents

The medial forebrain bundle (mfb) is a group of thin fibers that traverse the lateral zone of the hypothalamus. This bidirectional fiber tract provides extrinsic inputs to a number of hypothalamic nuclei and is used as a conduit for hypothalamic neurons to communicate with other regions of the neuraxis. Early nonspecific stimulation and lesion experiments incorrectly attributed certain functions to the lateral hypothalamus that actually are associated with axons passing through the mfb to other regions of the brain.

Monoaminergic axons arising from neurons in the midbrain and medulla are a major constituent of this fiber tract. They include axons from noradrenergic neurons in the locus coeruleus and lateral tegmental cell groups, as well as serotonergic neurons of the brain stem raphe nuclei. Many of these axons generate collaterals that terminate throughout the hypothalamus as they course rostrally to innervate other forebrain regions. Serotonergic neurons in the midbrain raphe nuclei also generate a dense plexus of axons that enter the cerebral ventricles and arborize on the luminal surface of the ependyma. The precise function of this intraventricular plexus is not known.

A number of systems not functionally associated with the hypothalamus also pass through the mfb. Prominent among these are dopaminergic axons arising from the substantia nigra and ventral tegmental area (VTA). The nigral component of this projection

plays an important role in the regulation of movement whereas the VTA exerts a widespread influence on the cortex as well as ventral striatal regions involved in motivated behaviors and addiction. These projection systems are distinct from the dopaminergic neurons in the hypothalamus (e.g., arcuate nuclei), which play an important role in neuroendocrine regulation.

### Projections from Limbic Regions

In the 1930s, James Papez (1937) suggested that components of “limbic circuitry” form part of a multi-synaptic pathway, classically known as Papez’s circuit, responsible for the expression of emotion. Although this function has not been confirmed, contemporary studies have demonstrated that both the hippocampus

and amygdala give rise to extensive topographically organized projections to the hypothalamus. Prominent among the observations that have forged this vision are studies demonstrating that the fornix influences the activity of the hypothalamus through both direct and indirect pathways. The direct path is a prominent component of Papez’s original circuit in that it is composed of axons that arise from neurons in the subicular complex of the hippocampal formation and terminate in the mammillary bodies. The indirect, or “precommissural,” fornix influences the hypothalamus through a synaptic relay in the septum.

Risold and Swanson (1996) demonstrated that the precommissural projection arises from the hippocampus proper, is organized topographically, and terminates densely within the hypothalamus (Fig. 34.3). The

**FIGURE 34.3** The organization of pathways that bring hippocampal input to hypothalamic columns is illustrated. The hippocampal formation projects topographically upon the lateral subdivision of the septum which, in turn, projects topographically upon the periventricular (red), medial (blue), and lateral (green) zones of the hypothalamus. Subfields of the hippocampal formation (CA1, CA3, subiculum) are represented on the flat map of the unfolded hippocampus in the upper right. The topography of the projection systems is coded in the colors, numbers (1, 2, 3, 4), and small letters (a, b, c) included in the maps of hippocampus, septum, and hypothalamus. ACB, nucleus accumbens; AHN, anterior hypothalamic nucleus; ARH, arcuate nucleus; AVPV, anteroventral periventricular nucleus; BST, bed nucleus of stria terminalis; DMH, dorsomedial nucleus; ENK, enkephalin; fi, fimbria of fornix; fx, fornix; GLU, glutamate; LS, lateral septum (small letters designate rostral, caudal, and ventral subdivisions); MB, mammillary body; ME, median eminence; mfb, medial forebrain bundle; MPN, medial preoptic nucleus; MS, medial septum; NDB, nucleus of the diagonal band; PVH, paraventricular nucleus; SH, septohippocampal nucleus; SS, somatostatin; SUM, supramammillary nucleus; VL, lateral ventricle; VMH, ventromedial nucleus. Reprinted with permission from Risold and Swanson (1996).

topography of this projection is apparent at its origin in the hippocampus and is preserved in the lateral septal nuclei and in the hypothalamus where second order projections innervate the three longitudinally organized columns of the hypothalamus, although not equally. Thus, this projection system is in a position to regulate neuroendocrine and autonomic function and ingestive behavior (periventricular zone), modulate motivated reproductive and agonistic behaviors (rostral medial zone), and also provide polysynaptic feedback projections to the hippocampus via the mammillary complex. The demonstration of “place” and “head-direction” cells in the hippocampal formation suggests that this projection is the source of adaptive multimodal sensory information relevant to a variety of hypothalamic functions (e.g., foraging).

Limbic projections arising from the amygdala also have a prominent influence on hypothalamic function through two projection pathways. The stria terminalis arises from neurons in the amygdala and follows a looping trajectory similar to the course of the fornix. Axons coursing through this pathway ramify within the bed nucleus and then enter the hypothalamus rostrally. Amygdala neurons also innervate the hypothalamus via the ventral amygdalofugal bundle, which passes directly over the optic tract to the hypothalamus. The demonstrated role of the amygdaloid complex in the expression of fear suggests that these projections play an important role in orchestrating the endocrine and autonomic components of the fear response.

### Circumventricular Organs

Not all sensory information reaching the hypothalamus is of synaptic origin. Some regions of the CNS are chemosensitive to blood-borne molecules. Such information about body fluid composition has important implications for the maintenance of homeostasis. Circumventricular organs (CVOs) are integral to this regulation. Seven CVOs surround the ventricular system in the diencephalon, midbrain, and hindbrain (Fig. 34.4). These include the subfornical organ (SFO), the vascular organ of the lamina terminalis (OVLT), the median eminence (ME), the pituitary gland (PG), the pineal gland (P), the subcommissural organ (SCO), and the area postrema (AP) (Fig. 34.3). Three of these regions, the OVLT, ME, and PG, are components of the hypothalamus. Two others, the SFO and AP, have extensive connections with hypothalamic nuclei involved in neuroendocrine and homeostatic function. Paul Ehrlich identified these regions in the late 1800s when he noted that they selectively accumulated vital dyes injected into the peripheral vasculature. Later

studies demonstrated that the dye accumulated due to fenestrations in the capillaries in these regions that permitted relatively large molecules to leave the vascular lumen and enter the extracellular milieu. As a result, CVO neurons are accessible to blood-borne molecules that cannot enter other regions of the brain. The absence of a blood–brain barrier also allows CVOs to influence peripheral function through the release of bioactive molecules. Thus, CVOs represent important “windows” through which the brain controls peripheral function and, importantly, that render CNS neurons responsive to feedback regulation by the secretory products of the target organs that they modulate. This type of architecture is fundamental to the way in which the hypothalamus achieves tightly regulated control over the pituitary and, by extension, its peripheral targets.

## EFFECTOR SYSTEMS OF THE HYPOTHALAMUS ARE HORMONAL AND SYNAPTIC

The extensive influence of the hypothalamus on behavior and physiology is reflected in its effector systems. The hypothalamus has conventional synaptic connections with essentially every major subdivision of the CNS and plays a major role in the control of behavioral state. As noted earlier, it also has regulatory control over the pituitary gland and thereby exerts a profound influence over peripheral physiology. Thus, the output of hypothalamic systems is integral to the integrated expression of physiology and behavior.

### Behavioral State Control

Regulation of the sleep–wake cycle is a distributed process that involves the integrated action of the reticular activating system and the diencephalon. Early studies employing lesions and knife cuts conducted by Moruzzi, Magoun, and Bremer demonstrated the importance of the brain stem reticular activating system in the generation of consciousness. Subsequently, Nauta postulated the existence of sleep centers in the hypothalamus based upon the consequences of lesions to the rostral or caudal hypothalamus. In those rodent studies, he demonstrated that lesions of the preoptic region produced insomnia and that somnolence resulted from lesions of the caudal hypothalamus.

Until recently, little was known regarding the specific hypothalamic cell groups involved in sleep regulation. However, identification of the circadian

**FIGURE 34.4** The location of the seven circumventricular organs (shown in red) in the rat brain (midsagittal section) are illustrated. Three CVOs that have an intimate functional association with the hypothalamus are illustrated in transverse sections in the lower figures. AP, area postrema; ARH, arcuate nucleus; cc, corpus callosum; CU, cuneate nucleus; df, dorsal fornix; DMHa, anterior portion of the dorsomedial nucleus; DMHp, posterior portion of dorsomedial nucleus; DMHv, ventral portion of dorsomedial nucleus; DMX, dorsal motor vagal nucleus; GR, gracile nucleus; ME, median eminence; mlf, medial longitudinal fasciculus; co, commissural portion of the nucleus of the solitary tract; NTSi, lateral portion of the nucleus of the solitary tract; NTSm, medial portion of the nucleus of the solitary tract; OVL, vascular organ of the lamina terminalis; PH, posterior hypothalamus; P, pineal gland; PMR, paramedian reticular nucleus; PVi, intermediate part of periventricular nucleus; SCO, subcommissural organ; SF, septofimbrial nucleus; SFO, subfornical organ; ts, tractus solitarius; V-III, third ventricle; VMHc, central part of ventromedial nucleus; VMHvl, ventrolateral part of ventromedial nucleus; XII, hypoglossal nucleus.

pacemaker in the early 1970s marked the beginning of an era in which the hypothalamic contributions to behavioral state regulation have become increasingly clear. This literature has confirmed the early hypotheses of Nauta and identified cell groups in the rostral and caudal hypothalamus whose activity correlates with sleep or arousal.

The rostral hypothalamus is resident to two cell groups that are influential in the regulation of the sleep-wake cycle. Of these, the suprachiasmatic nuclei, or "Mind's Clock," are well known for their genetically determined oscillatory activity. A large literature has established that SCN activity opposes the homeostatic drive for sleep (Chapter 42). In contrast, Saper and colleagues (Sherin *et al.*, 1996) identified a group of hypothalamic neurons that become active at the onset

of sleep in rats. These cells, located in the ventrolateral preoptic region, contain the inhibitory neurotransmitter GABA and project to the tuberomammillary nuclei in the caudal hypothalamus. The tuberomammillary nuclei, a histaminergic cell group, diffusely innervate the cerebral cortex and have been implicated in arousal. These observations reveal a circuitry whose function coincides with the opposing effects of the rostral and caudal hypothalamus in sleep regulation documented by Nauta.

Compelling evidence also supports the conclusion that the caudal hypothalamus contains another population of neurons that, like the tuberomammillary nuclei, is diffusely projecting and implicated in the control of arousal. These neurons are found within the posterior and lateral hypothalamus and contain a

recently discovered peptide known as hypocretin (or orexin). Studies of the causal mechanisms underlying the sleep disorder known as narcolepsy implicate this population of neurons in the regulation of behavioral state. Narcolepsy is a disorder characterized by excessive daytime sleepiness and sudden inappropriate intrusion of sleep during waking. A defect in one of the hypocretin receptors has been demonstrated in a canine model widely employed to study the disease, and transgenic mice lacking the hypocretin gene display sleep–wake disturbances similar to narcolepsy. Additionally, cerebrospinal fluid (CSF) levels of hypocretin are reduced in humans suffering from this disorder, and postmortem analysis of the hypothalamus of narcoleptics has demonstrated substantial reductions in the number of hypocretin neurons.

These findings, along with the aforementioned literature and the documented influence of the biological clock on the temporal organization of the sleep–wake cycle, are consistent with an important role for the hypothalamus in the regulation of behavioral state. Nevertheless, it is important to emphasize that the hypothalamus functions within a larger ensemble of neurons devoted to behavioral state regulation. Particularly important in this regard are monoaminergic and cholinergic brain stem neurons, as well as thalamic and basal forebrain cell groups (Chapter 42). Understanding how these distributed systems function in an integrated fashion to control behavioral state remains an important goal.

### Neuroendocrine Regulation through the Pituitary Gland

The median eminence is the gateway through which the hypothalamus exerts regulatory control over peripheral organ systems. This CVO is continuous with the pituitary gland through a thin tissue bridge known as the infundibular stalk. Hypothalamic neurons exercise this regulatory control via the release of peptides and dopamine (DA) into the vasculature and the infundibular stalk is essential to this regulation.

Magnocellular neurons in the supraoptic and paraventricular nuclei give rise to axons that project through the median eminence and infundibular stalk to terminate in the posterior lobe of the pituitary (Fig. 34.5). This projection system, the tuberohypophyseal tract, is the only direct neural connection between the hypothalamus and the pituitary and permits magnocellular neurons to release vasopressin or oxytocin into the peripheral circulation in the posterior pituitary. These peptides are well known for their influences on fluid homeostasis (vasopressin) and milk letdown in lactating females (oxytocin).

Extensive hypothalamic control over peripheral organ systems is achieved through the release of peptides and DA into fenestrated capillaries in the median eminence. These fenestrated capillaries loop through the median eminence and coalesce to form long portal vessels that travel along the infundibular stalk to terminate in the vascular sinuses in the anterior pituitary. A variety of parvicellular (small) neurosecretory neurons distinguished by peptide phenotype contribute to this regulation either by stimulating or by inhibiting the release of hormones from the anterior lobe of the pituitary. The PVH and arcuate nuclei contain a large proportion of these neurons. PVH neurons are found within the parvicellular subdivisions of the nucleus and produce a diverse group of peptides, such as corticotropin-releasing hormone and thyrotropin-releasing hormone. Similarly, neurons in the arcuate nucleus produce peptides, such as growth hormone-releasing hormone, and neurotransmitters, such as dopamine, that influence the secretory activity of the anterior pituitary. Thus, the synaptic activity of neurons projecting on these hypothalamic neurons is integrated, and the information is converted to a hormonal signal that ultimately influences peripheral physiology.

**FIGURE 34.5** Functional associations of the paraventricular nucleus (PVH) with endocrine and autonomic systems are illustrated. Axons of magnocellular neurons in the PVH and supraoptic nuclei (SON) (shown in red) traverse the internal layer of the median eminence (ME) and the infundibular stalk to terminate on a vascular plexus in the neural (posterior) lobe of the pituitary gland (NL). Parvicellular PVH neurons influence the functional activity of the anterior lobe of the pituitary gland (AL) through projections (shown in blue) that terminate on a fenestrated capillary plexus, the portal plexus, in the external zone of the median eminence. The terminals of these axons release peptides and neurotransmitters into the portal vasculature, which carries them to the anterior lobe of the pituitary. Parvicellular PVH neurons also give rise to descending projections (shown in turquoise) to autonomic nuclei in the brain stem and spinal cord. ac, anterior commissure; och, optic chiasm.

## Reproductive Function

The ability of mammals to reproduce depends on the function of the hypothalamus and its ability to communicate with the pituitary gland. This is especially true for the production of gametes, whose maturation and release in both males and females require a functionally intact hypothalamic–pituitary axis. The hypothalamus also plays an essential role in the organization and expression of the complex behaviors necessary for copulation (see Chapter 40).

Experimental studies in rodents have demonstrated that the rostral medial zone of the hypothalamus plays an important role in orchestrating reproductive behaviors. The medial preoptic region participates in the control of masculine sexual behavior, such as erection, mounting, and ejaculation, whereas ventral regions of the hypothalamus play a major role in the control of feminine sexual behaviors, such as lordosis.

A number of hypothalamic cell groups implicated in reproductive function are sexually dimorphic. For example, ultrastructural studies of a preoptic region in male and female rats have demonstrated differences in synaptology that develop in response to perinatal exposure to androgens. Also, differences in the size and serotonergic innervation of the medial preoptic nuclei of male and female rats have been demonstrated. The possibility that similar dimorphisms are present in the human hypothalamus is supported by the identification of a region of the human preoptic region that is approximately twice as large in males as in females. Although the functional significance of sexual dimorphism in the structure and connectivity of the hypothalamus remains to be established, the gender of the brain is clearly determined by the hormonal milieu present during a critical period of development.

Much is known about the hypothalamic cell groups that influence the production of gametes. The production of ova and sperm is controlled by the release of gonadotropins from the anterior pituitary gland, which is in turn regulated by the hypothalamus in a gender specific manner. For example, spermatogenesis occurs in response to constant release of gonadotropins in males, whereas ovulation is a cyclic event initiated by a rhythmic surge in gonadotropin release in females. In both cases, hypothalamic neurons produce gonadotropin-releasing hormone (GnRH) to stimulate the release of gonadotropin from the anterior lobe of the pituitary. The gender-specific patterns of gonadotropin release imply that there are sexual differences in the functional organization of circuitry that controls the activity of GnRH neurons. One postulated sexually dimorphic difference is a central pattern generator, thought to be responsible for the cyclic release of

GnRH in females. The identity, organization, and regulation of the cell groups that contribute to this pattern generator remain an active and important focus of investigation.

## Central Integration of Autonomic Function

The hypothalamus is a prominent component of the central network of neurons that regulates autonomic function. Descending projections from the hypothalamus to autonomic cell groups in the brain stem and spinal cord exert a strong influence upon the sympathetic (thoracic) and parasympathetic (cranial-lumbosacral) divisions of the autonomic nervous system (ANS). Several hypothalamic cell groups also indirectly influence the ANS through relays that integrate processed sensory information and project to the preganglionic neurons of the spinal cord that are the final common pathway for autonomic outflow. Brain stem neurons involved in cardiovascular regulation are among the best-characterized examples of such relays. For example, brain stem neurons in the rostro-ventrolateral medulla (RVLM) exert control over mean arterial pressure through direct projections to sympathetic preganglionic neurons in the intermediolateral cell column of thoracic spinal cord. The activity of these neurons is controlled in a reflex manner through a caudal brain stem circuit that integrates baroreceptor sensory input terminating in the NTS (Chapter 36). However, descending projections from the hypothalamus (e.g., paraventricular nucleus) and other CNS cell groups important for coordinating autonomic function and behavioral responses to environmental challenges also influence the activity of RVLM neurons. This is one of many relays through which the central network devoted to autonomic control provides a dynamic regulatory capacity ideally suited for maintaining homeostasis and ensuring adaptive changes in physiology to environmental challenges.

## Immune Function and Thermoregulation

Like homeostasis, the hypothalamus exerts an influence over the immune system through neuroendocrine output and through the ANS. Szentivanyi and colleagues examined the effects of hypothalamic lesions and stimulation on anaphylactic responses and found that the diencephalon may influence immune function. Felten and colleagues (1987) have shown that the activity of immune cells of the spleen is influenced directly by “synaptic-like” contacts of noradrenergic neurons of the sympathetic ANS. Neuroendocrine influences also have been demonstrated in work pioneered by Hugo Besedovsky. Nevertheless, the mechanisms

through which this regulation is achieved remain unclear, and the extent to which the nervous system controls immune function remains to be established. This remains an active and important area of investigation (for a review, use Ader, 1996).

Fever is one consequence of an activated immune system. Thus, the neural circuits that control temperature regulation provide important insights into neural-immune interactions. In this regard, it is well known that the hypothalamus contains populations of neurons that either stimulate or inhibit heat production. These include heat sensitive neurons in the medial preoptic area that act to reduce core body temperature by inhibiting other neurons in the hypothalamus and caudal brainstem that induce thermogenesis when activated (Morrison, 2005). In rodents and other small mammals, nonshivering thermogenesis is achieved through the activation of sympathetic outflow to brown adipose tissue (BAT). The mitochondria of BAT adipocytes contain an uncoupling protein that converts energy from fatty acid metabolism to heat, a process that is increased by sympathetic activity. Understanding the identity and organization of the central pathways involved in the control of core body temperature has benefited considerably from analysis of this regulatory circuit. Interestingly, there is considerable overlap of cell groups that regulate energy balance, stress, and fever. Although there is much to be learned regarding the neural systems involved in temperature regulation, it is clear that the hypothalamus is at the center of the sensory integration necessary to respond to challenges generated within (e.g., inflammatory responses to infection) as well as those encountered in the environment.

### Fluid Homeostasis and Thirst

Insight into the regions of the brain involved in fluid homeostasis has come from observing the response of neurons to dehydration and other experimental changes in the internal milieu. The hypothalamus is a prominent component of a set of CNS nuclei in which neurons respond to dehydration (an increase in fluid osmolarity) and changes in blood volume by increasing their metabolic activity. Activated neurons have been demonstrated in the subfornical organ, the paraventricular and supraoptic nuclei, and an area of the rostral hypothalamus known as the AV3V region, which includes the median preoptic nucleus and the OVLT. These regions interact with neurons in the area postrema, the nucleus of the solitary tract, the noradrenergic cell groups of the brain stem, and the parabrachial nucleus to integrate peripheral stimuli and elicit adaptive changes in the fluid environment of the

organism. CVOs subserve prominent regulatory functions within this circuitry.

The SFO has dense projections to the supraoptic and paraventricular nuclei, to the region adjacent to the OVLT, and to the perifornical region of the lateral hypothalamic area. Such projections are consistent with postulated roles of the SFO in autonomic and homeostatic functions. The peptide hormone angiotensin II (AII) is integral to the way in which the SFO transduces peripheral signals and then produces compensatory neural responses. When blood pressure falls, the kidneys release renin into the bloodstream. Renin triggers a biochemical cascade that produces AII. Because of the absence of a blood-brain barrier in the SFO, circulating AII can enter the SFO and bind AII receptors on SFO neurons. Interestingly, SFO neurons appear to use AII as a neurotransmitter in projections to hypothalamic cells that are involved in the control of fluid dynamics. In this example, activation of hypothalamic systems that elicit drinking and reduce fluid excretion at the kidneys would produce the adaptive compensatory homeostatic increase in blood pressure. Further details on the components of the regulatory system are provided in Chapter 36.

Different populations of hypothalamic neurons elicit adaptive responses to changes in fluid osmolarity. Osmosensitive neurons are located primarily in the AV3V region, which includes the OVLT. The response of these neurons to alterations in fluid osmolarity elicits an adaptive compensatory thirst. The neural circuitry that modulates this response is not fully understood but is known to involve input from the OVLT, SFO, and NTS. Further, it takes advantage of the same output regulatory pathway, hypothalamic magnocellular neurons, utilized by the SFO. Chapter 39 considers the hypothalamic role in fluid homeostasis in greater detail.

### Food Intake

The consumption of food is another complex behavior that involves several regions of the brain. The hypothalamus plays an essential role in this circuitry as an integrative center for a variety of sensory stimuli, both synaptic and hormonal. It also serves to modulate autonomic outflow to the viscera. This modern view of neural regulation of food intake is a substantial modification of the simple concept of opposing centers for hunger and satiety that was popular in the older literature. Chapter 38 contains a detailed discussion of literature that has contributed to the modern view of the neural control of food intake. The following descrip-

tion summarizes the functional organization of hypothalamic nuclei that regulate food intake.

When food is consumed, hormones are released from the viscera, and sensory pathways innervating the alimentary tract are stimulated. These sensory pathways regulate neurons in the area postrema and NTS that are connected bidirectionally with hypothalamic nuclei. Hypothalamic nuclei are also subject to feedback regulation from hormonal signals arising in the gut. At least four hypothalamic nuclei are involved in the control of feeding, and a prominent part of their influence is exerted via descending projections to autonomic nuclei in the brain stem and spinal cord. Paraventricular nuclei provide a prominent descending hypothalamic influence. In particular, parvocellular oxytocinergic neurons in the PVH provide an important descending projection to the dorsal vagal complex (including the NTS) and the sympathetic preganglionic neurons of the thoracic spinal cord. At least some of this descending influence appears to be under the control of neuropeptide Y (NPY)-containing neurons that project from the arcuate nucleus to the PVH. In experiments, infusion of NPY into the PVH stimulates food intake and NPY-containing neurons in the arcuate nucleus are inhibited by insulin released into the peripheral circulation after a meal and by leptin, a peptide released from adipose tissue. Thus, hypothalamic nuclei regulate food intake through the autonomic nervous system, and a subset of these neurons is influenced by peripheral signals from the periphery (see Chapter 38).

## Summary

It is clear that the hypothalamus plays a pivotal regulatory role central to the survival and propagation of vertebrate species. This regulation is achieved by output pathways that utilize both synaptic and hormonal mechanisms and is subject to feedback regulation by sensory information derived from the systems that they regulate. The integrative capacities of the hypothalamus are fundamental to its ability to orchestrate the complex and diverse adaptive behaviors that underlie homeostasis, reproduction of the species, and motivated behaviors. Within this context it is important to view the hypothalamus as an integral component of ensembles of neurons devoted to specific functions rather than an individual unit. Swanson has advanced a conceptual framework consistent with this philosophy. In this formulation, the hypothalamus is part of a "behavioral control column" that functions as a topographically organized integrative center subject to the control of cerebral hemispheres. The functional organization of this column is consistent with the dis-

tributed localization of functions classically associated with the hypothalamus. For example, the rostral portion of the column is devoted to the control of ingestive (eating and drinking) and social (defensive and reproductive) behaviors, whereas the caudal portion, which is continuous with the substantia nigra, functions in support of exploration and foraging. Modulation of these functions is under the control of the cerebral hemispheres through three descending projections involving the cortex, striatum, and pallidum. The role of the hypothalamus in imparting temporal organization on the behavioral state and physiology is an important component of this organizational framework. The explosion of organizational and functional data that has accumulated over recent decades has expanded our understanding of hypothalamic function and established this small but complex subdivision of the diencephalon as an important integrative unit for the expression of behavior and maintenance of homeostasis.

## Central Control of Autonomic Functions: Organization of the Autonomic Nervous System

The autonomic nervous system (ANS) consists of the neural circuitry that controls the body's physiology. This network is a morphologically, embryologically, functionally, and pharmacologically distinct division of the nervous system. Working in concert with neuroendocrine mechanisms, the ANS is responsible for homeostasis.

Unlike the skeletal motor system, which innervates striated muscles, the autonomic nervous system innervates the body's smooth muscle organs and tissues. The ANS projects to, and forms plexuses within, the hollow organs, or viscera, such as the heart and lungs in the thorax, and the gastrointestinal, genital, and urinary tracts in the abdomen. It also projects to the blood vessels, glands, and other target tissues found within trunk muscles, limb muscles, and skin.

The ANS coordinates what Walter B. Cannon (1939) referred to as the "wisdom of the body"; specifically it provides the tissue-, organ-, and system-level integration of the body's physiology to achieve homeostasis and support behavior. In tandem with endocrine controls, the ANS orchestrates the continuous adjustments in blood chemistry, respiration, circulation, digestion, reproductive status, and immune responses that protect the integrity of the internal milieu and enable the functioning and coordination of skeletal muscles and exteroceptive senses into what we know as behavior. Autonomic adjustments are often phasic responses that occur with latencies typical of neural reflexes; in contrast, endocrine responses usually occur more

slowly, taking anywhere from minutes to hours to seasons for full expression.

Autonomic impairments lead to the loss of ability to mobilize physiological responses and adaptations to challenges to homeostasis. For example, Cannon (1939), in his landmark physiological experiments on the ANS, found that destruction of different autonomic pathways devastated the ability of an animal to regulate its body temperature, to respond to perturbations of its fluid and electrolyte balance, to control its blood sugar homeostasis, or to mobilize in response to threats.

A familiar experience illustrates autonomic operations: Occasionally, when you have been lying down resting and then jump up suddenly, you may feel dizzy, your vision may become blurred, and you may momentarily have trouble maintaining your balance—let alone doing something active and coordinated. This phenomenon is postural, or orthostatic, hypotension and is caused by insufficient oxygenated blood reaching your brain under the altered hemodynamic conditions produced by the rapid change in posture. Most people experience postural hypotension only occasionally, though for some it is a chronic medical problem. Indeed, it is a debilitating condition in people with various forms of dysautonomia (Bannister, 1989).

The principle underscored by postural hypotension is that even something as mundane as a change in posture requires a near-instantaneous redistribution of

blood flow throughout the body to protect the privileged flow of blood, and thus oxygen and glucose, to the brain. The demands of postural adjustments require unceasing monitoring and rebalancing of circulatory loads. The fact that these adjustments happen continuously and automatically is testimony to the efficiency of the ANS in producing homeostatic adjustments. This example also illustrates two other characteristics of many autonomic responses: (1) Often the responses either are initiated in anticipation of the perturbation or implemented so rapidly that the individual does not experience a deficit and (2) the activity of the ANS is linked to and coordinated with activity of the somatic nervous system.

The range of autonomic functions is hard to overemphasize. They are by no means limited to cardiovascular and metabolic operations, to “fight or flight” situations, or to short-term adjustments. The ANS has equally essential roles, for example, in all reproductive behavior and physiology, including the choreographies of copulation, gestation, parturition, and lactation. Autonomic reflexes control, on a continuous basis, all bodily interfaces with the environment (e.g., the dermal, respiratory, and digestive epithelia). And the ANS plays critical roles in immune system responses; it also coordinates the elimination of metabolic waste products.

The autonomous nature of ANS function is another characteristic of autonomic control. We are rarely aware of ongoing reflex adjustments made to maintain cardiovascular and regulatory dynamics, fluid and electrolyte homeostasis, energy balance, immune system operations, and our reproductive functions. Like the batch files of a computer, which execute without normally intruding on the screen or requiring attention, the autonomic reflex adjustments run unceasingly in the “background,” whereas other sensory events and functional decisions occupy the “foreground.” In one of his delightful and trenchant essays, Lewis Thomas (1974) speculates on how disastrous and overwhelmingly confusing it would be if he were put in charge of his liver—if he had to consider all visceral inputs and make a conscious decision for all adjustments in liver function. The ANS takes care of such hepatic, as well as all other visceral decisions automatically, allowing the individual to focus on the behavioral and cognitive functions that typically require awareness.

The hub of the autonomic nervous system is the visceral motor outflow, which is divided into *sympathetic* (SNS) and *parasympathetic* (PSNS) divisions. Each division is organized hierarchically into pre- and postganglionic levels (Fig. 35.1). The cell bodies of the preganglionic neurons lie within the central nervous

**FIGURE 35.1** Somatic and autonomic styles of motor innervation are different. In the somatic motor pattern (A), motor neurons of the spinal cord and cranial nerve nuclei project directly to striated muscles to form neuromuscular junctions. In the autonomic or visceral pattern (B and C), in contrast, motor neurons in the central nervous system project to peripheral postganglionic neurons that in turn innervate smooth muscles. (B) The SNS has preganglionic neurons in the thoracic and lumbar spinal cord (intermediolateral cell column) that project to postganglionic motor neurons in para- and prevertebral autonomic ganglia. (C) The PSNS consists of preganglionic neurons in brain stem cranial nerve nuclei and in the sacral spinal cord (intermediomedial cell column) that project to postganglionic motor neurons in ganglia located near or inside the viscera. From Nauta and Feirtag (1986).

system, specifically in the brain stem and spinal cord. Descending projections from more rostral levels of the neuroaxis converge on these ANS preganglionic motor neurons in a pattern similar to that of the centrifugal projections to somatic motor neurons of the brain stem and spinal cord. However, unlike the outflow pattern of the skeletal motor system, in which neurons of the ventral horn or the cranial nerve nuclei project directly to the effector or muscle target, autonomic preganglionic neurons project to peripheral ganglia located between the last CNS station and the target tissues. These ganglia of the ANS contain the postganglionic motor neurons that project to the effector tissues. The extra synapse interrupting the autonomic outflows at peripheral ganglia allows for more divergence, as well as the possibility of more local integrative circuitry to impinge on the outflow. Different locations both of the preganglionic motor neurons in the CNS and of the

TABLE 35.1 Classical Comparisons of Sympathetic and Parasympathetic Divisions of the ANS<sup>a</sup>

	SNS	PSNS
Location of preganglionic somata	Thoracolumbar cord	Cranial neuroaxis; sacral cord
Location of ganglia (and postganglionic somata)	Distant from target organ	Near or in target organ
Postganglionic transmitter	Norepinephrine	Acetylcholine
Length of preganglionic axon	Relatively short	Relatively long
Length of postganglionic axon	Relatively long	Relatively short
Divergence of preganglionic axonal projection	One to many	One to few
Functions	Catabolic	Anabolic
Innervates trunk and limbs in addition to viscera	Yes	No

<sup>a</sup>Langley (1921) stressed the contrasting and distinguishing traits of the two divisions of the ANS. Since his time, most discussions have identified several contrasting features. Most of these distinctions apply generally but not universally. Although many of these distinctions have blurred (e.g., transmitter) or may be completely unfounded (e.g., divergence), they often are discussed.

ganglia containing the somata of the postganglionic motor neurons in the periphery are distinguishing features of the two principal divisions of the autonomic nervous system (Langley, 1921; see Table 35.1).

### SYMPATHETIC DIVISION: ORGANIZED TO MOBILIZE THE BODY FOR ACTIVITY

#### Sympathetic Responses Predominately Produce Energy Expenditure, Catabolic Functions, and Adjustments for Intense Activity

"Fight or flight," Cannon's prototypical example, epitomizes the operation of the sympathetic division of the ANS: You are walking alone at night in an unfamiliar part of town. Although the area is somewhat unsafe and it is too dark to see much of your surroundings, the night is quiet, and you manage to relax. After walking for several minutes, however, there is a sudden, loud, and unfamiliar noise close by and behind you. In literally the time of a heart beat or two, your physiology moves into high gear. Your heart races; your blood pressure rises. Blood vessels in your skeletal muscles dilate, increasing the flow of oxygen and energy. At the same time, blood vessels in your gastrointestinal tract and skin constrict, making more blood available to be shunted to skeletal muscle. Digestion is inhibited; release of glucose from the liver is facilitated. Your pupils dilate, improving vision. You begin to sweat, a response serving several functions, including promoting additional dissipation of heat so

muscles can work efficiently. Multiple other smooth and cardiac muscle adjustments occur automatically and almost all of them are affected by the sympathetic division of the ANS.

This fight-or-flight example illustrates important features of the ANS generally and its SNS division more particularly. First, the situation points out the utility of the housekeeping functions of the ANS: If the alarming noise turns out to be a threat and it is necessary to fight or flee, skeletal muscles must be optimally tuned and provisioned. Extra quantities of oxygen and energy are essential. Second, the synergy of adjustments indicates a coordinated and adaptive program of responses, which in this case happen immediately, almost before cognitive evaluation. Third, the short latency of the response is characteristic (and in such a case possibly critical). Some of the physiological adjustments could be accomplished by hormonal mechanisms, but such adjustments would be too slow to be of much immediate help if the noise should signal a bona fide threat.

Though the flight-or-flight scenario highlights short-latency responses, not all sympathetic (or parasympathetic) responses happen on such short time scales. ANS operations also involve continuous, ongoing adjustments. Textbook accounts of the emergency functions of the ANS and of single, isolated reflex adjustments sometimes leave the incorrect impression that the ANS is quiescent in the absence of a threat or specific stimulus. Instead, the autonomic nervous system, like the somatic nervous system, always maintains an operating tone. Even during rest, the system maintains appropriate homeostatic balances and autonomic programs.

## Preganglionic Neurons of the Sympathetic Nervous System Are Located in the Thoracic and Lumbar Spinal Cord

Sympathetic preganglionic neurons occupy the *intermediolateral nucleus*, a columnar grouping of cells running longitudinally through much of the spinal cord, in the lateral horn of the spinal gray. In humans, these cells are found between the first thoracic spinal segment (T1) and the third lumbar segment (L3) (Fig. 35.2A). The location of these preganglionic neurons and their axonal outflow gives the SNS another of its names, the *thoracolumbar division*. Cells within the intermediolateral column show a tendency to segmental aggregation. There is a rostral-to-caudal viscerotopic organization to the distribution (Fig. 35.2A). The column is found bilaterally, and preganglionics on one side send their axons out the ipsilateral ventral root. The axon of a preganglionic neuron typically exits from the segment in which its soma is located. Many of the preganglionic axons are lightly myelinated, and, as they separate from the ventral root to project to the appropriate peripheral ganglion, they form a *white ramus*, a connective that takes its descriptive name from myelinated fibers.

Sympathetic postganglionic neurons are found in two distinct types of peripheral ganglia: paravertebral and prevertebral. *Paravertebral ganglia*, as the name implies, are adjacent to the spinal cord bilaterally, in a position slightly ventral and lateral to the vertebral column (Figs. 35.3 and 35.4). Each ganglion receives a white ramus from the appropriate ventral root. These ganglia also are interconnected longitudinally into a sympathetic chain linked by axons from the preganglionic neurons that run rostrally or caudally to neighboring ganglia of the chain. Axons of the postganglionic neurons of the paravertebral ganglia course centrifugally out of the ganglion to join the peripheral nerves that will carry the individual fibers to their targets. Because most postganglionic axons in the sympathetic nervous system are unmyelinated, these connectives joining the ventral roots are called *gray rami*.

Paravertebral ganglia of the sympathetic chain supply the postganglionic innervation of the head, thorax, trunk, and limbs. For the trunk and limbs, postganglionic axons course both alongside and within the somatic peripheral nerve innervating the region. These autonomic fibers innervate the blood vessels in the muscles (vasoconstrictor fibers), as well as different targets within the skin, including the sweat glands (sudomotor fibers) and erector pili muscles of erectile hairs (pilomotor fibers).

At the rostral end of the sympathetic chain, individual segmental ganglia are fused into aggregate

**FIGURE 35.2** Details of the organization of the SNS and its sensory inputs. In thoracic and lumbar levels of the spinal cord, preganglionic neuronal somata located in the intermediolateral cell column project through ventral roots to either paravertebral chain ganglia or prevertebral ganglia, as illustrated for the splanchnic nerve (A). Visceral sensory neurons located in the dorsal root ganglia transmit information from innervated visceral organs to interneurons in the spinal cord to complete autonomic reflex arcs at the spinal level (B). From Loewy and Spyer (1990).

**FIGURE 35.3** The SNS is organized segmentally. As illustrated here for segments T3 and T4 of the thoracic spinal cord, preganglionic axons exit through the ventral root of the segment in which the preganglionic cell body is located. These preganglionic axons can be myelinated (solid red lines) or unmyelinated (dashed red lines) and can project to the paravertebral ganglion associated with the segment, to neighboring paravertebral ganglia through the sympathetic chain, to postganglionic neurons located distally in the prevertebral ganglia, or through one of the autonomic nerves (splanchnic nerve is illustrated). T3 and T4, segments of the thoracic spinal cord; VH, ventral horn of spinal cord. From Loewy and Spyer (1990).

ganglionic groupings. The sympathetic chain, in a modification of the paravertebral chain pattern (Figs. 35.4 and 35.6), innervates the head and the thoracic viscera. The most rostral group, the *superior cervical ganglion* (supplied from the first and second thoracic segments), supplies the head and neck. The targets of its projections are extensive, including the eyes, salivary glands, lacrimal glands, blood vessels of the cranial muscles, and even the blood vessels of the brain. The paravertebral ganglia just caudal to the superior cervical ganglion form the *middle cervical ganglion* and, moving caudally, the *stellate ganglion*. These latter ganglia supply the postganglionic sympathetic outflows that innervate the heart, lungs, and bronchi.

Unlike the trunk, limbs, head, heart, and lungs, organs of the abdominal cavity are innervated by postganglionic neurons in ganglia situated distal to both the spinal cord and the paravertebral sympathetic chain in locations closer to the target tissue. These sites give the ganglia their distinguishing name, *prevertebral ganglia*. The preganglionic neurons innervating these

sets of postganglionic neurons are located in the intermediolateral column of the spinal cord, like those innervating the paravertebral chain, but their axons pass through the white rami, the chain ganglia, and the gray rami without synapsing. They then make contact with the peripherally situated prevertebral ganglion cells (Fig. 35.3).

There are four major prevertebral postganglionic stations. The more rostral three are located at points where major abdominal arteries separate from the descending aorta, and the ganglia take their names from their associated arteries (Fig. 35.5). Moving from more rostral to caudal, the *celiac*, *superior mesenteric*, and *inferior mesenteric ganglia* innervate the gastrointestinal tract. The celiac ganglion (also commonly called the solar plexus because its connectives radiate from it) projects predominantly to the stomach and rostral-most parts of the foregut and its embryological derivatives, such as the liver and pancreas. Consistent with their progressively more caudal locations, the middle and inferior mesenteric ganglia innervate the mid- and

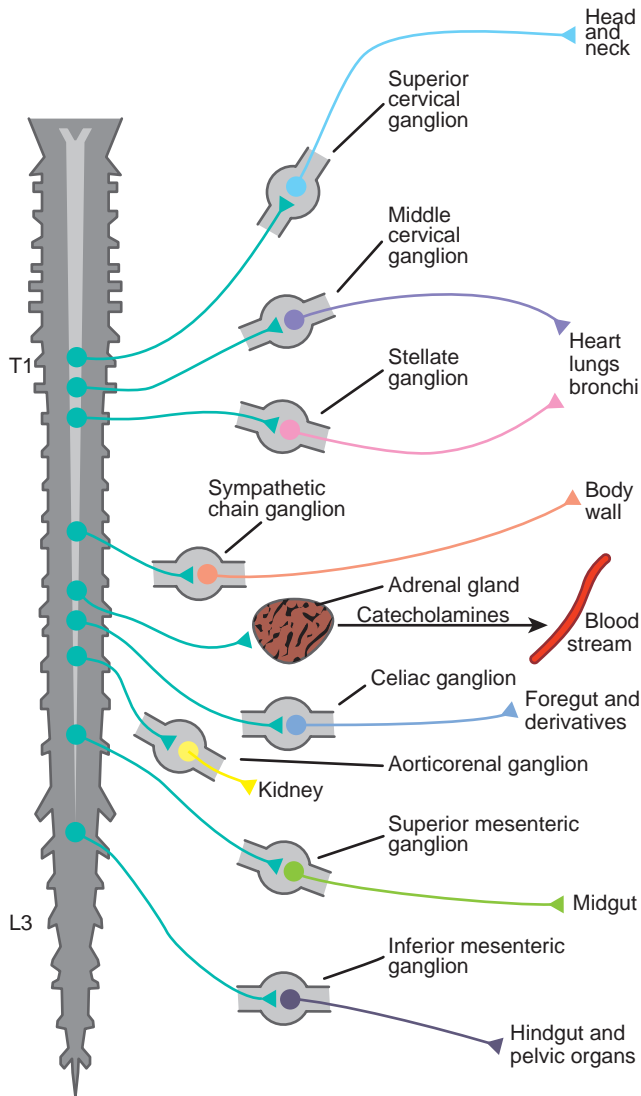

FIGURE 35.4 Summary of the major SNS ganglia and their target organs or tissues. Spinal cord is illustrated on the left. From Loewy and Spyer (1990).

hindgut tissues, respectively. The inferior mesenteric ganglion also supplies the postganglionic innervation to the pelvic organs. The fourth, and most caudal, prevertebral ganglion is the *pelvic-hypogastric plexus*, which innervates urinary and genital tissues. Perhaps because these prevertebral ganglia are located farther from the spinal cord and closer to the target organs (than the paravertebral ganglia) and because they coordinate responses of visceral organs containing separate nerve networks (the enteric nervous system is described later), these prevertebral ganglia may have more complex neural organization than the paravertebral chain ganglia.

The adrenal medulla is a unique variant of the sympathetic postganglionic pattern. By several criteria, the adrenal medulla is a sympathetic prevertebral ganglion containing postganglionics. However, neurons of this medullary ganglion, rather than issuing axons to innervate target organs, function as a neuroendocrine organ. The adrenal medulla secretes the classical postganglionic sympathetic transmitter norepinephrine, as well as epinephrine, directly into the bloodstream. These catecholamines then circulate as hormones. Release of catecholamines from the adrenals during sympathetic activation provides powerful reinforcement and modulation of the more focal release of catecholamines at traditional—and local—effector sites.

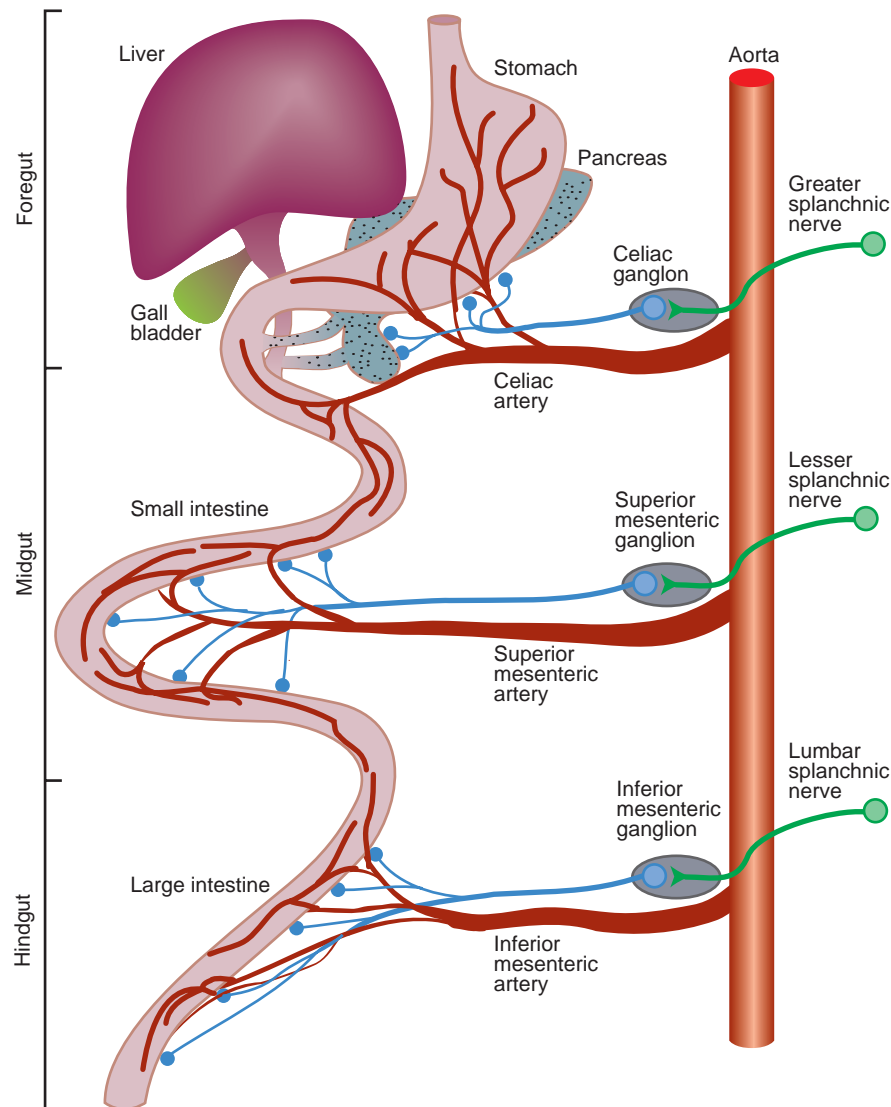

### Summary

Overall, the two major motor outflows, or divisions, of the ANS are responsible for the maintenance of homeostasis, but the sympathetic nervous system is the branch specialized for the mobilization of energy. The SNS provides the vascular, glandular, metabolic, and other physiological adjustments that optimize behavioral responses, particularly in emergency situations and conditions requiring activity. The SNS efferent outflow consists of preganglionic neurons, which are located in the intermediolateral column of the thoracic and lumbar spinal cord. SNS efferent axons course to paravertebral and prevertebral ganglia containing the postganglionic neurons, the axons of these postganglionic neurons project to the target tissues.

## PARASYMPATHETIC DIVISION: ORGANIZED FOR ENERGY CONSERVATION

### Parasympathetic Nervous System Functions Reduce Energy Expenditure and Increase Energy Stores

Functionally, the parasympathetic nervous system mobilizes homeostatic adjustments that are often opposite and reciprocal to those activated by the SNS (see Table 35.1). In particular, PSNS adjustments usually are considered “rest and digest” responses, in contrast to the “fight or flight” sympathetic activation. The PSNS promotes anabolic processing, whereas the sympathetic nervous system augments catabolic activity. The PSNS promotes the gastrointestinal processes required to digest and absorb nutrients effectively. This branch of the ANS also augments the efficient use

**FIGURE 35.5** SNS innervation of the gastrointestinal tract. This more detailed schematic (compared to Fig. 35.4) illustrates how separate segmental levels of the spinal cord and the associated prevertebral ganglia innervate targets in a topographic, specifically viscerotopic, pattern. The association of autonomic pathways and vasculature is also shown. From Loewy and Spyer (1990).

of energy and the storage of extra calories as fat and glycogen. The PSNS, particularly the vagus nerve, plays a central role in controlling the flow of body reserves or energy between storage depots and the tissues that use the energy. The body's energy reserves are fat in adipose tissue and glycogen in liver and muscle. After a meal, the gastrointestinal tract serves as an additional reservoir of potential energy for the body. By mobilizing triglycerides from adipose tissue or glycogen from liver and muscle, the ANS can make reserves available for metabolism; similarly, by moving nutrient stores (e.g., from the stomach) and promoting

their digestion and absorption from the intestines into the bloodstream, the ANS can supply energy to fuel metabolism or to restock triglyceride and glycogen stores, as needed.

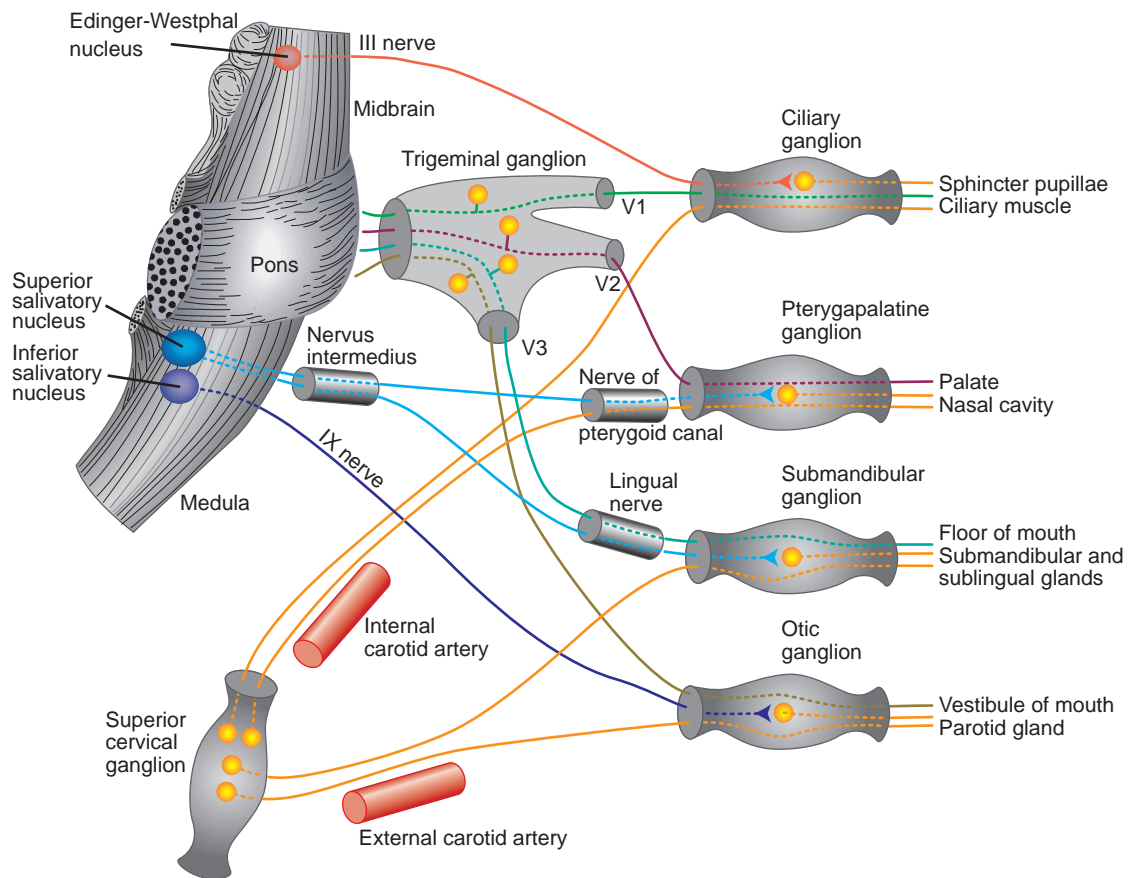

### Preganglionic Neurons of the Parasympathetic Nervous System Are Located in the Brain Stem and the Sacral Spinal Cord

One of the features distinguishing the PSNS from the SNS is the location of their respective preganglionic neurons. PSNS preganglionic neurons are located

in two longitudinal columns of neurons: one in the brain stem and the other in the sacral spinal cord. These locations of PSNS preganglionic neurons are responsible for the alternative name of this division of the ANS, the *craniosacral* (or *bulbosacral*) *division*. The longitudinal column of motor neurons in the brain stem is the general visceral cell column, which condenses into a number of nuclei ventrolateral to the cerebral aqueduct system within the brain. These nuclei then project through cranial nerves to targets in the head (cranial nerves III, VII, and IX) or thorax and abdomen (cranial nerve X) (Fig. 35.6). Cranial nerve III, the oculomotor nerve, carries the axons of the accessory, or autonomic, nucleus of the Edinger–Westphal complex, which participate in the control of the pupillary sphincter and ciliary muscles. Cranial nerve VII, the facial nerve, carries preganglionic axons of the superior salivatory nucleus and controls the submaxillary and sublingual salivary glands, as well as the lac-

rimal glands. Cranial nerve IX, the glossopharyngeal nerve, carries axons of the inferior salivatory nucleus, which control the parotid salivary glands and mucus secretion.

Preganglionic motor neurons of the Xth cranial nerve, the vagus nerve, control smooth muscles and glands throughout the digestive tract, from the pharynx to the distal colon, including viscera such as the liver and pancreas. These Xth nerve neurons occupy the dorsal motor nucleus of the vagus, a long fusiform nucleus in the medulla oblongata (Fig. 35.7). They control numerous motor and secretomotor responses that participate in the ingestion and digestion of food, as well as in the assimilation of the nutrients. The vagus nerve also carries motor fibers of a special visceral nucleus, the nucleus ambiguus or ventral vagal nucleus, which controls the striated muscles of the pharynx, larynx, and esophagus and the cardiac muscle of the heart. Much like the case described for sympa-

**FIGURE 35.6** Autonomic innervation of the head by both sympathetic (superior cervical ganglion) and parasympathetic (cranial nerve nuclei in the medulla and midbrain projecting to the several prevertebral ganglia) pathways. Visceral afferents associated with the autonomic nervous system are found in the trigeminal nerve (cranial nerve V) ganglion. From Loewy and Spyer (1990).

**FIGURE 35.7** Parasympathetic projections of the vagal motor pathways, the most extensive of the PSNS circuits, to the viscera of the thorax and abdomen. From Loewy and Spyer (1990).

thetic neurons, motor neurons of the dorsal motor nucleus of the vagus and the nucleus ambiguus are organized into viscerotopic subnuclei (e.g., Bieger and Hopkins, 1987; Fox and Powley, 1992).

The central representation of the more caudal part of the PSNS is found in the sacral spinal cord, in humans the second (S2) through fourth (S4) sacral segments (Fig. 35.8). The parasympathetic preganglionic somata occupy two longitudinal groupings: one column immediately dorsolateral to the central canal and the other in roughly the same transverse location as that of the intermediolateral column of cells, which sympathetic preganglionics occupy in the thoracic and lumbar cord. Axons of the sacral preganglionics exit the cord in the ventral roots, run in a sacral plexus, and project to the target organs. The sacral preganglionic cell columns control parasympathetic motor, vasomotor, and secretomotor functions of the kidneys, bladder, transverse and distal colon, and reproductive organs.

The locations of their respective postganglionic neurons constitute another feature that distinguishes the PSNS from the SNS. Ganglia containing the PSNS postganglionic neurons are juxtaposed to, on the surface of, or even in, the target organ, in contrast to the para- and prevertebral locations of the SNS (Fig. 35.1c). These juxta- and intramural stations often are called *plexuses*, rather than ganglia. Like SNS prever-

**FIGURE 35.8** Spinal cord organization of the sacral division of the craniosacral, or parasympathetic, nervous system. From Loewy and Spyer (1990).

tebral ganglia, the PSNS postganglionic plexuses are complex integrative sites that typically receive inputs not only from preganglionic neurons, but also from afferents within the plexuses or target tissues. Because the PSNS postganglionic neurons are situated so near their targets, the parasympathetic division of the ANS has, perforce, longer preganglionic axons and shorter postganglionic fibers than the sympathetic division. The relative lengths of the postganglionic fibers in the two divisions have been taken as evidence that individual axons of the SNS may diverge more extensively and innervate larger projection fields, whereas the PSNS may exhibit less divergence and more localized projections. (For counterarguments, see Wang *et al.*, 1995.)

## Summary

The parasympathetic nervous system or craniosacral division (i.e., the second major outflow of the ANS) is organized to digest, assimilate, and conserve energy as well as promote rest. Its anabolic functions include not only those associated with the metabolism of nutrients, but also numerous protective reflexes, such as those that limit heat loss, reduce energy expenditure, and slow the heart. The PSNS outflow consists of preganglionic neurons located in brain stem cranial nerve nuclei or the autonomic columns of the sacral spinal cord. Their axons project to the postganglionic neurons located in ganglia situated near or in the target organs. Postganglionic neurons, in turn, project to the smooth muscle of the target viscera.

## THE ENTERIC DIVISION OF THE ANS: THE NERVE NET FOUND IN THE WALLS OF VISCERAL ORGANS

Discussions of the ANS sometimes focus on the SNS and PSNS, but there is a third division as well. When Langley articulated the classic definition of the ANS, he identified the *enteric nervous system* (ENS) as the third division. The alimentary canal, or “entrum,” and the tissues derived from it, such as those in the pancreas and liver, contain extensive and well-formed neural networks. In particular, the gastrointestinal tract contains two well-organized major plexuses that contain as many neurons as the entire spinal cord (Fig. 35.9). Each plexus consists of an extensive sheet of small nodes of cells linked by connectives. One plexus, the myenteric plexus, is situated between outer longitudinal and inner circular muscle layers of the viscus. The other plexus, the submucosal or submucous plexus, is located between the circular muscle layer and the luminal mucosal layer of the viscera. As illustrated in Figure 35.9, there are additional, less extensive, enteric networks as well.

The number of neurons in the enteric plexuses, their extensive interconnections, and their capacity to support motility have led to proposals that the enteric nervous system serves as a more or less independent “brain” in the gut. Early descriptions emphasized the autonomy of the ENS by observing that the gastrointestinal tract could exhibit movement, peristalsis, even after all extrinsic connections to it were cut. However, fully integrated or coordinated responses of the gastrointestinal tract, including motor responses other than peristalsis, as well as absorptive and secretory responses, involve extrinsic projections from the central nervous system to the enteric nervous system.

Because the preganglionic neurons of the vagus nerve project to the enteric ganglia rather than to independent postganglionic stations, the enteric nervous system serves as an extensive postganglionic relay station for the vagus.

### Summary

The ENS or enteric nervous system, the third division of the ANS, consists of ganglia and plexuses of intrinsic neurons in the walls of the viscera such as the gastrointestinal tract. These nerve networks contain intrinsic afferents, interneurons, and efferents that control local functions; they also receive extrinsic inputs from autonomic preganglionic efferents, particularly those PSNS projections coursing in the vagus nerve.

### ANS PHARMACOLOGY: TRANSMITTER AND RECEPTOR CODING

Early in the twentieth century, pharmacological studies performed with naturally occurring agonists and antagonists provided the basis for the original differentiation of two major ANS divisions—the SNS and PSNS. Prior to the pharmacological analyses, the two often had been lumped together. Dale (the contributor of “Dale’s law” of neurotransmitters), Langley, and a number of other early investigators applied natural extracts such as muscarine, nicotine, *d*-tubocurarine, and others to autonomic ganglia while measuring responses in order to infer the chemical taxonomy of the ANS. Subsequent experiments have replicated the basic distinctions made by these investigators, but this newer research, with access to a pharmacopoeia of synthetic agonists and antagonists, as well as to immunocytochemistry for the characterization of transmitter substances, has described a much richer and more complicated multiplicity of neurotransmitters, neuromodulators, and receptor subtypes in autonomic nerves (Lundberg, 1996).

### Preganglionic Neurons Use Acetylcholine as a Transmitter

Most preganglionic neurons of both the SNS and PSNS have a cholinergic transmitter phenotype. Only

**FIGURE 35.9** (A) The enteric nervous system plexuses in the wall of the intestine. Enteric neurons form two conspicuous and extensive networks, or plexuses, of ganglia and connectives located between the longitudinal and circular muscle layers of the wall (the myenteric plexus) and the circular muscle layer and the inner mucosal layer (the submucous plexus). The deep muscular plexus, periglandular plexus, and villous plexus are additional networks of enteric neurons and their processes. From Costa *et al.* (1987). (B) Autonomic preganglionic terminals innervating postganglionic neurons. This example of vagal preganglionic projections (labeled with the tracer *Phaseolus vulgaris*) innervating myenteric ganglion neurons (stained with Cuprolinic blue) in the stomach wall illustrates that autonomic preganglionic axons can form extensive networks controlling postganglionics. From Holst *et al.* (1997).

relatively small subpopulations of preganglionic neurons express other (e.g., dopaminergic or adrenergic) phenotypes. In the peripheral ganglia of these two divisions of the ANS, most postganglionic neurons, which receive inputs from the preganglionics, express a predominance of a nicotinic form of the cholinergic receptor on their somata. As discovered by the early autonomic pharmacologists, nicotine can serve as a general “ganglionic blocker” to thwart transmission at these synapses. Additional specificity and response selectivity, or coding, at the ganglionic level normally are maintained by the segregation of sympathetic and parasympathetic postganglionic neurons in separate ganglia, by point-to-point axonal projections, by distinguishing neuropeptides colocalized with the transmitter, and by the spatial separation of synapses within ganglia.

### SNS and PSNS Postganglionic Neurons Use Different Transmitters

The respective transmitter phenotypes of the postganglionic neurons constitute one of the cardinal defining differences between the sympathetic and parasympathetic nervous system. The majority of SNS postganglionic neurons release the transmitter norepinephrine, whereas PSNS postganglionic neurons release primarily acetylcholine. Such a two-transmitter chemical code produces push-pull or positive bidirectional control of individual targets.

The biomechanics of smooth muscle are quite different from the biomechanics of striated muscle. In contrast to skeletal muscle, smooth muscle is not always organized into antagonistic pairs, with each member of the pair being innervated by a different motor neuron. Also, the smooth (and cardiac) muscles forming the walls of the viscera are not differentially attached to a hard frame to provide mechanical leverage through opposition activity. Reciprocal motor programs of the viscera, for the most part, involve active, phased contraction and relaxation of the same muscle to achieve coordination. To produce these patterns of excitation and inhibition, the target organs and tissues express both adrenergic and cholinergic receptors and have different, often antagonistic or complementary, responses to selective activation of the different receptors.

Response patterns of smooth muscle are further differentiated by specializations of the receptors. Adrenergic receptors, influenced by the catecholaminergic transmitter released by sympathetic fibers, are differentiated into at least four different metabotropic subtypes linked to different intracellular pathways. Similarly, the muscarinic acetylcholine receptor, influ-

enced by the cholinergic transmitter released by parasympathetic postganglionic neurons, is differentiated into at least three ionotropic subtypes with differential influences on intracellular transduction. These heterogeneities of transmitter species and receptor types make it practical to mobilize multiple, different, and potentially highly differentiated responses from one effector tissue (Box 35.1).

Response selection may also be facilitated by neuropeptides that the postganglionic neurons synthesize and corelease during activity. Somatostatin, neuropeptide Y, or both are found in many sympathetic neurons; vasoactive intestinal polypeptide and calcitonin gene-related peptide are often coexpressed in parasympathetic neurons. These peptides may serve as neuromodulators that vary postsynaptic responses to the conventional autonomic neurotransmitters. The release of different neuropeptides and cotransmitters can vary with different rates or patterns of firing and is not invariantly proportional to transmitter release. Thus, a heterogeneity of different cotransmitter and transmitter release patterns can be produced by a single fiber or fiber type, depending on firing pattern and other local factors at the synapse (e.g., Lundberg, 1996).

Although dual innervation in an oppositional or push-pull pattern is presumed to yield faster, more responsive adjustments and to provide a mechanism that can adjust response gain, some tissues are innervated by only one arm of the ANS. The SNS has a wider distribution than the PSNS. In particular, white and brown adipose tissue, peripheral blood vessels, and sweat glands are innervated by the SNS without reciprocal PSNS projections. One possible explanation for this arrangement is that the functions of these particular effectors do not require the speed associated with push-pull projection patterns, particularly in terminating responses once activated. Furthermore, in the evolution of the autonomic nervous system, the SNS is thought to be the older, and correspondingly more extensive, network, whereas the PSNS occurred more recently in phylogeny and therefore has less widespread projections.

Finally, the enteric nervous system also has an extensively varied set of transmitters, cotransmitters, and neuromodulators, providing highly differentiated chemical coding of local functions (Furness, 2006; Lundberg, 1996).

### Summary

Both the SNS and the PSNS use acetylcholine as a preganglionic transmitter, but they are distinguished by different postganglionic phenotypes: most SNS

## BOX 35.1

## AUTONOMIC POSTGANGLIONIC NEURONS CAN CHANGE THEIR TRANSMITTER PHENOTYPES

Transmitter phenotypes of autonomic neurons generally seem fixed, dictated by both intrinsic and extrinsic developmental cues. At least some ANS neurons, however, can alter their phenotypes under appropriate environmental conditions. This conclusion first was reached when populations of postmitotic adrenergic and cholinergic neurons were cocultured *in vitro* in different media or in the presence of different tissues. Without changes in overall cell number, the percentages of adrenergic and cholinergic neurons in a given culture changed over time. Even more definitively, when single postganglionic cells were grown in microculture wells, the presence of a medium conditioned by heart cells caused some of these mature neurons to change from an adrenergic to a cholinergic phenotype (Potter *et al.*, 1980).

This phenotypic switching does not appear to be an artifact of cell culture situations; the change appears to occur normally *in vivo* in development to generate the specialized minority of sympathetic postganglionic neurons that are cholinergic (e.g., for innervation of sweat glands). Landis and Keefe (1983) have verified this hypothesis by using rat foot pad sweat gland innervation *in vivo* and characterizing the transmitter phenotype of the autonomic projections at different stages of development. The developing sympathetic postganglionic innervation of the sweat glands initially expresses a typical adrenergic phenotype as the axon grows toward its target. Once the sweat gland target is innervated, however, the

tissue induces the change in neurotransmitter phenotype to a cholinergic one.

Such changes in transmitter are not unique to these examples. Perhaps reflecting pluripotential patterns seen earlier in phylogeny, at least some cholinergic neurons (e.g., avian ciliary ganglion cells) appear to remodel into an adrenergic phenotype, whereas other cells (e.g., maturing neural crest cells in the developing gut wall) exhibit a transient catecholaminergic stage that is lost during the ingrowth of extramural innervation.

Finally, in addition to such switching, autonomic postganglionic neurons also have been shown to exhibit plasticity in altering their levels of transmitters and cotransmitters as a function of the activity of their preganglionic inputs. For example, after preganglionic inputs are blocked or transected pharmacologically, postganglionic neurons of the superior cervical ganglion decrease their levels of tyrosine hydroxylase while increasing their level of substance P.

postganglionic neurons are catecholaminergic; most PSNS postganglionics are cholinergic. The different neurotransmitter and cotransmitter elements expressed in the postganglionic neurons, as well as numerous postsynaptic receptor subtypes, provide the chemical coding for responses of the PSNS and SNS. This functional organization ensures a varied, powerful, and dynamic push–pull operation of homeostatic systems.

## AUTONOMIC COORDINATION OF HOMEOSTASIS

The “self-governing” or autonomic characteristic that gives its name to the ANS is based largely on

reflexes that involve more than peripheral efferent pathways. Though the early history of autonomic neuroscience emphasized this motor outflow, homeostasis is maintained through the cross-coupling and coordination of multiple reflex arcs. These reflexes involve afferent inputs as well as efferent outputs.

Two major inflows of visceral, or autonomic, afferents (Box 35.2) establish the input arms of the basic reflex arcs. These visceral afferents also provide critical cross-linked feedback between the sympathetic and the parasympathetic outflows, keeping them in balance. For example, sympathetic activity can increase heart rate (tachycardia) and produce constriction of vascular beds, thus leading to an increase in blood pressure. This increase in blood pressure, in turn, is detected by vagus nerve baroreceptors in the aortic arch and other sites. Visceral afferents in the vagus can

## BOX 35.2

### AUTONOMIC REFLEXES: ACTIVATED BY VISCERAL AFFERENTS, AUTONOMIC AFFERENTS, OR JUST AFFERENTS?

A long-standing dispute about terminology still influences discussions of autonomic reflexes. Some authors (and textbooks) adhere to the original autonomic classification of Langley, who considered the ANS a motor system without a corresponding sensory inflow. This classic view acknowledges that autonomic effectors are influenced by afferents but considers visceral afferents, as well as somatic afferents, as independent of the ANS. Conversely, other scientists (and textbooks) consider afferents arising in and associated with the viscera as the necessary counterpart to autonomic efferents and label them autonomic afferents.

The controversy goes back to Langley's concentration on a pharmacological definition of the ANS. In his initial studies, Langley speculated about the existence of autonomic afferents, but was unable to find a neurochemical marker to distinguish visceral from somatic afferents. He sidelined the issue pending more information (his seminal book is subtitled Part I), focused his studies on efferents, and never returned to the search for an afferent marker

(Part II never appeared). Adherents to his original motor-only classification stress that somatic and visceral afferents can elicit autonomic responses and that both classes of afferents elicit somatic responses, as well.

However, advocates for including visceral afferents within the autonomic schema argue that these afferents innervate the target tissues of the ANS efferents, share similar embryological histories with autonomic efferents, course in the same peripheral nerves as the autonomic efferents (e.g., the vagus), and form mono- and oligo-synaptic reflex arcs influencing autonomic preganglionic neurons. These proponents for revision of the autonomic terminology also point out that more recent analyses have identified neuropeptide markers shared by visceral afferents (but not somatic afferents) and autonomic motor neurons. This more inclusive view of the autonomic nervous system seems to be gaining ground. It works more naturally for the discussion of reflexes, and we have adopted it in this text.

*Terry L. Powley*

then reflexively stimulate vagal parasympathetic efferents that slow heart rate (bradycardia). The visceral afferents monitoring the effects of autonomic activity produce positive, reciprocal, and dynamic regulation of physiological responses. When a more sustained adjustment in blood pressure is required (e.g., in the general arousal of the fight-or-flight response discussed earlier), these outflows are adjusted centrally in a process akin to the  $\alpha$ - $\gamma$  linkage so that sympathetic activation is not nullified by parasympathetic responses damping the needed activation.

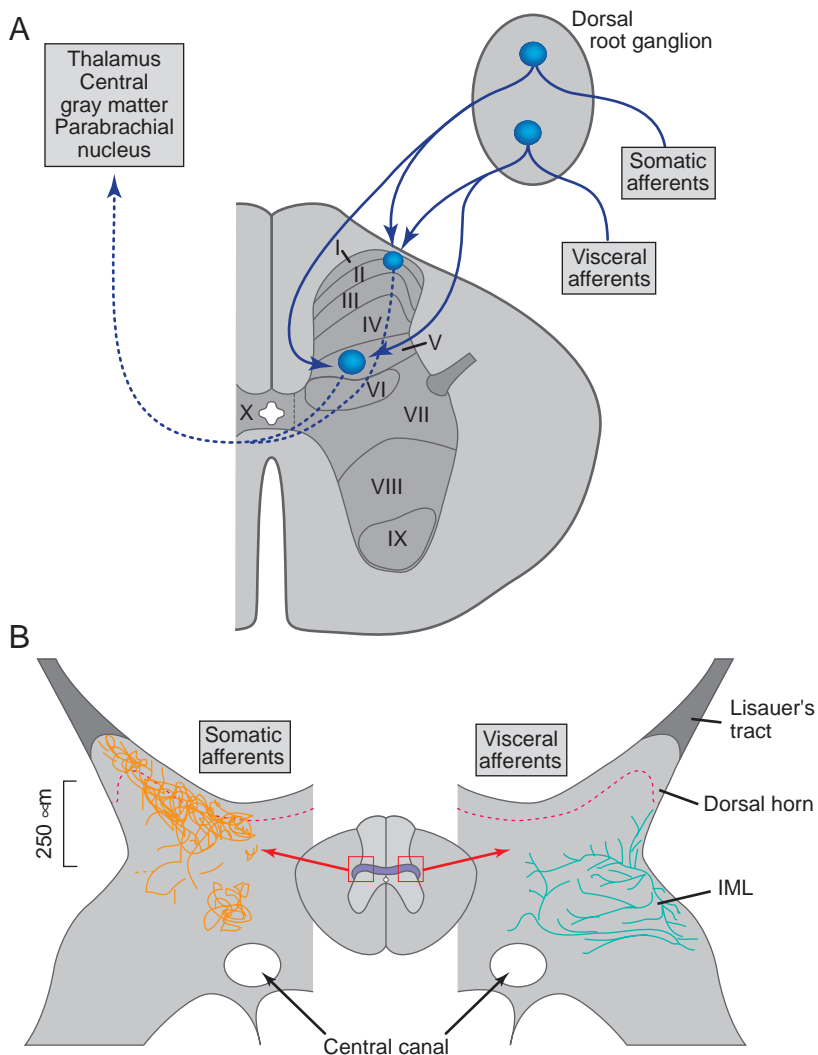

#### Visceral Afferents Link Target Tissues and the CNS

In the case of the sympathetic nervous system, motor neurons receive direct afferent input from most of the autonomic targets. The cell bodies of these primary afferents are located in the dorsal root ganglia of the spinal cord segment(s) in which the corresponding preganglionic neurons are located (Figs. 35.2B and 35.10). Afferent somata are similar to other dorsal root

ganglion cells, although they frequently are distinguishable as small, dark neurons or B afferents. From endings in the innervated viscera or tissue, the centripetally directed peripheral processes of the afferents typically course in mixed nerves that also contain the motor outflow. These processes then reach the dorsal roots through the major peripheral nerves. The central processes of these visceral afferents enter the spinal cord in association with Lissauer's tract, ending in laminae I and V of the dorsal horn (Cervero and Foreman, 1990). For many of these visceral afferents, their endings in the periphery and in the spinal cord contain substance P (SP) and other neuropeptides of the tachykinin family, such as neurokinin A (NKA) and neurokinin B (NKB) (see Lundberg, 1996).

Visceral afferent nerves relay sensory information about visceral volume, pressure, contents, or nociceptive stimuli to spinal centers, where automatic responses are interpreted and functional responses are generated.

In the parasympathetic limb of the ANS, there are two major afferent inflows with different organization.

**FIGURE 35.10** Visceral and somatic afferents follow parallel but distinct paths in the central nervous system. Visceral and somatic afferents consist of different populations of dorsal root ganglion neurons that project to laminae I and V of the dorsal horn of the spinal cord. These relay sites provide local spinal reflexes and also project to higher autonomic and somatic sites, respectively, in the brain (A). Although visceral and somatic afferents follow similar trajectories, more detailed analyses indicate the two types of afferents end in distinctly different distributions and densities within the spinal cord (B). IML, intermediolateral cell column. From Cervero and Foreman (1990).

In the cranial division, visceral afferents most often are found in the same cranial nerve as their corresponding motor counterparts. These mixed cranial nerves have sensory ganglia located outside the cranium, and the cell bodies of the afferents are found in these ganglia. Like other visceral afferents, these neurons are typically pseudounipolar neurons with a peripheral neurite extending to the target tissue and a central process projecting to the CNS. The central terminals of these afferents end in a cranial nerve sensory nucleus. Visceral afferents associated with the outflow of cranial nerve III are complex and enter through different channels (e.g., cranial nerve V, the trigeminal nerve).

Most of the visceral afferents associated with cranial nerve autonomic reflexes terminate in the extensive nucleus of the solitary tract, which is located immediately dorsal to the general visceral column of the brain stem. Specifically, afferents of VII, IX, and X all end in the nucleus of the solitary tract. These inputs form a viscerotopy in the nucleus, with facial gustatory information projecting most rostrally and medially, the glossopharyngeal information somewhat more caudally, and the afferents of the different branches of the vagus nerve terminating most caudally in different subnuclei of the nucleus of the solitary tract. As the largest and most complex of the visceral afferent relays

in the brain, the nucleus of the solitary tract also receives afferent inputs from the spinal division of the trigeminal nerve and second-order inputs from the dorsal column nuclei.

Like visceral afferents associated with the SNS, visceral afferents associated with the PSNS contain SP and other tachykinins. In addition, several neuropeptides found in the gut are also found in some of these afferents. For example, the gut hormone and neuropeptide cholecystokinin (CCK) is found in vagal afferents relaying information from the gastrointestinal tract to the brain. CCK is also found in higher order ascending relays of vagal projections in the neuraxis, leading some to argue that CCK provides chemical coding for visceral afferents associated with the gastrointestinal tract.

The second major inflow of afferents to the parasympathetic limb of the ANS is associated with the sacral division. Visceral afferents in this division are organized much like the spinal afferents associated with the thoracolumbar or sympathetic division of the ANS (e.g., Morgan *et al.*, 1991).

At the central relays of autonomic reflex arcs, the thoracolumbar circuitry of sympathetic reflexes and the craniosacral circuitry of parasympathetic responses have similar morphological elements. The SNS motor neurons preferentially distribute their dendrites within the long longitudinally oriented column that constitutes the intermediolateral nucleus of the spinal cord. The neurons also distribute a subset of their dendrites dorsolaterally in an arch that brings the dendrites into contact with the incoming visceral afferents (e.g., Dembowsky *et al.*, 1985). Parasympathetic preganglionics exhibit similar dendroarchitecture (e.g., Fox and Powley, 1992). This characteristic dendroarchitecture

is consistent with the ideas that local mono- or oligosynaptic reflexes are organized segmentally and at the preganglionic outflows.

### Visceral Afferents Also Organize Axon Reflexes and Signal Visceral Pain

In addition to forming conventional reflex circuits throughout the ANS, at least some visceral afferents support effector responses known as an *axon reflexes*. Unlike a conventional reflex, which typically involves an afferent neuron, at least one central nervous system synapse, and an efferent neuron, axon reflexes involve only the afferent neuron and they occur in the target tissue—without a CNS relay. The phenomenon can be seen clearly in the type of experiment that was instrumental in establishing the existence of axon reflexes. If all motor axons projecting to a target tissue are eliminated by surgery or other appropriate means while sparing the afferent innervation of the site, the afferent axons can be stimulated selectively. When the afferent axons are stimulated such that their peripheral processes innervating the target are invaded antidromically, one can measure an effector response or assay the release of a neuropeptide from the peripheral afferent neurite. Such experiments performed on a variety of different visceral and cutaneous afferent systems have demonstrated that axon reflexes produce a number of inflammatory and vascular effector responses (Lundberg, 1996).

When a peripheral ending of a visceral afferent transduces a stimulus, the resulting action potential can release the neuropeptide contained in vesicles in that ending (Fig. 35.11). The released compound then acts as a neuromodulator or neurotransmitter to

**FIGURE 35.11** The architecture of visceral afferents that produce axon reflexes. Visceral and cutaneous afferents release transmitters from the tachykinin family. When action potentials (indicated by arrows) are generated peripherally, they are propagated centrally. Peripherally generated action potentials also produce a local release of tachykinins in the affected terminals and in terminals of the peripheral collaterals. From Cervero and Foreman (1990).

produce local changes on smooth muscle—a local, or peripheral, axon reflex. The response is also relayed to neighboring tissues. When an action potential is transmitted centrally in an afferent axon, it can also be transmitted centrifugally by collaterals of the same fiber, and release of the neuromodulator from these collateral endings can propagate the reflex in the immediate area. The inflammatory responses and extravasation associated with the classic “wheal and flare” reaction to skin damage were the first axon reflexes analyzed and are a classic illustration of the phenomenon. Such local responses have been widely documented not only in the skin, but also in viscera such as the lungs.

Finally, visceral afferents, particularly those associated with SNS pathways, are responsible for visceral pain (Craig, 2002; Jänig, 1996).

### Summary

Visceral afferents innervate the target tissues of the ANS, and their axons frequently course in the same peripheral nerves as autonomic efferents. Also commonly called autonomic afferents, these sensory elements associated with the ANS constitute the afferent limbs of autonomic reflexes and carry the inputs recognized as visceral pain. Visceral afferents also mediate axon reflexes and are cross-linked with somatic, as well as autonomic, nervous system activity.

## HIERARCHICALLY ORGANIZED ANS CIRCUITS IN THE CNS

Homeostasis no more occurs through isolated autonomic reflexes than posture is maintained, or movement is executed, through isolated somatic reflexes. Nevertheless, methodological and historical considerations have yielded a tendency to focus on individual autonomic reflexes. Methodologically, the need for experimental control typically dictates that experiments isolate a reflex (or small set of reflexes) for examination. In addition, historically, the ANS was conceptualized primarily as a motor branch of the peripheral nervous system.

Though the separate-reflex perspective shapes a view of ANS functions as a collection of individual motor responses, autonomic activity typically involves finely coordinated, fully integrated adjustments of multiple outflows. Just as somatic posture and movement are coordinated by supraspinal CNS controls, autonomic integration is achieved by supraspinal controls. The preganglionic motor pools of the cranio-

sacral and thoracolumbar outflows are final common paths for descending projections from the CNS. Similarly, the first- and second-order visceral afferent relays (e.g., the nucleus of the solitary tract and the spinal lamina V), which form short, mono-, or oligosynaptic reflex arcs with these preganglionic motor pools, are targets of rostral CNS stations that coordinate and modulate the autonomic outflows.

The CNS coordination of autonomic activity achieves a number of integrative functions:

- Much like the suprasegmental organization of skeletal motor responses, central ANS stations provide coordination and sequencing of different local autonomic reflexes. These stations provide, for example, the efferent choreography necessary to coordinate the sequential autonomic responses in the mouth, stomach, intestines, and pancreas during and after a meal. Such programs coordinate brain stem and spinal cord efferents, as well as reflexes within the SNS and PSNS divisions of the autonomic outflow.
- Central ANS circuitry also cross-links autonomic activity and somatic motor activity. The example used earlier of cardiovascular adjustments occurring in concert with postural adjustments illustrates such linkage between autonomic and somatic nervous system outflows.
- The CNS stations of the autonomic nervous system also provide the information, as well as the organization and planning, that enables an organism to mobilize autonomic adjustments or responses in anticipation of environmental contingencies and developing needs. For example, both fluid and energy homeostasis involve physiological adjustments in anticipation of major imbalances or deficits, responses that cannot be explained solely by reactive reflexes.

The importance and the nature of central autonomic controls are underscored by clinical disorders that result from interruptions in the connections between the central autonomic circuitry and the preganglionic motor neurons (Box 35.3). Quadriplegia and paraplegia, which result from injuries that divide the separate thoracic and lumbar sympathetic loops and sacral parasympathetic pathways from higher central regions, illustrate how essential these longitudinal connections are. Interruption of the longitudinal connections causes loss of voluntary bladder and bowel control. Disruption of the spinal cord also causes men to become impotent because penile tumescence is a predominantly parasympathetic response and ejaculation is a sympathetic response. Although erections can occasionally be elicited as local reflexes caused by direct

## BOX 35.3

## DISEASES AND AGING IMPAIR THE AUTONOMIC WISDOM OF THE BODY

The importance of the autonomic nervous system to health often goes unnoticed. When ANS functions operate normally, they typically occur automatically, without the individual being aware of any adjustments. Nevertheless, loss of an autonomic response can be disruptive, and autonomic disorders can be debilitating (Bannister, 1989). In a classic example of ANS degeneration known as multiple system atrophy and autonomic failure, or the Shy-Drager syndrome, individuals exhibit postural hypotension, urinary and fecal incontinence, sexual impotence, loss of sweating, cranial nerve palsies, and a movement disorder similar to Parkinson's disease. Disconnection of the suprasegmental autonomic stations from the spinal cord can occur in neurological disorders, such as multiple sclerosis, and traumatic spinal cord injury. As a result, bowel and bladder control are lost, and impotence is caused by a loss of autonomic genital reflexes.

Some autonomic disorders are less conspicuous. In part, the apparently more subtle deficits may be ones that are less important in the carefully controlled environments found in modern societies. For example, impaired thermoregulatory responses may be tolerated well by a person living in a climate-controlled environment. Also, metabolic emergencies are unlikely to occur and need autonomic compensation if a person regularly eats enough food. Nevertheless, autonomic disorders occasion a number of serious, even life-threatening, health problems.

Autonomic imbalances can take many different forms. Excess activation of the ANS is implicated in various stress-related disorders, including ulcers, colitis, high blood pressure, and heart attacks. As discussed earlier,

chronic failure of autonomic cardiovascular homeostasis can cause debilitating postural hypotension. Developmental autonomic disorders, such as immature or anomalous medullary respiratory circuitry, are thought to contribute to sudden infant death syndrome. Some sleep disorders, such as sleep apnea, are also thought to have autonomic elements. Furthermore, widespread autonomic dysfunction resulting from autonomic neuropathies of diabetes, alcoholism, and Parkinson's disease complicates the primary diseases. Autonomic disturbances can also underlie metabolic disorders, such as stress-induced diabetes and reactive hypoglycemia. Autonomic disturbances have also been hypothesized to be a cause of obesity.

Autonomic function is not only impaired by diseases, it is also compromised by aging processes—even those of healthy aging (Amenta, 1993). With aging, both cell losses and neuropathies of surviving neurons occur in ANS circuits. Such age-related changes in the ANS reduce an individual's ability to optimize and sustain homeostatic responses. These consequences of aging produce both primary autonomic disorders and secondary complications and vulnerabilities when the individual is challenged by disease or injury.

mechanical stimulation, ejaculations, which require suprasegmental coordination, almost universally disappear. In addition, numerous vascular and glandular reflexes are also disordered by the interruption of long autonomic pathways connecting the brain and spinal cord (Bannister, 1989).

### Early Stimulation and Lesion Experiments Identified a Central Component of the ANS

Like the concept of the ANS itself, the corollary that the ANS includes a hierarchy of central mechanisms

was first demonstrated by physiological experiments. Nineteenth- and early twentieth-century experiments manipulating the brain caused autonomic disturbances. In one classical experiment, for example, Claude Bernard demonstrated that localized mechanical lesions, or stab wounds, in the floor of the fourth ventricle near the dorsal vagal complex produced a "pique glycosurique," a disturbance of blood glucose homeostasis characterized by a diabetes-like condition in which glucose spills into the urine. Subsequent lesion and stimulation studies identified a number of "centers" for micturition, respiration, and

other autonomic functions in the medulla oblongata and pons.

Other experiments implicated the hypothalamus in even more extensively coordinated and cross-linked autonomic patterns. This work led to the concept of the hypothalamus as the "head ganglion" of the autonomic nervous system. Following an earlier application of electrical stimulation to the hypothalamus by Karplus and Kreidl, Walter Hess found that focal electrical stimulation of regions of the hypothalamus elicited coordinated patterns of sympathetic and parasympathetic adjustments (e.g., changes in pupil size, piloerection, and respiration) and affective responses that were appropriate to behavioral responses elicited from the same loci. In fact, central manipulations that affect autonomic function seem practically invariably to produce adjustments of both SNS and PSNS outputs, an observation that underscores the integrative role the brain plays in ANS function.

Brain lesions in virtually all limbic system regions, and notably in the septal area, amygdala, hippocampus, frontal cortex, cingulate cortex, and insular cortex, have been shown to exaggerate, dissociate, blunt, or in other ways distort autonomic responses to environmental situations.

### **Anatomical Mapping Experiments Have Identified Multiple Hierarchically Organized, Reciprocally Interconnected Stations of the Visceral Neuroaxis That Control Autonomic Activity**

As neuroscience tracing tools have become more powerful, they have revealed an extensive CNS autonomic control hierarchy coupling visceral afferent inputs with autonomic efferent outflows, linking the SNS and PSNS divisions of the ANS, and interconnecting the central autonomic stations with somatic and endocrine pathways in the brain (Box 35.4). This central autonomic circuitry has been considered a "central visceromotor system" (Nauta, 1972) or a "central autonomic network" (Loewy, 1981). These studies revealed a network of multisynaptic relays descending from the hypothalamus and midbrain to preganglionic neurons in the brain stem and spinal cord. Similar projections, both direct and relayed through the hypothalamus, were also found for a number of limbic system nuclei, including most prominently the amygdala (Nauta, 1972). Neural tracers, immunocytochemical techniques, and electron microscopy subsequently have increased the resolution of the maps of this circuitry and its transmitters (e.g., Loewy, 1981).

The paraventricular nucleus of the hypothalamus is a prototype of the extensive and profound central autonomic coordination. Parvocellular neurons in the paraventricular nucleus project monosynaptically to preganglionic neurons in the dorsal motor nucleus of the vagus and preganglionics in the intermediolateral column of the spinal cord. The paraventricular nucleus also projects to the visceral afferent relay nuclei associated with each of these efferent outflows (the nucleus of the solitary tract and spinal lamina V, respectively). These descending projections influence several cardiovascular and gastrointestinal responses. Illustrating the extent of the central integration of responses, additional neurons of the paraventricular nucleus control corticotropin-releasing factor and oxytocin neuron responses, which often are activated or modulated in association with autonomic functions.

Most mesencephalic, diencephalic, and telencephalic nuclei considered part of the limbic system affect visceral motor outflows and are now included in the concept of the central visceromotor system. In addition to the central gray and paramedian regions of the mesencephalon and the entire hypothalamus, including the preoptic hypothalamus, these limbic sites include the amygdala, bed nucleus of the stria terminalis, septal region, hippocampus, cingulate cortex, orbital frontal cortex, and insular and rhinal cortices.

### **Summary**

Multiple subcortical and diencephalic structures impose special controls over the ANS. This network of hierarchically organized central stations, many of them part of the limbic system, forms a central visceral neuroaxis that receives inputs from visceral afferents and issues descending projections to the ANS preganglionic neurons in the brain stem and spinal cord. This central autonomic circuitry organizes and sequences sets of separate autonomic reflexes, coordinates SNS and PSNS responses so that they are synergistic, cross-links autonomic and skeletal responses, and integrates autonomic activity with ongoing and anticipated behavior of the individual.

## **PERSPECTIVE: FUTURE OF THE AUTONOMIC NERVOUS SYSTEM**

Our understanding of the autonomic nervous system is incomplete and evolving, driven by the technological advances in neuroscience. Molecular biology, immunocytochemistry, electron microscopy, and other

## BOX 35.4

## CENTRAL ANS CIRCUITS INTEGRATE AUTONOMIC REFLEXES WITH AFFECTIVE OR EMOTIONAL RESPONSES

The autonomic nervous system participates in emotion and motivation. Consider the fight-or-flight example that Cannon used in his characterizations of autonomic adjustments and that was discussed earlier in this chapter: The somatic and autonomic adjustments in this emergency situation contain elements we associate with anger or fear. The central relays, including the limbic circuitry just discussed, organize the autonomic components of these responses to external environmental stimuli and coordinate them with the appropriate somatic responses. Thus, the central ANS circuitry is involved in the *expression* of emotional reactions. This central circuitry has been called the “emotional motor system.”

Some have hypothesized that in addition to being involved in the expression of emotions, the ANS is the substrate for the *experience* of emotions. The classic theory of this type was suggested over a century ago independently by James and Lange, who speculated that afferent experience resulting from autonomic adjustments might be the basis of emotional experiences. For the fight-or-flight example, the James–Lange idea could be considered the proposition that “you do not run because you are afraid; you are afraid because you run (and mobilize the requisite autonomic adjustments).” Cannon, in the early twentieth century, offered an influential refutation of the James–Lange theory and delayed general acceptance of these ideas, but most of his argument was based on now-outmoded ideas about the ANS and on a lack of distinction between expression and experience.

In an experiment designed to examine the James–Lange idea, Hohmann (1962) surveyed army veterans

who had sustained spinal cord injuries at different levels. Consistent with a prediction of the theory, Hohmann found that, for the veterans’ self-reported experiences of both fear and anger, the higher their spinal cord lesions (and thus the more of their visceral afferent inflow that was disconnected from the brain), the greater the reduction in their affective experiences.

More recently, extensive observations with neuropsychological analyses of patients with brain damage and spinal injury, with fMRI and other scanning techniques, and with modern electrophysiological techniques combined with tracing, have converged to suggest that emotions or “feelings” are central—specifically limbic system—representations of visceral afferent inputs. Recently, in views compatible with the James–Lange account of emotion, Damasio (1999), Craig (2002), and others have suggested that emotional experience is to the autonomic adjustments of the body what proprioception and somatosensation are to skeletal nervous system operations.

modern techniques are changing the autonomic nervous system definition that was derived with the techniques available to Langley and contemporaries at the beginning of the twentieth century. The distinction that sympathetic postganglionic neurons are noradrenergic whereas parasympathetic postganglionics are cholinergic has been blurred by the recognition of non-adrenergic noncholinergic (NANC) neurons, nitric oxide synthetase (NOS)-containing neurons, puriner-

gic synapses, a large number of colocalized and co-released neuropeptides, postganglionic neurons changing their neurotransmitter phenotypes, and other exceptions that broaden the view developed by Langley’s pharmacological studies. The canon that the ANS is strictly a motor system without an afferent counterpart is challenged by many who argue on functional and molecular biological grounds that “visceral afferents” belong to the ANS (Box 35.2).

The proposal that functional differences between the SNS and PSNS divisions of the ANS can be attributed to their contrasting patterns of projection (the sympathetic system preganglionics projecting to postganglionics in a one-to-many pattern; the parasympathetic system projecting in a one-to-few pattern) has not been substantiated by modern analyses of divergence (Wang *et al.*, 1995). Continued application of modern technologies and the prospect of continuing developments promise to define an autonomic nervous system quite different from that envisioned by Langley.

## SUMMARY AND GENERAL CONCLUSIONS

The autonomic nervous system is the neural circuitry that maintains homeostasis and health. It is responsible for the physiological adjustments that achieve what Cannon recognized as the "wisdom of the body." With its sophisticated motor repertoire and complexes of reflexes, including local axon reflexes, segmental or oligosynaptic reflexes, and polysynaptic suprasegmental cascades, the ANS continuously adjusts and defends the body's physiology. The importance of these processes was summarized succinctly by Nauta and Feirtag (1986): "Life depends on the innervation of the viscera; in a way all the rest is biological luxury." The processes go on, for the most part, without awareness or cognitive representations.

The hub of the ANS consists of two separate motor outflows, each hierarchically organized with preganglionic neurons stationed in the CNS and postganglionic neurons located in peripheral ganglia. The sympathetic, or thoracolumbar, division facilitates the mobilization of energy, increases catabolism, and promotes physiological responses that support activity, including emergency responses such as "fight" or "flight." The parasympathetic, or craniosacral, division facilitates conservation of energy, increases anabolism, and supports physiological responses that typically promote rest, digestion, and restoration of body reserves. The adrenergic phenotype of sympathetic postganglionic neurons, the cholinergic phenotype of parasympathetic neurons, and distinguishing complements of neuropeptides and receptor specializations provide neurochemical coding for the two divisions of the ANS. A key peripheral pole—and third distinct division of the ANS—is the enteric nervous system found in the wall of the digestive tract.

The motor outflows of the ANS are efferent limbs of reflexes triggered by visceral and, in some cases,

somatic afferents. These reflex circuits have second-order visceral afferent nuclei located adjacent to spinal and medullary nuclei of preganglionic motor neurons (laminae I and V and the nucleus of the solitary tract, respectively).

Higher order CNS circuitry, including the hypothalamus, limbic system, and a variety of cortical sites, provides hierarchical control and integration of autonomic reflexes. This hierarchy is responsible for coordinating different autonomic reflexes, integrating autonomic function with somatic activity, and executing response programs that anticipate needs and regulate physiology over more extended time scales than those represented by isolated reflexes.

# Neural Regulation of the Cardiovascular System

The circulatory system, which includes the heart and the vascular system, distributes oxygen and nutrients and eliminates waste products of metabolically active cells in all organs. The heart's synchronized muscular pumping action provides kinetic energy to circulate blood that is distributed in accordance with the particular needs of each organ. Organ blood flow is critically dependent on driving pressure (blood pressure) and regional vascular resistance. The nervous system regulates vascular resistance, cardiac output, and hence arterial blood pressure.

The body must cope with diverse conditions varying from bed rest to maximal exercise, cold to hot environments, ocean depths to sea level to high altitude, including space flight, and fear to arousal. Clinical conditions like hypotension or hypertension, myocardial infarction and congestive heart failure, acute asthma (bronchoconstriction), and chronic renal failure represent a few of the varied conditions to which the cardiovascular system must respond to provide optimal organ function.

Short- and long-term regulatory mechanisms allow the cardiovascular system to meet these challenges. Two are critically important for short-term cardiovascular adjustments. These include neural reflexes activated by sensory systems that monitor the internal and external environment and rapidly alter cardiovascular function. Second, behavioral changes adjust cardiovascular function to cope with the environment, including, among others, changes in body position, activity level, and conscious changes in environmental exposure, such as avoidance. Other behavioral changes like the defense reaction or central command are involuntary and constitute primitive survival mechanisms, allowing higher organisms to respond quickly to adverse or stressful conditions like

exercise. This chapter focuses on neural regulation of the cardiovascular system, rather than on behavioral modifications.

## AN ANATOMICAL FRAMEWORK

Neural regulation of the cardiovascular system includes two sets of interactive functional elements. One set of regulatory elements consists of regions in the central nervous system (CNS) that maintain basal or tonic output that, through the autonomic nervous system, continuously influences effector organ function, the heart and vascular system. The second system provides phasic regulation of cardiovascular function and consists of a large number of neural reflexes, each of which is composed of an afferent or sensory arm, regions in the CNS that integrate multiple sensory inputs, and an efferent or autonomic arm. *Cardiovascular reflexes* are differentiated by unique features of their sensory component and effector organ responses. Short and long-loop reflexes are initiated by stimulation of sensory nerve endings positioned in locations that provide the ability to sense the local environment. These afferent endings are depolarized by chemical, mechanical, or thermal stimuli or to a combination of events (i.e., bimodal or polymodal function). Afferent impulse activity is transmitted through finely myelinated or unmyelinated, group III/A $\delta$  and group IV/C somatic and visceral nerve fibers. The sympathetic nervous system responds not globally but with individual patterns of activity depending on the reflex (e.g., baroreceptor, chemoreceptor, and cardiopulmonary) as a result of supraspinal organization. Several CNS regions are involved in the integrative aspect of

the reflexes, as well as the autonomic component of the responses.

### Anatomy of Somatic and Sympathetic Afferent Reflexes

Sympathetic or spinal afferent systems initiating somatic and visceral cardiovascular reflexes are stimulated by *nociceptive* and *non-nociceptive signals*. Primary afferents, with cell bodies in dorsal root ganglia, transmit nociceptive signals to the spinal cord through Lissauer's tract to laminae I and V of the dorsal horn gray matter. Fine afferents may contain substance P, calcitonin gene-related peptide, somatostatin, and vasoactive intestinal polypeptide. Spinal pathways ascend one or two segments before crossing to the contralateral side. Through *spinothalamic*, *spinoreticular*, *spinomesencephalic*, and *spinosolitary tracts*, these systems transmit information to the brain stem and thalamus, ultimately influencing autonomic outflow to the cardiovascular system, in addition to providing sensory perception. Many cells in these tracts respond to noxious stimuli and are classified as low-threshold, wide dynamic range (most common) and high-threshold (nociceptive). Neurons in the lateral spinothalamic tract ascend to the ventral and ventral posterior lateral thalamus where they mediate discriminative or localization of pain. Neurons in the medial spinothalamic tract projecting to the medial and intralaminar nuclear complex of the thalamus transmit information leading to affective responses, including autonomic adjustments. Cells in the spinoreticular tract respond to chemical (bradykinin) and mechanical (premature beats) stimulation of cardiac ventricular afferents. They project to the gigantocellular tegmental field (paramedian reticular formation) and, to a lesser extent, to the caudal raphe nuclei and magnocellular tegmental field (ventromedial reticular formation), which, in turn, project to the intralaminar region of the thalamus.

The medial reticular formation mediates motor responses to visceral (including cardiac) pain and altered sympathetic function through premotor collaterals to spinal intermediolateral column (IML) containing *sympathetic preganglionic neurons* or through interneurons projecting to other regions, such as the nucleus tractus solitarii (NTS) and rostral ventral lateral medulla (rVLM), concerned with integration of sensory signals that drive autonomic outflow. The spinomesencephalic tract sends information to the central periaqueductal gray (PAG, also called the central gray matter) and parabrachial nucleus (PBN) in the rostral pons, and possibly the ventral lateral nucleus of the thalamus. The spinosolitary tract projects to the caudal NTS (Loewy and Spyer, 1990).

### Anatomy and Pharmacology of Baro- and Chemoreflex Pathways

The IX (glossopharyngeal) and X (vagus) cranial nerves transmit signals from arterial baroreceptors and chemoreceptors, as well as cardiac receptors, including both atrial and ventricular receptors to the CNS. Temporal and spatial integration of sensory information occurs in the CNS, in addition to modification resulting from convergent input from other afferent pathways. Important "cardiovascular" CNS regions that process sensory input include, among others, the NTS, caudal ventral lateral medulla (cVLM), rVLM, PBN, raphe nuclei, and lateral tegmental field (LTF). Other areas in the medulla, hypothalamus, and midbrain identified as important sites of integration include the area postrema, PAG, vestibular region, arcuate nucleus, and paraventricular nucleus. Each region receives input either directly from afferents or, more commonly, through second or higher order interconnections (interneurons) from other nuclei. Each participates in signal conditioning to an extent dictated by the overall input and underlying conditions. Thus, many central autonomic pathways form the anatomical substrate for reflexes involved in cardiovascular regulation. Although these can be separated broadly into CNS regions subserving spinal or sympathetic sensory pathways and regions that integrate visceral vagal afferent input, there is significant overlap of regions that process information from the two systems.

### Nucleus Tractus Solitarii

The NTS receives direct input from vagal and glossopharyngeal sensory nerves originating in the heart and large arteries (mechano- or baro- and chemosensitive regions). It lies just ventral to the dorsal columns and is divided into the rostral, intermediate, and caudal NTS, relative to the obex. The intermediate NTS contains a central fiber bundle or solitary tract formed by sensory input from VII, IX, and X cranial nerves. Visceral afferents from the heart, lungs, and gastrointestinal regions project to neurons in the commissural medial NTS. Cardiovascular afferents from the heart and great vessels project to the dorsolateral, medial, and commissural regions of the NTS. Few solitary tract neurons have pulse synchronous activity, possibly due to convergent input from baroreceptor and nonbaroreceptor inputs. Ionotropic glutamatergic receptors, including *N*-methyl-D-aspartate (NMDA) and non-NMDA (e.g.,  $\alpha$ -amino-3-hydroxy-5 methyl-4-isoxazolepropionate, AMPA) subtypes, excite neurons in the NTS and throughout many other regions of the

CNS that process cardiovascular reflexes. Non-NMDA glutamate receptors mediate fast synaptic transmission, whereas NMDA receptors provide slower and longer signaling. Although glutamate appears to be the most important neurotransmitter for reflex transmission and processing in the NTS, other neurotransmitters, neuropeptides, and neuromodulators, including catecholamines, acetylcholine,  $\gamma$ -aminobutyric acid (GABA), substance P, angiotensin, nitric oxide (NO), and opioids, regulate activity of these interneurons.

There are important interactions between the NTS and other nearby nuclei like the area postrema, which functions as a *circumventricular organ*, since it is devoid of tight endothelial junctions that form the blood brain barrier. Neurons in the NTS project to forebrain nuclei including the limbic system, central nucleus of the amygdala, paraventricular, and median hypothalamic preoptic nuclei. There also are reciprocal connections between the NTS and A5 cell group, caudal raphe nuclei, rVLM, PAG, paraventricular, and lateral hypothalamic regions. Reciprocal connections are a major feature of this central autonomic network, which serves as a microprocessor to integrate signals from receptive regions important in cardiovascular control that change autonomic and neuroendocrine outflow and modify behavior ultimately to regulate cardiovascular function (Undem and Weinreich, 2005).

### Caudal Ventrolateral Medulla

Second-order neurons from the NTS project to the cVLM where they provide tonic excitation mediated by an NMDA glutamatergic mechanism. Excitation from angiotensin II and inhibition from GABA, glycine (or a glycine-like compound), and opioids also tonically regulate activity of cVLM neurons. Third-order neurons from the cVLM, through a GABAergic mechanism, influence the activity of sympathetic premotor neurons in the rVLM and A5 cell group (Fig. 36.1). The cVLM contains noradrenergic (A1) and nonadrenergic (retro or caudal periaqueductal area) neurons. Lesions of the cVLM increase arterial blood pressure, whereas microinjections of glutamate into this region cause depressor responses resulting from sympathoinhibition and, to a lesser extent, activation of vagal motoneurons in the nearby nucleus ambiguus. Mapping studies suggest that cVLM depressor sites do not involve the A1 noradrenergic cell group.

### Rostral Ventrolateral Medulla

The rVLM, also called the *subretrofacial nucleus*, located rostral to the lateral reticular nucleus, caudal

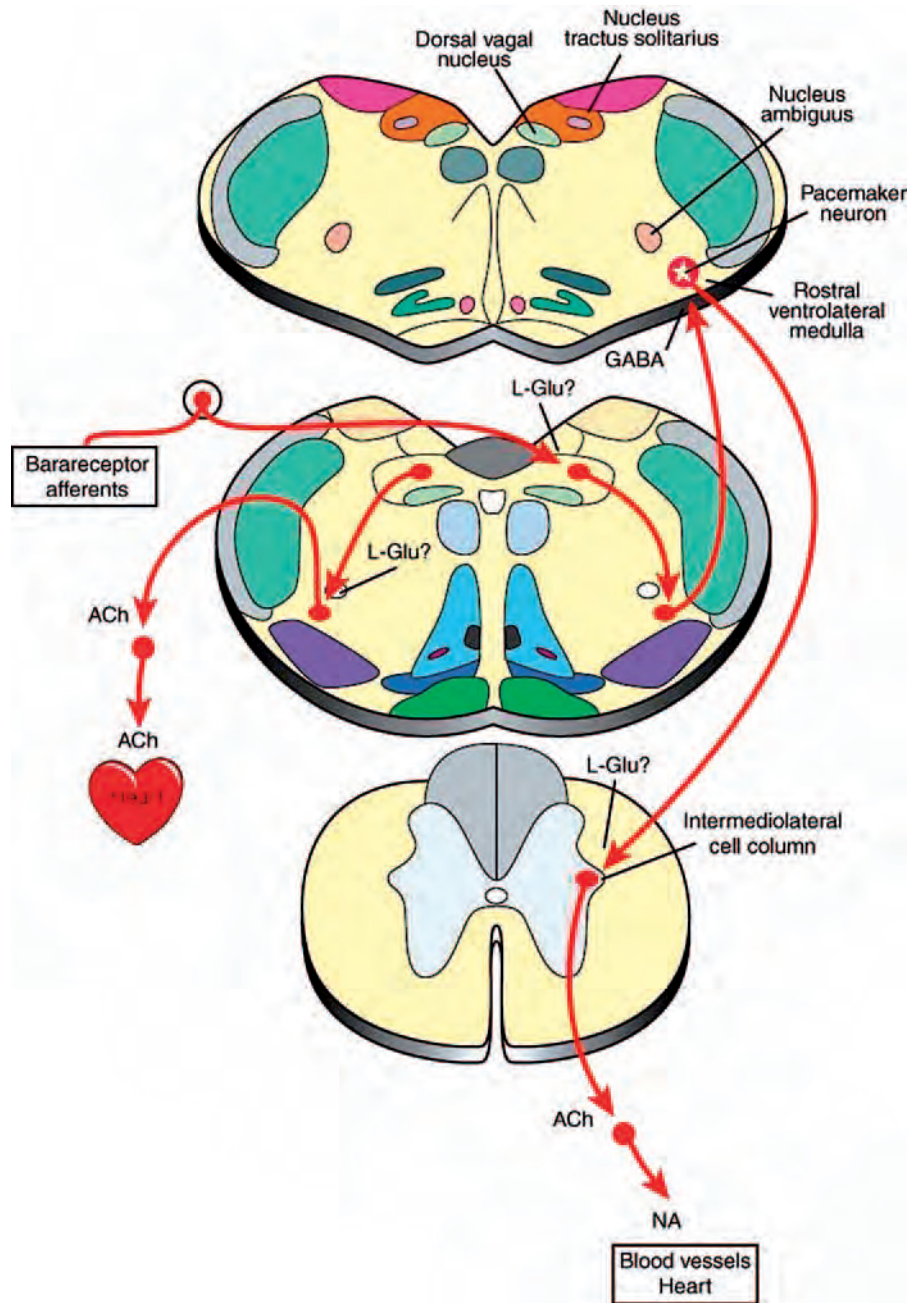

to the facial nucleus, and lateral to the olivary nucleus, is an important site of integration. The medial region of this nucleus is the source of many bulbospinal sympathetic premotor cells that project to the IML located in the lateral horn of spinal gray matter. The rVLM is subdivided into a lateral subretrofacial nucleus and a medial nucleus paragigantocellularis (PGL), called pressor regions because chemical lesions elevate blood pressure. The rostral extension of the PGL is concerned with pain control rather than cardiovascular regulation. In addition to reciprocal connections between the rVLM and the medial NTS, the rVLM receives inputs from the area postrema, cVLM, and is connected reciprocally to midline (raphe) medullary nuclei, parabrachial complex, PAG, lateral hypothalamic area, zona incerta, and paraventricular hypothalamus.

A number of sympathetic premotor neurons receive convergent input from somatic and visceral afferents. Although many rVLM neurons are phenotypically adrenergic (C1 group), glutamate is the principal excitatory neurotransmitter. Blockade of excitatory amino acids does not alter resting blood pressure, indicating that tonic excitatory outflow does not exist. Conversely, blockade of GABA, which serves as the inhibitory neurotransmitter in barosensitive premotor sympathetic neurons projecting from cVLM to rVLM, increases their discharge activity and blood pressure. Other important neurotransmitters in the rVLM include acetylcholine and angiotensin, which also may be tonically active. Opioids (enkephalins, endorphins, endomorphin, and dynorphin), serotonin, neuropeptide Y, nociceptin, substance P, somatostatin, nitric oxide, and/or thyrotropin-releasing hormone are not tonically active and may act as neuromodulators.

Some vasomotor cells in the rVLM discharge with a cardiovascular rhythm, which can be measured directly or over time with pulse or spike triggered averaging, a time domain analysis relating intermittent unit activity to the cardiovascular cycle or sympathetic activity (Fig. 36.2). Many nonadrenergic rVLM cells display intrinsic pacemaker activity with spontaneous depolarization (see later for more detail). Most C1 cells containing phenylethanolamine-N-methyltransferase or tyrosine hydroxylase do not show pacemaker activity. Clusters of rVLM neurons provide selective input to regional vascular beds like skin and muscle (Fig. 36.3) (Loewy and Spyer, 1990).

### A5 Cell Group

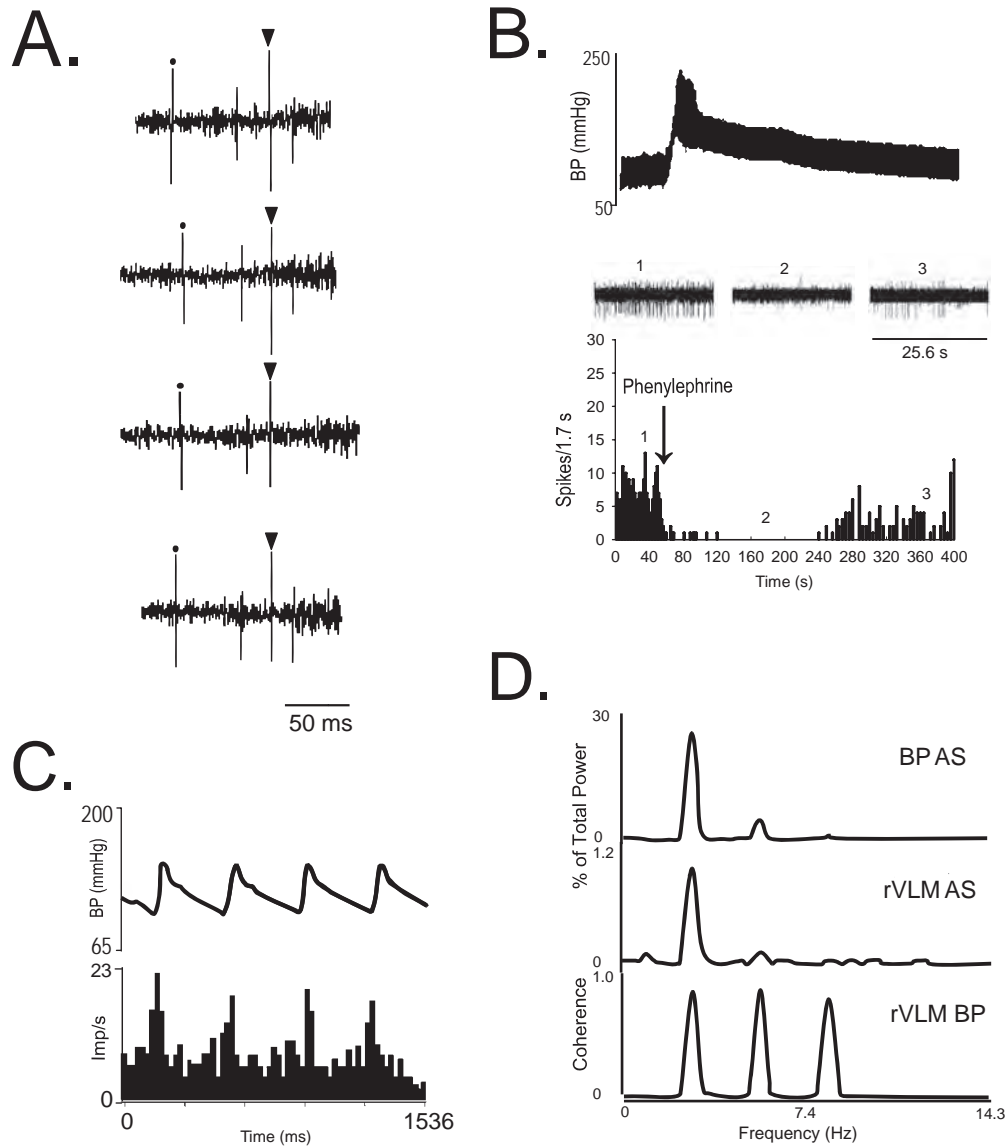

The A5 noradrenergic cell group located in the rostral-most portion of the ventrolateral medulla is distinct from the rVLM. These neurons receive input

**FIGURE 36.1** Neural pathways for the arterial baroreflex. Primary afferents in the IX and X cranial nerves project to the NTS. As shown on the right, interneurons forming sympathetic pathways project from the NTS to the caudal ventrolateral medulla, which in turn project to the rVLM, the source of reticulospinal projections to the intermediolateral columns in the spinal cord. Pathways from the NTS to the nucleus ambiguus form the major parasympathetic arm of the reflex, GABA,  $\gamma$ -aminobutyric; L-glu, L-glutamate; ACh, acetylcholine; NA, norepinephrine (Guyenet, 1990).

from the paraventricular hypothalamic nucleus, parafornical hypothalamic area, PBN, NTS, raphe obscurus, and cVLM. In turn, A5 neurons project to the NTS, dorsal vagal nucleus, PBN, lateral hypothalamic area, paraventricular thalamic nucleus, PAG, central nucleus of the amygdala, and the IML. The function of this cell

group is unclear, although it probably does not tonically regulate blood pressure (Loewy and Spyer, 1990). Stimulation of cells in this region decreases blood pressure and redistributes blood flow. A5 cells are inhibited by baroreceptor input and thus are sympathoexcitatory (Dampney, 1994a).

**FIGURE 36.2** Responses of excitatory cardiovascular sympathetic premotor rVLM neuron receiving convergent input from ventrolateral PAG, median and splanchnic nerves. The bulbospinal projection of this neuron was demonstrated when an evoked orthodromic rVLM action potential (●) collided with an antidromic potential from the IML (▼), canceling the orthodromic spike (A, third sweep). Stimulation of baroreceptors with phenylephrine-evoked increase in blood pressure transiently reduced discharge of the sympathoexcitatory cardiovascular rVLM neuron (B) that discharged with a cardiovascular rhythmicity, shown by time domain pulse triggered averaging (C) and frequency domain coherence analyses (D). See text and Figure 36.6 for further explanation of mathematical methods used to assess relationship between neuronal and cardiovascular activity. (Modified from Tjen-A-Looi *et al.*, 2006.)

## Intermediate Ventrolateral Medulla

The iVLM, located between the cVLM and the rVLM, is an essential component of the baroreflex in rabbits and possibly rats. Like the cVLM, the iVLM projects to the rVLM. Most neurons are not immunoreactive for tyrosine hydroxylase and therefore are distinguished from A1 cells located in this region (Dampney, 1994a).

## A1 Cell Group

The noradrenergic A1 cell group in the cVLM is an important central component of the baroreflex. These neurons project directly to supraoptic and paraventricular hypothalamic regions and mediate vasopressin release during baroreflex unloading. Cells in the A1 region are under tonic GABA inhibition from the NTS.

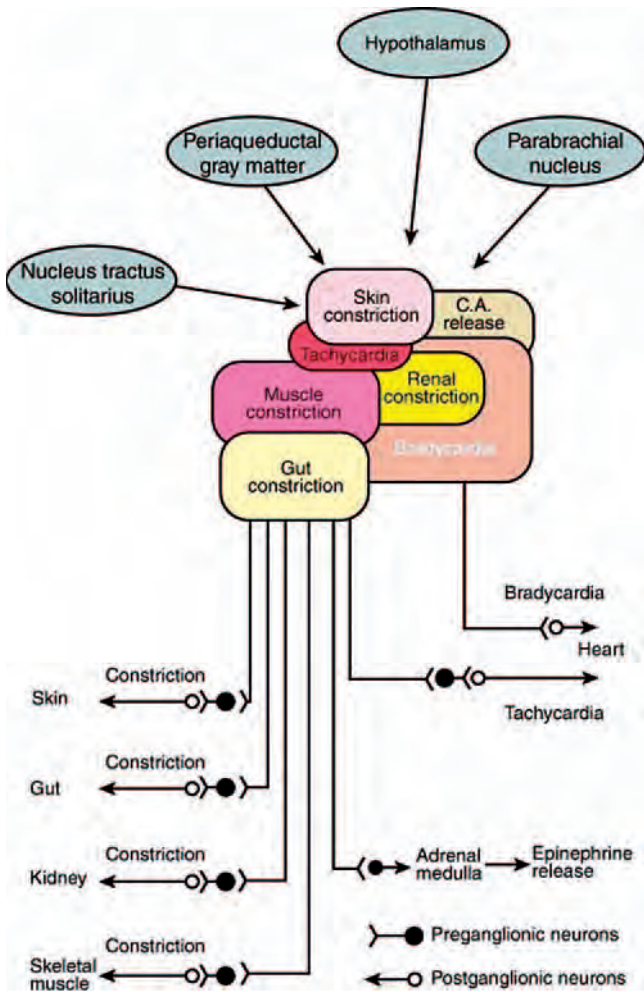

FIGURE 36.3 Inputs and outputs from the rVLM. A number of regions in the hypothalamus, midbrain, and medulla project either directly or indirectly to presympathetic neurons in the rVLM. Distinct but overlapping pools of neurons are present in this region that provide separate sympathetic inputs to different regional vascular beds, the heart, and the adrenal medulla. C.A., catecholamine (Lovick, 1987).

### Periaqueductal Gray

The PAG, surrounding the cerebral aqueduct in the midbrain, receives inputs from NTS, hypothalamus, and PBN and projects to the medullary reticular formation. Activation of the dorsolateral PAG leads to a defense reaction, including an increase in blood pressure (Box 36.1). The ventrolateral PAG is a depressor region that receives input from the arcuate nucleus, medullary raphe nuclei, visceral and somatosensory systems. It regulates sympathetic outflow to muscle and kidney in a viscerotopic manner by influencing activity in the rVLM (Tjen-A-Looi *et al.*, 2006).

### Hypothalamus

Several specialized groups of hypothalamic neurons are important in cardiovascular regulation. The hypothalamus is divided into the anterior, posterior, and middle regions. The anterior region, overlying the optic chiasm, includes the circadian pacemaker (suprachiasmatic nucleus) as part of the preoptic nucleus, which controls blood pressure cycles, body temperature, and a number of hormones. The middle portion of the hypothalamus, overlying the pituitary stalk, is composed of dorsomedial, ventromedial, paraventricular, supraoptic, and arcuate nuclei. The paraventricular nucleus projects to sympathetic and parasympathetic premotor neurons in the medulla and spinal cord. The arcuate nucleus synthesizes opioid peptides, which modulate neuronal function in regions like the ventrolateral PAG and rVLM. The arcuate nucleus is part of a long-loop pathway that modulates visceral afferent related increases in sympathetic outflow during somatic afferent stimulation (see section on reflex interactions).

The hypothalamus directly and indirectly controls endocrine function. Large (magnocellular) neurons in paraventricular and supraoptic nuclei release vasopressin or oxytocin into the circulation from the posterior pituitary. *Vasopressin* neurons in magnocellular and paraventricular nuclei have a phasic pacemaker pattern of discharge activity. Vasopressin is produced as a prohormone in the cell bodies. Prohormones are cleaved as they are transported down axons in vesicles to the posterior pituitary where they are released as the active hormone. As suggested by its name, vasopressin vasoconstricts many regional circulations, particularly skin and muscle. Vasopressin also is called antidiuretic hormone (ADH) since it promotes water reabsorption in renal collecting tubules and expands plasma volume; both actions augment blood pressure. Hypothalamic input from atrial, baroreceptor, chemoreceptor, and somatic (muscle) afferents leads to vasopressin release.

## ANATOMY AND CHEMICAL PROPERTIES OF AUTONOMIC PATHWAYS

### Sympathetic

Outputs from the CNS to effector organs involved in cardiovascular reflex regulation pass through sympathetic and parasympathetic branches of the autonomic nervous system. *Cardiovascular sympathetic premotor neurons* in the brain stem and the diencepha-

## BOX 36.1

## DEFENSE REACTION

The central and autonomic nervous systems play crucial roles in modulating cardiovascular activity for appropriate responses to aversive stimuli. Behaviors studied include the *flight or fight* response, frequently called the defense reaction, and the *playing dead* response (Jordan, 1990). A number of stimuli, including visual, auditory, and somatosensory threats, cause the defense response in several species in the awake condition. This response can also be conditioned to occur. It consists of stereotypical behaviors and cardiovascular responses, including posturing in the crouched position, retraction of the head and ears, vocalization, piloerection, pupillary dilation, heightened alertness, increased blood pressure, heart rate, myocardial contractility, and differential activation of sympathetic output to regional circulatory beds, including arteriolar constriction in mesenteric, renal, and cutaneous circulations and, in the naive condition, vasodilation of vessels in skeletal muscle and widespread venoconstriction. This preparatory reflex sets the stage for maximal action. It is evoked by stimulating a number of regions in the brain, including the dorsolateral PAG and other hypothalamic and midbrain regions ranging from the limbic system amygdala to the medulla. The PAG

likely plays a central role in organizing and integrating this response (Fig. 36.7). Outflow from the PAG projects to neurons in the NTS (inhibiting neurons that receive baroreceptor input) and to the rVLM. Lesions in substantia nigra dorsal to the cerebral peduncles abolish vasodilation in skeletal muscle. This reaction may conserve cardiac output by redirecting it to those regions that promote escape and ensure survival. In a few species, like the rabbit and opossum, the playing dead fear response is characterized by pronounced bradycardia and hypotension (along with increased muscle blood flow), locomotor paralysis, pupillary dilation, and rapid shallow breathing. Stimulation of the central nucleus of the amygdala largely replicates the response observed in the awake animal.

lon, including regions in the medulla, pons, and hypothalamus, project to the spinal cord IML. Retrograde transneuronal viral labeling of cell bodies has identified five principal areas in the brain that innervate all levels of sympathetic outflow. These include the paraventricular hypothalamic nucleus, A5 noradrenergic cell group, caudal raphe region, rVLM, and ventromedial medulla (Fig. 36.4). Hindbrain pontine projections to the IML originate from the Kölliker–Fuse and A5 cell groups. Paraventricular and lateral hypothalamic nuclei also provide input to sympathetic preganglionic neurons in the IML. To a lesser extent they also innervate the lateral funicular area (lateral and dorsal to IML in white matter of lateral funiculus), intercalated cell group (medial to IML), and central autonomic nucleus (also referred to as nucleus intercalatus pars paraependymalis, located dorsal to the spinal central canal). There is *viscerotopographic clustering* of spinal sympathetic preganglionic neurons in restricted regions of the spinal cord, including C8, entire thoracic, and upper lumbar (thoracolumbar) and caudal lumbar regions (L<sub>3</sub>–L<sub>5</sub>). Sympathetic neurons exit the spinal cord through the ventral roots and synapse with postgan-

glionic neurons in para- or prevertebral ganglia. Phenotypically, many terminals surrounding sympathetic preganglionic cells are catecholaminergic (from rVLM) or serotonergic (from caudal raphe, including raphe pallidus and obscurus, and ventromedial medulla). However, the principal neurotransmitter in terminals synapsing with sympathetic preganglionic cells likely is glutamate (two-thirds of synaptic boutons) or an inhibitory neurotransmitter, GABA (one-third of axons). Serotonin, acetylcholine, enkephalins, substance P, neurotensin, leuteinizing hormone-releasing hormone, and somatostatin are collocated in many cells and presumably function as pre- or postsynaptic neuromodulators. Ultrastructural studies have demonstrated over 20 other transmitter-specific synapses on sympathetic preganglionic neurons.

## Parasympathetic

Cardiac preganglionic parasympathetic neurons originate in the *nucleus ambiguus* in the ventrolateral medullary reticular formation and the *dorsal motor nucleus of the vagus* in the dorsomedial region of the

**FIGURE 36.4** Direct preganglionic sympathetic inputs to the IML of the spinal cord. Projections from the raphe pallidus, obscurus, magnus, and the ventral medulla contain serotonin, whereas catecholaminergic A1 and A5 contain epinephrine and norepinephrine, respectively. The neurotransmitter for many of these neurons is glutamate or another excitatory amino acid (Loewy and Neil, 1981).

caudal medulla near the fourth ventricle (Fig. 36.5). Myelinated B fiber neurons from ventrolateral nucleus ambiguus and unmyelinated C fibers from dorsal vagal nucleus control heart rate and, to a lesser extent, contractility and coronary flow. Many preganglionic

neurons discharge in synchrony with the cardiac cycle because they receive input from arterial baroreceptors. They also are excited by input from peripheral chemoreceptors, cardiac receptors, and trigeminal receptors (diving reflex). The NTS provides the major afferent

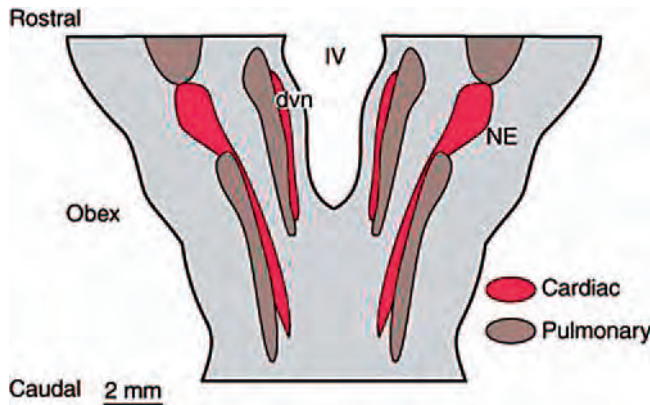

FIGURE 36.5 Horizontal view of preganglionic parasympathetic cardiac and pulmonary motoneurons in the nucleus ambiguus (nA) and dorsal motor nucleus of the vagus (dmv). The fourth (IV) ventricle and the obex are shown for reference (Jordan, 1995).

input into these regions. Fewer afferents originate from the medial and lateral PBN, paraventricular hypothalamic nucleus, Kölliker–Fuse cell group, ventrolateral nucleus of the solitary tract, caudal portion of the nucleus ambiguus, and contralateral rostral nucleus ambiguus. Although neurons in the dorsal motor nucleus and the nucleus ambiguus are phenotypically cholinergic, excitation from second order projections in the baroreflex from the NTS to the nucleus ambiguus is mediated by an excitatory amino acid. Some cardio-inhibitory neurons in the nucleus ambiguus are under tonic GABA inhibitory control. Calcitonin gene related peptide, galanin, serotonin, and opioid peptides are collocated in some cholinergic neurons and likely function as neuromodulators. Laterality of cardiac motor neurons exists in the nucleus ambiguus. Electrical stimulation on the right inhibits the sinoatrial node, whereas stimulation of the left side inhibits atrioventricular (A-V) node conduction (Dampney, 1994a; Loewy and Spyer, 1990; Izzo, Deuchars and Spyer, 1993).

## Summary

Substantial information is available about the principal components of the anatomical system responsible for neural reflex control of the cardiovascular system, particularly the better studied visceral and somatic cardiovascular reflexes. Concepts of central integration have undergone substantial refinement over the last several decades. However, despite the substantial new knowledge that has been gained, we are just beginning to understand the interactive nature of the various central nuclei, pathways, and processes responsible for controlling the cardiovascular system in many conditions associated with afferent activation.

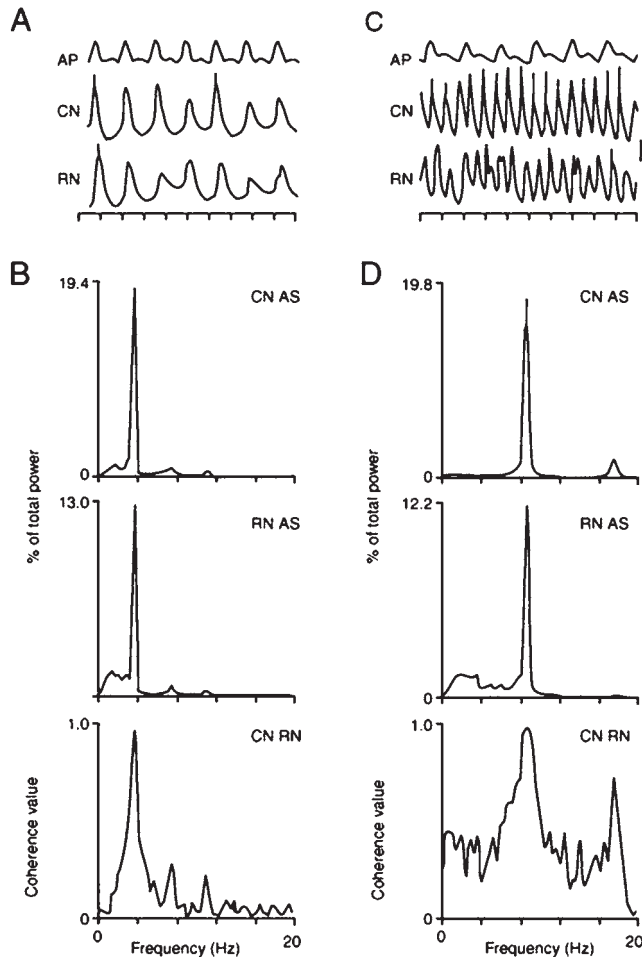

## NETWORK GENERATORS

Blood pressure is governed by circulating blood and plasma volume and the caliber of blood vessels. Neural mechanisms regulate vascular resistance/conductance through tonic sympathetic activity called *sympathetic tone* that actively regulates basal constriction (*vascular smooth muscle tone*) of resistance vessels. These small arterioles of 250–100  $\mu\text{m}$  diameter are heavily innervated by a surrounding sympathetic neural meshwork. Neurally mediated changes in arteriolar lumen diameter occur in virtually all regional circulatory systems and hence are important in the regulation of arterial blood pressure. Sympathetic tone originates from higher brain centers in the medulla and medial diencephalon and exists even in the absence of input into these regions from external sensors (Dampney, 1994a).

Chemosensitivity and pacemaker activity contribute to tonic activity of premotor sympathetic neurons that generate basal sympathetic tone (Dampney, 1994a). Networks of cells in the rVLM, caudal medullary raphe (CMR), caudal ventrolateral (cVLP) and rostral dorsolateral pons (rDLP), LTF, and possibly the cVLM function as *network oscillators* that maintain tonic sympathetic activity (Barman and Gebber, 2000). Time and frequency domain analysis of neural activity in each of these regions in relation to cardiovascular activity, including coherence analysis and pulse or spike-triggered averaging, has demonstrated cardiovascular and/or 10-Hz rhythms that likely underlie tonic sympathetic activity (Fig. 36.6). The *cardiovascular rhythm* of 2–6 Hz largely originates from the LTF, rVLM, cVLM, cVLP, and rDLP. These rhythms are modified by baroreceptor input, but are apparent in its absence. The *10-Hz rhythm* originating mainly in the cVLM, cVLP, and rDLP and, to a lesser extent, the rVLM and CMR, is less well understood. The change from a cardiovascular to a 10-Hz rhythm is associated with an increase in blood pressure, whereas elimination of this rhythm leads to a fall in blood pressure. This rhythm may underlie the differential regional vascular responses during certain alerting conditions, like the defense reaction (Loewy and Spyer, 1990).

## Summary

The cardiovascular system is controlled by networks of oscillators that help maintain blood pressure and the cardiovascular responses to a complex environment. Central generators responsible for cardiovascular and 10-Hz rhythms are distributed over a wide region in the brain stem. Additional investigation is required to understand how the rhythms are created and the mechanisms underlying the contribution of

**FIGURE 36.6** Spontaneous arterial pulse pressure (AP) and activity in the inferior cardiac (CN) and renal (RN) sympathetic nerves in an anesthetized baroreceptor-intact cat. Wide band-pass recordings of the time domain demonstrate activity phase locked with the cardiac rhythm (A) when mean blood pressure was 149 mmHg or with a peak at 10 Hz when blood pressure was 103 mmHg. Frequency domain autospectra (AS) of the cardiac and renal nerves and coherence between the two nerves (CN-RN) are shown in B (2–6 Hz) and D (10 Hz). Coherence analysis allows linear correlation of two signals, as a function of frequency, with 1.0 representing perfect correlation and 0 the absence of any relationship. Calibration in C is 50  $\mu$ V (Barman and Gebber, 2000).

these rhythms to altered sympathetic outflow in diverse states requiring immediate or long-term cardiovascular responses.

### SHORT-TERM CONTROL MECHANISMS

The cardiovascular system must respond quickly to cope with demands originating from changes in the internal and external environments. Rapid changes in autonomic tone occur principally by one of two mechanisms, alterations in activity originating from the

brain or through a reflex event. Alterations in autonomic activity originating as the result of voluntary or involuntary actions like exercise (Box 36.2) or the defense reaction, in part, originate from the brain and are termed feed-forward mechanisms, to be distinguished from the feedback component involving true reflexes. Feed-forward events lack an afferent limb characteristic of reflex events, although visual, auditory, or other forms of sensory input provide the input leading to initiation of the response. Reflex events involve afferent and efferent neural limbs and a central neural integration component.

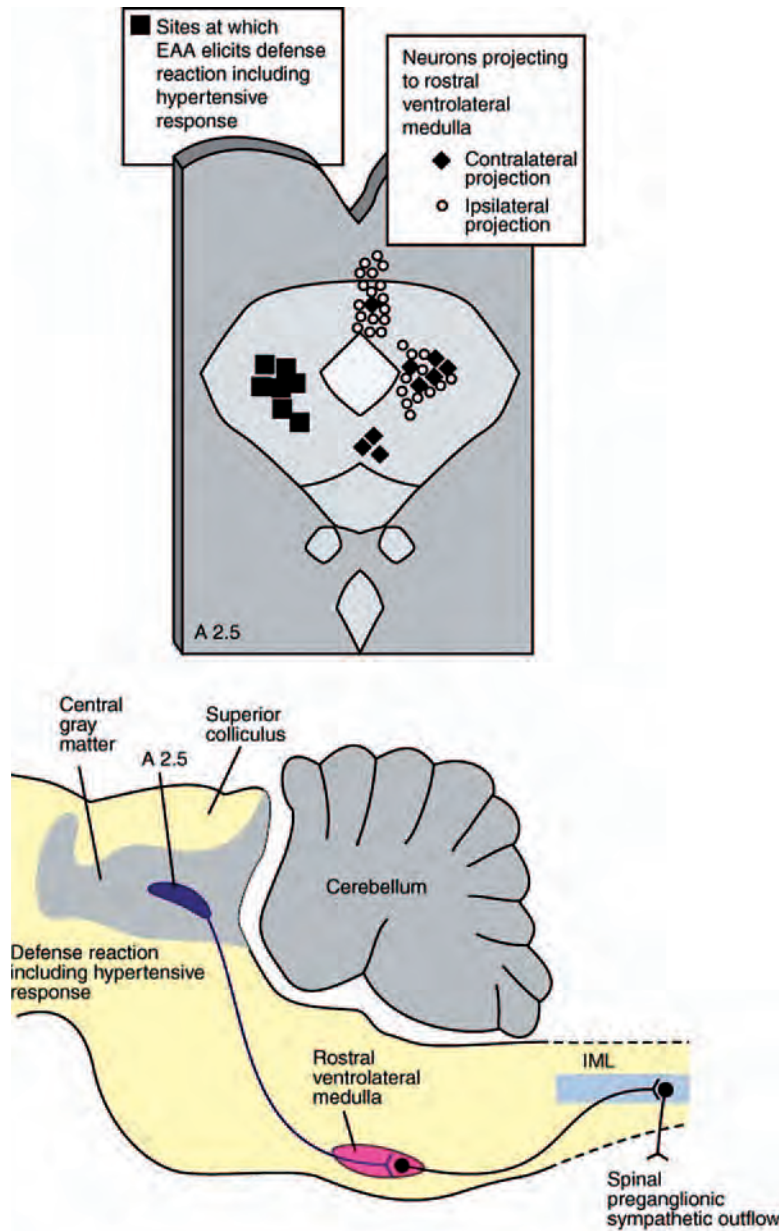

## REFLEX CONTROL OF THE CARDIOVASCULAR SYSTEM

The primary function of various reflex mechanisms concerned with cardiovascular control is to maintain homeostasis. Blood pressure, blood flow, and the local metabolic environment, especially blood pH and oxygen tension, are some of the most important variables controlled. Sensory endings of afferent fibers initiating these reflexes function as mechano- or chemoreceptors. This section describes several of the more important reflex pathways, including the sensory transduction mechanism, afferent limb, central neural integration, autonomic outflow, and effector organ responses.

### ARTERIAL BARORECEPTORS

#### Anatomy

The heart and blood vessels distribute oxygen and nutrients to every cell in the body and, in turn, eliminate metabolic waste products through the lungs and kidneys. These actions are accomplished by appropriate function of the heart, which pumps blood, and optimal distribution of cardiac output to organs that need a variable supply of blood, depending on the underlying conditions. Maintenance of an adequate blood pressure as the driving force for blood flow allows appropriate perfusion of organs. Mechanosensitive nerve endings in baroreceptor regions are present predominately in two locations: bifurcation of common and internal carotid arteries (carotid sinus) and aortic arch. Although the vessel walls are elastic in nature, they also contain smooth muscle. Baroreceptor nerve endings branch to form loops and rings existing as either large compact endings or terminal fibrillar expansions in adventitia or at the border of adventitia and media between muscle cells, elastic, and collagen

**FIGURE 36.7** Coronal section displaying sites in PAG (also called the central gray matter) that elicited a defense reaction after microinjection of excitatory amino acid (EAA) (top). Sagittal section of the area in the PAG that causes the hypertensive response, overlapping with the area projecting to sympathoexcitatory cells in the rVLM that, in turn, project to the IML (bottom) (Carrive *et al.*, 1988).

fibers in vessel walls; a few endings terminate in the media. End organ anatomy of baroreceptors is speculative, as there are no recordings of intracellular activity in stretch sensitive endings whose anatomy has been described. Impulse activity in both A and C fiber afferent pathways is generated by changes in pressure or, more correctly, the resulting stretch and tension in vessel walls. Unmyelinated baroreceptor afferents greatly outnumber myelinated fibers. Carotid baroreceptor afferents course in the carotid sinus nerve to the glossopharyngeal or IX cranial nerve in most species;

cell bodies are in the *petrosal ganglion*. Afferents from the aortic arch are located in either a separate aortic depressor pathway or as part of the common vagus (cranial nerve X) bundle of nerves; cell bodies of aortic baroreceptor afferents reside in the *nodose ganglion*. Primary baroreceptor afferent fibers terminate mainly in the ipsilateral NTS and, to a lesser extent, in the paramedian reticular nucleus and area postrema. Secondary projections extend to the pontoreticular region (cVLM and rVLM), nucleus ambiguus, and dorsal motor nucleus of the vagus (Loewy and Spyer, 1990).

## BOX 36.2

## EXERCISE

Voluntary exercise leads to a number of hemodynamic changes, including increases in blood pressure, heart rate, myocardial contractility, stroke volume, cardiac output, and vasoconstriction of inactive regional circulations. Vasoconstrictor responses compete with vasodilation caused by increased metabolic activity and flow-mediated vasodilation in active regions of the body. These changes are the result of increased neurohumoral activity. In particular, changes in autonomic neural tone include increased sympathetic and withdrawal of parasympathetic activity to the heart and vasculature. Alterations in autonomic tone, particularly decreased activity in vagal motor nerves to the heart, begin immediately after exercise starts. Two processes drive these autonomic changes, including the *feed forward activity* or *central command* and the *exercise pressor reflex*. Central command or “cortical irradiation” originates in a number of supraspinal regions in the CNS, including motor cortex, premotor cortex, and supplementary motor cortex, subthalamic (hypothalamic) locomotor region or H1 and H2 fields of Forel in the diencephalon, midbrain mesencephalic locomotor region, and the pontomedullary locomotor strip. The hypothalamic locomotor region likely is part of the defense area (Box 36.1). Ultimately, one or more of these sites acts through medullary centers to regulate autonomic neural tone. Stimulation of the mesencephalic locomotor region in paralyzed animals either electrically or with a GABA antagonist evokes locomotion, hemodynamic, and respiratory changes quite similar to those observed during

voluntary exercise. Stimulation of the subthalamic locomotor region also inhibits the baroreceptor reflex, consistent with observed suppression of this reflex during high-intensity exercise. In humans, central command is responsible for early cardiorespiratory changes that occur during dynamic and static exercise. In addition to central command, stimulation of both mechano- and chemosensitive receptors in active muscle, mediated largely by group III and IV afferents, also controls cardiovascular and respiratory changes associated with static and dynamic exercise in experimental models and humans. Changes in muscle tension and/or stretch predominately activate finely myelinated afferents to evoke early changes in heart rate and respiration. Production of a number of chemical metabolic factors produced after a few seconds or minutes leads to slightly later activation of unmyelinated muscle afferents and helps maintain cardiorespiratory responses. The nature of metabolic products that stimulate muscle afferents during exercise likely is linked to an imbalance between oxygen supply and demand—that is, a mismatch or error signal. Potential candidates include lactic acid, changes in pH, potassium, and perhaps kinins. Prostaglandins sensitize these sensory endings to the action of other metabolic products. Other metabolites, including adenosine, vasopressin, nicotine, angiotensin, catecholamines, and angiotensin, either do not cause cardiovascular responses when injected into muscle or are associated with pain rather than nonpainful reflex responses.

John C. Longhurst

### Reflex Cardiovascular Responses

Stretching a vessel wall containing baroreceptor afferent endings, most commonly resulting from an increase in blood pressure, causes negative chronotropic and inotropic events, systemic arteriolar and venular vasodilation, as well as changes in the rate of secretion of vasopressin. The resulting decrease in blood pressure opposes the original change in transmural pressure and reduces baroreceptor stimulation, leading to the term *closed loop negative feedback reflex* (Sagawa, 1983).

### Chronotropic Responses

Decreased heart rate, in response to increased blood pressure, is a function of an immediate increase in

vagal motor tone and a slower decrease in sympathetic activity, depending on the initial heart rate. At low basal or resting heart rates, with significant parasympathetic and little sympathetic tone, decreased chronotropy chiefly results from a further increase in vagal activity. At high heart rates, increased parasympathetic activity and withdrawal of sympathetic activity contribute to the negative chronic response.

Baroreflex sensitivity in human subjects is increased at slow heart rates and during expiration, providing a partial explanation for sinus arrhythmia (Mark and Mancia, 1983). The influence of respiration on baroreflex sensitivity continuously oscillates throughout the respiratory cycle, either from interaction of the central respiratory generators with the reflex or from the influence of changes in arterial PCO<sub>2</sub> on the reflex–heart rate response. Altered vagal activity in humans mediates

heart rate responses to increased carotid sinus pressure (after 200–600 ms latency), whereas alterations in both vagal and sympathetic activity cause chronotropic changes during carotid sinus hypotension. Slowing of the heart rhythm depends on the timing of carotid sinus stimulation relative to the cardiac cycle and the duration of stimulation, with maximal changes occurring 750 ms before the P wave and with stimuli lasting 1.25 s. Phasic enhancement and rapid adaptation provide a substantial advantage of the reflex to regulate beat-to-beat changes in heart rate. Temporal summation occurs during maintained stimulation of the reflex, providing prolonged chronotropic suppression. However, even a single brief stimulation can elicit a chronotropic response that outlasts the stimulus due to central or effector organ prolongation of the reflex.

### Dromotropic Responses

Arterial baroreceptors, through a vagal mechanism, tonically influence the A-V cardiac conduction system and influence conduction through the His bundle during increases or decreases in pressure. This mechanism coordinates conduction between the upper and the lower cardiac chambers as heart rate varies, to optimize preload and stroke volume. Conversely, baroreceptors provide little regulation of atrial and ventricular conduction (bundle branches and Purkinje system).

### Inotropic Responses

Baroreceptor-mediated changes in sympathetic tone lead to large changes in myocardial ventricular contractility, whereas small reciprocal changes in myocardial function occur during changes in vagal motor activity. Contrasting influences of sympathetic and vagal efferent activity on inotropic performance are largely a function of differences in ventricular innervation by the two systems.

### Regional Vascular Responses

Studies in animals and humans have examined the influence of high-pressure baroreceptors on regional vascular resistance (Sagawa, 1983). Arterial vascular resistance in skeletal muscle and splanchnic regions is strongly regulated by baroreflexes. Baroreceptors control splanchnic vascular resistance in conscious but not anesthetized human subjects. Anesthesia, presumably through its action on central vasomotor centers, variably enhances or blunts the influence of baroreceptors on regional vascular resistance. Arterial baroreceptors do not regulate cutaneous sympathetic activity

or arterial resistance, although more investigation is warranted. Such studies are difficult because multiunit recordings include cutaneous sympathetic activity monitor sudomotor, thermoregulatory, and vasomotor fibers.

### Integrated Cardiovascular Responses

Arterial hypertension reflexly decreases heart rate and myocardial contractility, resulting in reduced cardiac output. Along with cardiac pump function changes, increased baroreceptor activity leads to withdrawal of sympathetic tone to arteries and veins, causing corresponding increases in caliber of resistance and capacitance vessels. Thus, increased arterial baroreceptor afferent activity in response to hypertension causes reflex arterial vasodilation, which, along with the decreased cardiac output, helps return blood pressure back toward normal. Concurrent venodilation, in most animal species studied, reduces venous return and cardiac preload. In contrast to observations in animals, human studies of baroreflex function have not documented significant changes in central venous pressure nor sustained changes in cutaneous venomotor tone (Mark and Mancia, 1983). During hypotension, reduced carotid baroreceptor stimulation causes reflex arterial vasoconstriction, indicating tonic regulation of vascular caliber by these receptors. High-pressure baroreceptors maintain systemic arterial pressure around a set point. The influence of carotid baroreflex deactivation on arterial blood pressure in humans is almost 50% greater than baroreflex activation. Conversely, the chronotropic influence of carotid baroreceptors is greater with reflex stimulation compared to inhibition. In contrast to the immediate influence on heart rate, the latency of the blood pressure response to baroreceptor stimulation is long (3 s) and the response is prolonged (10–30 s), reflecting the slower onset-offset of sympathetic-effector organ versus vagal neuroeffector responses; that is, vascular smooth muscle versus cardiac sinoatrial node. The adrenal medulla does not appear to contribute to reflex vascular responses to carotid baroreceptor stimulation or inactivation in humans.

### Baroreflex Interactions

Significant interactions exist between the right and left baroreceptor regions and between carotid and aortic regions (Sagawa, 1983). For example, summation of reflex responses occurs during bilateral carotid sinus input. Summation is nonlinear and central neural occlusion causes inhibition at high intrasinus pressures. Interaction tends to be facilitatory at low

pressures although, depending on the underlying experimental conditions, there can be mild inhibitory, additive or facilitatory interaction.

### Effective Stimuli

Carotid sinus and aortic arch baroreceptors respond to changes in mean pressure, pulse pressure, and the rate of rise of blood pressure (Fig. 36.8). Hence, they demonstrate dynamic sensitivity with greater responsiveness on the rising phase and decreased frequency on the falling phase of the sinusoidal pressure–response curve (Sagawa, 1983). Discharge activity adapts rapidly to maintained arterial pressure due to viscoelastic properties of the vascular wall and remains constant above 70 mm Hg. Compared to the carotid sinus, aortic

arch stretch receptors have a higher threshold, but once activated, they exhibit similar sensitivities.

More information is available on mechanisms of activation of myelinated compared to unmyelinated baroreceptor sensory nerve fibers and most of the earlier comments refer to the former group. Fundamental differences between these two sets of afferents include a higher threshold, reduced responsiveness to changes in intravascular pressure, less regular discharge, and lower maximal frequency of discharge activity of C versus A fibers. Unmyelinated baroreceptor afferents are relatively inactive under basal conditions. Conversely, the threshold for discharge of most myelinated baroreceptor afferents is near resting mean arterial pressure.

**FIGURE 36.8** Responses of unmyelinated aortic baroreceptor afferent fiber to ramp (A) and step changes in mean arterial pressure (B and C) and to phasic changes in blood pressure (D). The fiber demonstrated sparse activity at low pressures and irregular discharge activity as pressure was increased that became more constant at higher pressures. Pulse changes in pressure caused synchronous activity (Thoren and Jones, 1977).

### Adaptive Responses

Arterial baroreceptors can be reset (Fig. 36.9). *Resetting*, as originally defined by McCubbin, means that afferents respond differently to the same pressure after they have been subjected to an altered pressure for a period of time (Chapleau *et al.*, 1991; Mark and Mancia, 1983; Sagawa, 1983). Thus, resetting is defined as a shift in the relationship between arterial pressure and reflex hemodynamic or autonomic response. The period required to induce this phenomenon ranges from 15 to 30 min (acute resetting), which is promptly reversible, or hours to days (chronic resetting), which is slowly reversible or irreversible. Wall viscoelastic elements (creep/stress relaxation) and possibly changes in myogenic tone underlie acute resetting, whereas altered wall structure is involved in chronic resetting. Alterations in the afferents themselves,

**FIGURE 36.9** Acute and chronic resetting of arterial baroreceptors in response to a sustained increase in arterial blood pressure. Note that the immediate response occurring after seconds to minutes (C in middle panel) during an increase in blood pressure partially restores the increase in discharge frequency, whereas the chronic response occurring after days to weeks (D in right panel) completely restores the activity (A in all panels) (Chapleau *et al.*, 1989).

perhaps caused by changes in biophysical properties of sensory nerve membranes, such as ionic mechanisms or local release of substances from the endothelium and even resetting in the central nervous system, may underlie this phenomenon. Central resetting occurs when neural-humoral responses are altered during direct stimulation of afferent nerves. Although inhibition of central processing is observed most commonly, paradoxical central facilitation can occur and may briefly oppose central inhibition. Other than localized vascular changes that lead to resetting of afferent endings, mechanisms underlying peripheral and central neuronal resetting remain ill defined.

### Influence of Chemical Stimuli on Mechanoreflexes

Although arterial baroreceptors primarily act as mechanoreceptors, their function can be modified by changes in the regional chemical environment. For instance, circulating or locally released catecholamines constrict vascular smooth muscle and hence unload baroreceptor nerve endings (Chapleau *et al.*, 1991; Sagawa, 1983). Elevated catecholamines also directly excite myelinated and unmyelinated baroreceptor afferents. Other substances, like atrial natriuretic factor, substance P, and vasopressin, influence baroreceptor activity largely through their action on vascular smooth muscle. *Paracrine factors*, including NO, prostacyclin, reactive oxygen species, and various platelet-derived substances, modulate baroreceptor sensitivity by altering neural excitability (Chapleau, 2001). Stretch, shear stress, and chemical substances influence discharge activity of myelinated nerve endings by stimulating the release of NO or prostacyclin from vascular endothelium. Baroreceptors are sensitized by cyclooxygenase products, independent of changes in mechanical deformation. Group III mechanosensitive somatic sensory endings similarly are sensitized by paracrine factors during muscle contraction (Box 36.2).

Several hormonal systems, including *angiotensin*, *arginine vasopressin*, and *atrial natriuretic factor* (ANF), strongly influence the vascular system and end organ function, for example the kidney's regulation of body fluid balance. These hormones also influence blood pressure by regulating sympathetic tone, in part, through their baroreflex effects. Angiotensin and vasopressin are potent vasoconstrictors. Angiotensin also has many actions in the peripheral and central nervous systems, for example by facilitating activation of sympathetic ganglia and stimulating the adrenal medulla to release norepinephrine and epinephrine. Angiotensin decreases baroreflex sensitivity and facilitates its ability to increase blood pressure through a central

action on several circumventricular organs, including the area postrema in the hindbrain, the subfornical organ (SFO), anteroventral third ventricle (AV3V), organum vasculosum of the lamina terminalis, and median preoptic nucleus (MNO) in the forebrain. Through an action on  $V_1$  receptors in the area postrema, vasopressin acts on  $V_1$  receptors inhibit sympathetic outflow and facilitate baroreceptor reflex function. Likewise, ANF reduces sympathetic activity. Although controversial, ANF may stimulate cardiopulmonary afferents to suppress baroreflex function and promote renal sodium excretion. The AV3V region is critical for fluid and electrolyte balance and likely participates as part of a long-loop supramedullary pathway in the baroreflex (Dampney, 1994a).

### Baroreflexes in Health and Disease

The primary function of the arterial baroreflex system is to oppose changes in blood pressure (Longhurst, 1982), for example during changes in orthostatic position when an upright posture is assumed. Under normal circumstances, baroreceptor endings sense orthostatic-induced changes in arterial blood pressure and prevent syncope by increasing heart rate, cardiac output, and peripheral vascular resistance. Individuals who have a defect in the baroreflex arc (e.g., in multiple systems atrophy) have difficulty withstanding *orthostatic challenges*. In response to extreme changes in blood pressure, such as during shock, baroreceptors restore total peripheral resistance by 50 to 70% and increase heart rate sufficiently to increase cardiac output by 20 to 25%. Carotid baroreceptors likely contribute more to restoring blood pressure than aortic baroreceptors, as the threshold for afferent activation and reflex regulation of regional vascular resistance is higher for mechanoreceptors in the arch than in the sinus (100 vs. 60 mm Hg). As hemorrhage progresses, cardiopulmonary stretch receptors and both central and peripheral chemoreceptors, responding to changes in central filling pressures, blood gases and pH, contribute to increased sympathetic activity. Ultimately, in severe shock when blood pressure and acid-base balance are profoundly disordered, baroreflexes fail and may even contribute to terminal bradycardia and demise when stimulated paradoxically.

Abnormal baroreceptor function contributes to the pathogenesis of certain disorders like *hypertension* (Mark and Mancia, 1983; Oparil *et al.*, 1991). Reduced baroreflex function does not initiate hypertension, since complete denervation of both carotid and aortic afferent pathways does not cause sustained hypertension. However, baroreceptors adapt in chronic hypertension, documented by the downward resetting and

rightward shift of the blood pressure–afferent nerve activity relationship. Resetting to a higher set point prevents baroreceptor opposition of elevated blood pressure. Decreased elastin and increased collagen in the media of the walls of vessels in hypertensive patients reduces vascular compliance and ultimately the stretch of mechanosensitive nerve endings when arterial pressure is increased chronically. Similarly, as stiffening of vessels occurs in advancing age, baroreflex function is reduced (Mark and Mancia, 1983).

Aortic baroreflexes are more impaired in hypertension than carotid baroreflexes. Also, the heart rate component is affected more profoundly by hypertension than the blood pressure response, indicating that baroreflex control of parasympathetic activity is influenced more than sympathetic activity. Central resetting also occurs in hypertensive subjects although the underlying mechanisms are unknown.

Patients with *congestive heart failure* (CHF) experience baroreflex dysfunction (Zucker, 1991). Retained salt and water that decrease vascular compliance (increase stiffness) may reduce baroreceptor afferent activity. Additionally, physiological and pathological alterations of the heart, particularly in the atria, may influence arterial and cardiopulmonary baroreflex interactions and ultimately reflex responses to changes in arterial pressure.

*Carotid sinus hypersensitivity* results from local and systemic disease near the carotid bifurcation (Longhurst, 1982). Thus, tumors and atherosclerosis, digitalis intoxication, and Takayasu's arteritis, among other conditions, can cause profound bradycardia or arteriolar vasodilation, or a combination of the two, and recurrent presyncope or syncope.

## PERIPHERAL ARTERIAL CHEMORECEPTORS

### Anatomy

Arterial chemoreceptors are located principally in two regions along the great vessels: the *carotid bodies* at the bifurcation of the common carotid arteries and the *aortic bodies* in the aortic arch (Biscoe, 1971; Gonzalez *et al.*, 1994). Chemoreceptors are composed of clumps of *glomus* tissue perfused with a high blood flow by branches of the carotid artery or aorta. Glomera contain extensive capillary networks. A characteristic feature of carotid (and presumably aortic) bodies is their very high oxygen consumption, which is four times greater than brain. Glomus tissue includes type I (glomus or chemoreceptor) and type II (sustentacular, satellite, or supporting) cells. Type I cells, compris-

ing more than 75% of glomus cells, are secretory, contain catecholamines, and are heavily innervated by sensory nerves. Type II cells, closely associated with type I cells, are not innervated directly; rather, they encircle unmyelinated nerve fibers. Sympathetic and parasympathetic efferent fibers innervate blood vessels in chemoreceptor regions as well as type I and II cells. Carotid body parenchymal cells are essential for chemotransduction, although only afferent nerve endings are chemosensitive.

Sensory fibers from the carotid body course through the carotid sinus (Hering's) nerve, a branch of the glossopharyngeal (IX cranial) nerve; cell bodies of carotid body sensory afferents are in the petrosal and, to a smaller extent, superior cervical ganglia (Eyzaguirre *et al.*, 1983). Sensory pathways of aortic bodies travel in the aortic depressor (Cyan's) nerve, a branch of the vagus (X cranial) nerve, with perikarya in the nodose ganglia. Both A and C fiber chemoreceptor afferents exist. Unmyelinated afferents project to the lateral NTS, rostral to the obex, or to the medial and commissural NTS, caudal to the obex. Most chemoreceptor afferents terminate caudal to the obex, whereas baroreceptor afferents terminate mainly rostral to the obex. Chemoreceptor NTS inputs excite inspiratory neurons in the ventrolateral subnucleus and converge with baroreceptor inputs on nonrespiratory neurons in the ventrolateral subnucleus and neighboring reticular formation. The NTS projects to the rVLM where, along with cVLM-routed signals from baroreceptors, axons containing chemoreceptor information converge on common sympathoexcitatory premotor neurons (Spyer, 1990, 1994; Dampney, 1994b).

### Effective Stimuli

Carotid and aortic body chemoreceptors are stimulated by decreases in the partial pressure of oxygen ( $P_{aO_2}$ ), with a threshold beginning at about 85 mm Hg, and increases in partial pressure of carbon dioxide ( $P_{aCO_2}$ ) (Eyzaguirre *et al.*, 1983; Gonzalez *et al.*, 1994). Although  $CO_2$  stimulation of chemosensitive nerve endings occurs largely through carbonic anhydrase-mediated changes in  $H^+$ ,  $CO_2$  also exerts a small direct effect on these sensory endings. Aortic body afferents respond more vigorously to  $CO_2$  at low  $P_{aO_2}$  (Fig. 36.10). Aortic chemoreceptors are stimulated less than carotid body chemoreceptors by changes in  $P_{aO_2}$  (Fig. 36.11). Afferent activity is increased with maneuvers that influence local  $P_{aO_2}$ , including changes in arterial  $O_2$  content in response to carboxy-hemoglobinemia (aortic chemoreceptors), arterial hypotension (aortic chemoreceptors), and sympathetic vasoconstriction, which reduces local blood flow. Stimulation of para-

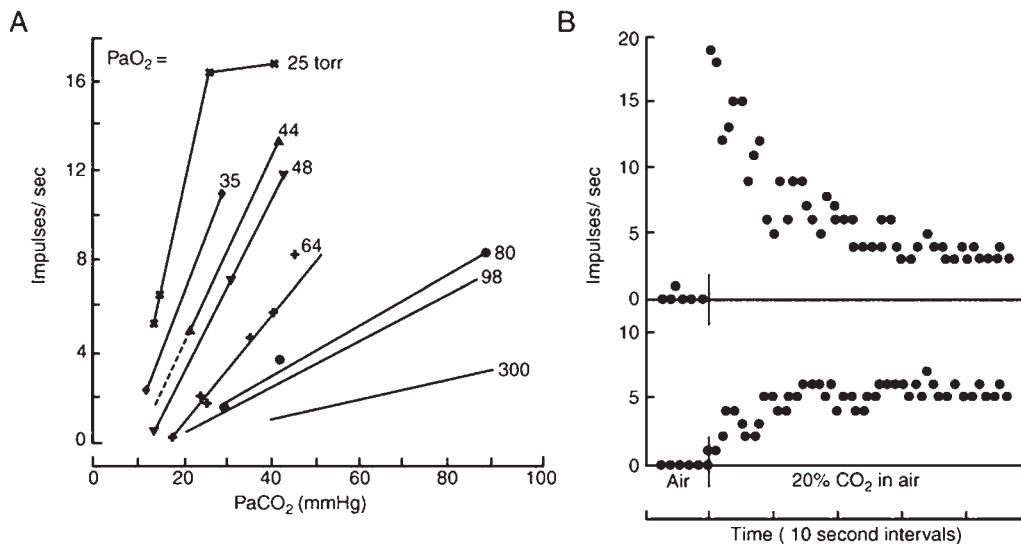

FIGURE 36.10 Response of single carotid body chemoreceptor fibers to increases in arterial  $P_{CO_2}$  (A). The response is diminished as  $P_{O_2}$  is increased. Inhibition of carbonic anhydrase, preventing production of  $H^+$ , reduces the immediate but not the more delayed response to a step increase in  $P_{CO_2}$  (B) (McCloskey, 1968).

FIGURE 36.11 Sensitivity of aortic and carotid body chemoreceptors to arterial hypoxia. Compared to discharge activity of carotid chemoreceptors, aortic chemoreceptors manifest a smaller response of the arterial  $P_{O_2}$  levels (Lahiri *et al.*, 1981).

sympathetic nerves to the carotid body reduces afferent discharge activity, either through an increase in blood flow or release of a local neurotransmitter, like dopamine from type I cells.

Peripheral chemoreceptors respond not only to changes in  $P_{aO_2}$ ,  $P_{aCO_2}$ , and pH, but also are strongly stimulated by chemicals like lobeline, nicotine, and cyanide (Eyzaguirre *et al.*, 1983) that have been used extensively in experimental studies of chemoreceptor function. Chemoreceptors also respond to changes in blood temperature and plasma osmolality. Their *thermosensitivity* may be explained by their high  $Q_{10}$  (75) and a high mean energy of activation (81.5 kcal/mol). The high  $Q_{10}$  value may represent multiplication of a series of reactions, each with a low individual  $Q_{10}$ . Their *osmoreceptor* response causes vasopressin release. Changes in blood temperature and plasma osmolality during prolonged exercise increase plasma ADH through a chemoreflex, which assists in reducing renal blood flow.

### Receptor Mechanisms

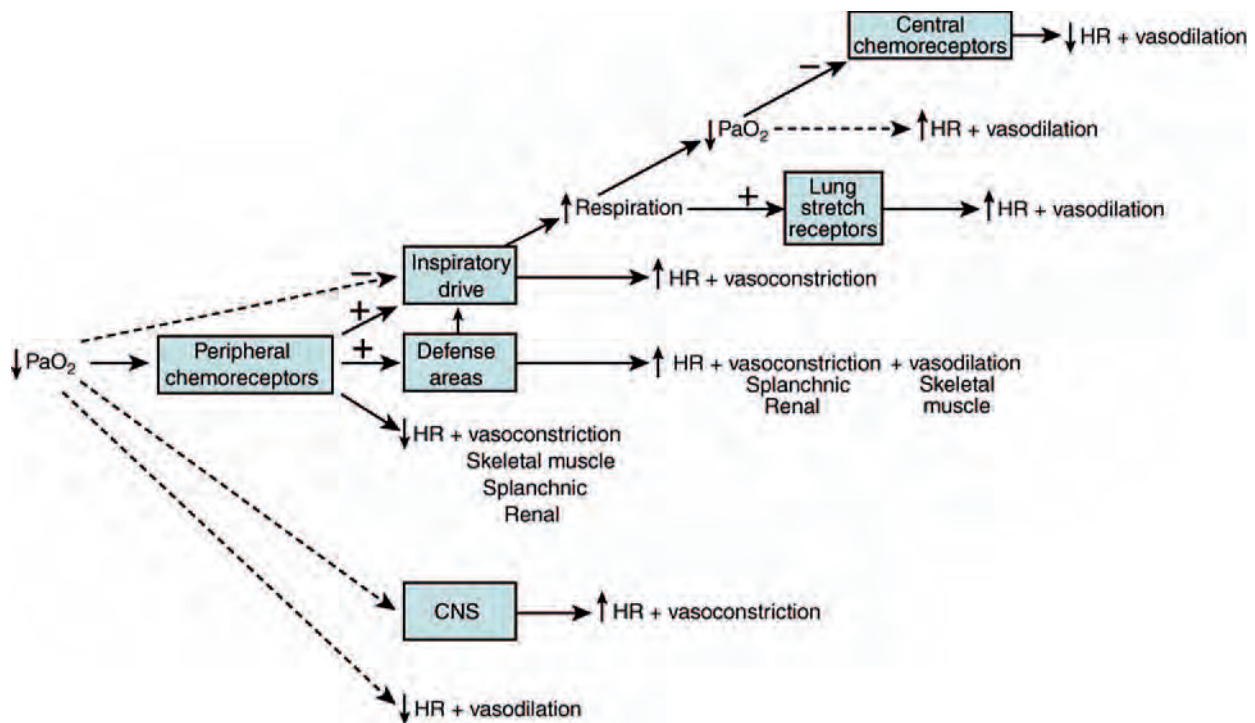

Oxygen sensing of the carotid body occurs as an instantaneous acute response and as a more chronic cellular change over days to weeks (Lahiri, 1996). Oxygen chemoreception is linked mainly to vesicular neurotransmitter release and generated neural discharge, although nonvesicular neurotransmitters like nitric oxide may play an important role. Functional neurotransmitters responsible for chemoreceptor stimulation have not been identified.

## Reflex Cardiovascular Responses

Although the best known effect of these receptors is on respiration, stimulation of peripheral chemoreceptors both directly and indirectly influences the cardiovascular system (Biscoe, 1971; Eyzaguirre *et al.*, 1983; Marshall, 1994). Ventilation is increased by the stimulation of aortic and carotid body chemoreceptors, although more profound responses result from the stimulation of carotid bodies. In the intact animal, carotid body stimulation evokes reflex hyperventilation, tachycardia, increased myocardial contractility and cardiac output, and decreased systemic vascular resistance (Fig. 36.12). When ventilation is controlled, stimulation of carotid bodies consistently causes reflex bradycardia, decreased cardiac output, and increased total peripheral resistance. In contrast, stimulation of aortic bodies with cyanide or nicotine during controlled respiration leads to tachycardia and hypertension, resulting from increases in cardiac contractility and vasoconstriction of both veins and arteries. Thus, the direct influence of chemoreceptor stimulation on the cardiovascular system is affected profoundly by their influence on respiration. The secondary reflex, caused by stimulation of pulmonary stretch receptors,

reverses the direct influence of the carotid chemoreceptors on the cardiovascular system. In addition, increased ventilation during chemoreceptor stimulation (e.g., during hypoxia) reduces arterial  $\text{PCO}_2$ , which further increases cardiac output and modulates reduced systemic vascular resistance.

Peripheral chemoreceptors are responsible for hypoxic (e.g., high altitude) arterial hypertension and venoconstriction, although CNS chemoreceptors may facilitate these reflexes. The vasoconstrictor response is modified to some extent by the direct effect of low  $\text{PO}_2$  that relaxes vascular smooth muscle. Carotid and aortic chemoreceptor stimulation generally causes vasoconstriction in skeletal muscle, kidney, and intestine and cutaneous vasodilation (Eyzaguirre *et al.*, 1983; Marshall, 1994). Chemoreceptor stimulation can lead to parasympathetic coronary vasodilation. Regional vasoconstriction observed in most circulations is reduced or reversed during arterial chemoreceptor stimulation as ventilation increases. Peripheral chemoreceptors do not regulate brain blood flow. Since there are species differences in chemoreceptor-related cardiovascular responses, extrapolation of responses across species should be made cautiously.

**FIGURE 36.12** Cardiovascular and respiratory responses induced by systemic hypoxia. The responses are a composite of the influence of low arterial  $\text{PO}_2$  on peripheral chemoreceptors and their influence on both respiratory and cardiovascular centers in the brain stem (solid arrows), as well as direct effects of low  $\text{PO}_2$  on the CNS and effector organs, including the heart and blood vessels (dotted arrows) (Marshall, 1994).

## CARDIAC RECEPTORS

Intravenous veratridine reduces heart rate and blood pressure through stimulation of cardiac vagal afferent endings, a response known as the *von Bezold-Jarisch reflex*. The heart is innervated by atrial and ventricular vagal and sympathetic afferent endings that respond to mechanical, chemical, or both types of stimuli. The term *cardiopulmonary baroreceptors* is used frequently to describe reflex vagal events that arise from the four cardiac chambers, great veins, and other vessels in the lungs. Cardiac vagal afferents first synapse in the medial subnucleus of the NTS. Like arterial baroreceptors, second-order cardiac reflex pathways project from the NTS to the cVLM (via glutaminergic synapses), which in turn sends GABAergic projections to sympathetic premotor neurons in the rVLM. Sympathetic afferents project to many regions in the hypothalamus, pons, midbrain, and brain stem, including the rVLM where they influence sympathetic outflow.

### Atrial Receptors and Reflexes

Receptive fields of myelinated afferents are located in venoatrial junctions; afferent connections to the CNS principally course through the vagus (Hainsworth, 1991) (Linden and Kappagoda, 1982). These sensory endings are stimulated by stretch and often fire either in late systole just after the upstroke of the aortic pressure wave (type B receptors) or just before the start of the atrial *a* wave (type A receptors). Discharge activity of type B receptors likely reflects atrial volume, whereas type A receptors are influenced more by heart rate. Thus, while the rate of firing of type A receptors generally is maximal for each cardiac cycle, type B receptors operate over a range of discharge frequencies (Fig. 36.13). Other myelinated atrial afferents

display both type A and B patterns of discharge activity.

In 1915, Bainbridge described a reflex increase in the heart rate in dogs in response to infusion of saline, most evident at low basal heart rates. Interestingly, despite the chronotropic response that originates from activation of myelinated afferents, arterial pressure, systemic vascular resistance, and myocardial contractility do not change consistently during stimulation of venoatrial junctions by distending small intravascular balloons. Several studies have failed to document the Bainbridge reflex in humans. Unmyelinated atrial vagal and sympathetic afferents also innervate atria, but their physiological function is uncertain.

### Atrial Reflexes in Humans

Mild *lower-body negative pressure* (LBNP), which primarily unloads cardiopulmonary receptors to reduce blood flow to both skin and muscle, has only a small effect on splanchnic resistance vessels and very little influence on capacitance vessels (Fig. 36.14) (Mark and Mancia, 1983). Contrast dye injection during cardiac angiography, in addition to a direct action on cardiac pacemaker cells, activates cardiac chemoreceptors (von Bezold-Jarisch reflex), causing profound reflex bradycardia in humans. In addition, cardiopulmonary baroreflex unloading potentiates arterial depressor baroreflex function. Cardiopulmonary afferents also oppose the somatic exercise pressor reflex.

### Cardiopulmonary Regulation of the Kidney

Cardiopulmonary receptor activation is more effective in decreasing renin and plasma vasopressin than arterial baroreceptors (Mark and Mancia, 1983). There is no clear consensus on the relative importance of vagal cardiopulmonary versus ventricular receptors in vasopressin regulation, as there is substantial variability between species. Studies of cardiac transplant recipients, although complicated by the underlying disorder, which frequently includes renal dysfunction, suggest an important role of cardiac reflexes in regulating renal function. Cardiopulmonary and ventricular receptors tonically inhibit cardiovascular sympathetic activity and renin release from the kidney (Goetz *et al.*, 1991). Ventricular receptors in humans primarily influence muscle resistance vessels, whereas arterial baroreceptors exert more control of the splanchnic circulation.

**FIGURE 36.13** Type A, B, and intermediate atrial myelinated afferent patterns of discharge activity. Activity of type A receptors correspond to atrial *a* wave, whereas type B receptor activity occur during atrial *v* wave. Receptors with an intermediate response coincide with both *a* and *v* waves (Kappagoda *et al.*, 1976).

**FIGURE 36.14** Effects of LBNP on aortic mean pressure (MP), aortic pulse pressure (PP), right atrial pressure (RAP), HR, splanchnic blood flow (SBF), and forearm blood flow (FBF). Low-level LBNP (0–20 mmHg) lowered venous return and RAP and, by unloading cardiopulmonary receptors, significantly decreased skin and muscle FBF and slightly reduced SBF. High-level LBNP (20–50 mmHg), which reduced aortic PP and eventually aortic MP (therefore also unloading high-pressure arterial baroreceptors), increased HR and decreased both FBF and SBF (Johnson *et al.*, 1974).

### Ventricular Receptors and Reflexes

Ventricular sensory receptors mostly exist as bare nerve endings situated in the interstitium. Finely myelinated (A $\delta$ ) or unmyelinated cardiac afferent

fibers (C) project to the CNS through vagal or sympathetic (spinal) pathways (Longhurst *et al.*, 2001). There is little difference in sensitivity between myelinated and unmyelinated cardiac afferents. Mechanosensitive cardiac C fibers respond mainly to changes in ventricular diastolic pressure, suggesting that they may be more responsive to stretch than to compression. Reflex depressor responses to changes in arterial pressure may originate from coronary rather than ventricular mechanoreceptors. Ventricular chemosensitive C fibers respond to exogenous stimuli such as veratridine or contrast dye injected during angiographic procedures and to a number of endogenous chemical stimuli produced during pathologic conditions like ischemia and reperfusion (Box 36.3). Cardiac transplantation and myocardial infarction globally or regionally interrupt ventricular afferent activity.

Reflex cardiovascular responses to stimulation of either mechano- or chemosensitive vagal endings are primarily inhibitory, resulting in reduced sympathetic nerve activity, depressor responses, and bradycardia. Conversely, activation of sympathetic cardiac ventricular afferents reflexly excites the cardiovascular system, leading to an increase in blood pressure and heart rate (Fig. 36.15). Although stimulation of ventricular vagal C fiber afferents causes bradycardia in anesthetized animals, heart rate is minimally altered in conscious animals and humans. Activation of ventricular vagal afferent endings attenuates baroreflex sensitivity and baroreflex control of heart rate.

### Cardiac Reflexes in Disease

Adverse cardiovascular reflexes originating from the atria and ventricles are associated with clinical conditions like *aortic stenosis*, where high left ventricular pressures generated during stress stimulates vagal afferent mechanoreceptors causing vasodilation and occasionally syncope (Longhurst, 1984).

Prolonged supraventricular tachyarrhythmias like atrial fibrillation and *paroxysmal supraventricular arrhythmias* are associated occasionally with reflex diuresis and orthostatic intolerance (Longhurst, 1984).

Hypertensive patients demonstrate reduced reflex forearm vasoconstriction during LBNP ranging from –5 to –40 mmHg, suggesting that both cardiopulmonary and arterial baroreflexes are impaired. Also, by reducing atrial compliance and diminishing responses of stretch sensitive atrial myelinated endings to elevated volume and pressure, CHF impairs the reflex response to increased plasma volume, thus promoting higher levels of circulating ADH and volume retention. As such, reduced cardiac afferent information in response to high atrial pressures contributes to periph-

## BOX 36.3

## CARDIAC RECEPTORS IN MYOCARDIAL ISCHEMIA

Myocardial ischemia is associated with a number of mechanical and chemical changes in myocardium. Chemosensitive receptors in the heart have been studied extensively. For instance, bradykinin is released, particularly during conditions of high sympathetic activity, reactive oxygen species are formed during ischemia and more so during reperfusion, and platelet activation during plaque rupture increases the regional concentration of 5-hydroxytryptamine, histamine and thromboxane A<sub>2</sub> (Longhurst *et al.*, 2001). Prostaglandins also are released during ischemia. Cyclooxygenase products either directly stimulate cardiac vagal afferents to induce a depressor response or sensitize vagal and sympathetic cardiac afferents to the action of other metabolic factors like bradykinin. These chemical mediators lead to profound stimulation of vagal and sympathetic cardiac afferents (Fig. 36.16). Receptive fields of vagal afferents are located transmurally, especially in the inferior-posterior ventricle, whereas sympathetic afferents are located closer to the epicardial surface and more in the anterior left ventricle. Thus, ischemia and reperfusion involving the inferior surface of the heart are associated more commonly with vasodepressor reflex responses, bradyarrhythmias, nausea, and vomiting, whereas excitatory pressor responses, including pain (*angina*), peripheral vasoconstriction, and tachyarrhythmias, are associated more commonly with anterior ischemia and reperfusion. Depressor reflexes reduce myocardial oxygen demand and thus lessen the

imbalance between oxygen supply and demand during ischemia. Conversely, in addition to the warning signs of angina, activation of sympathetic afferents improves coronary perfusion pressure and hence maintains myocardial blood flow. It is confusing to imagine, however, that two diametrically opposed reflexes are engendered by myocardial ischemia. Clearly, overactivity of either reflex could also result in untoward cardiac events by exaggerating ischemia, either through marked decreases in perfusion or through exaggerated increases in oxygen demand. However, simultaneous activation of both afferent pathways from the heart lessens the influence of either pathway alone due to neural occlusion that occurs in the NTS and perhaps elsewhere (Fig. 36.15). While stimulation of ventricular sensory endings by endogenous chemical mediators leads to complex but frequently observed clinical responses, the reflex role of cardiac mechanoreceptor stimulation by changes in regional or global wall motion abnormalities is much less clear and deserves further study.

eral edema and ascites (Schultz, 2005). Interestingly, digitalis glycosides can reverse the reduced cardiac sensory receptor responsiveness associated with CHF.

## ABDOMINAL VISCERAL REFLEXES

Studies of visceral reflexes have yielded substantial information on the mechanisms by which visceral spinal sensory nerve endings are activated as well as their central integrative mechanisms.

### Reflexes from Visceral Ischemia

Mesenteric ischemia reflexly increases blood pressure through temporal and spatial summation of input

to cardiovascular centers in the brain stem. The pattern of response includes increases in heart rate, myocardial contractility, maintenance of cardiac output in the face of increased afterload, and vasoconstriction of splanchnic, hindlimb, and the coronary arterial circulation. Chemical mediators formed during *mesenteric ischemia*, including bradykinin, prostaglandin E<sub>2</sub>, hydroxyl radicals, lactic acid, 8R,15S-dihydroxy-eicosan tetraenoic acid (diHETE), serotonin, and histamine, stimulate or sensitize predominantly unmyelinated afferent endings. Low PO<sub>2</sub> triggers sensory nerve discharge through the production of other chemical mediators. Conversely, leukotriene B<sub>4</sub> modulates the afferent response during regional ischemia, for example, in patients with splanchnic vascular atherosclerosis. Hypercapnia, prostacyclin, thromboxane A<sub>2</sub>, lactate, and mechanical stimulation are not involved in the ischemic reflex. The physiological importance of

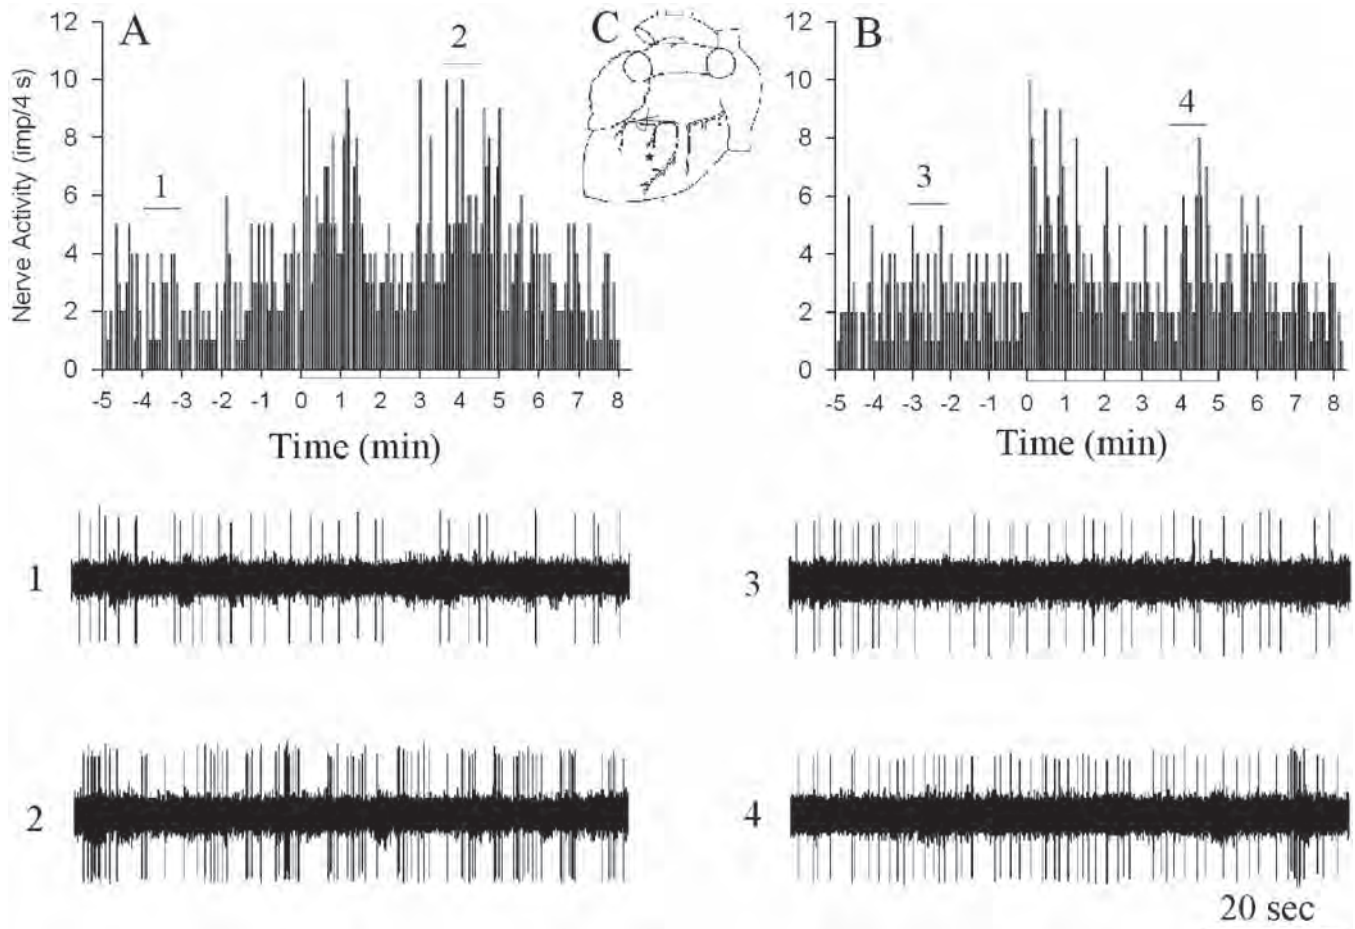

**FIGURE 36.15** Changes in mean arterial pressure (MAP), HR, and left ventricular  $dp/dt$  at 40 mmHg developed pressure, as an index of myocardial contractile function, during stimulation of the epicardial surface of the heart with increasing concentrations of the reactive oxygen species, hydrogen peroxide ( $H_2O_2$ ). Transection of both vagi to interrupt the afferents coursing in this pathway, leaving the sympathetic afferent system intact (middle panels), resulted in a concentration-dependent reflex pressor response in association with increases in HR and myocardial contractility. Deneration of sympathetic (spinal) afferent pathways from the heart, leaving the vagal afferent system intact (right panels), converted the response to reflex cardiovascular inhibition, consisting of graded reductions in MAP, HR, and  $dp/dt$ . Stimulation of the ventricle when both afferent pathways were intact (left panels) led to a small pressor response with little change in HR or  $dp/dt$  as a result of occlusive interaction in the NTS (Huang *et al.*, 1995).

mechanoreceptor activation in the abdomen in ischemically mediated sympathoexcitation requires further investigation.

## Renal Reflexes

The kidney is innervated by myelinated mechanosensitive and chemosensitive afferents. Myelinated afferents respond to increased ureteral pressure and distension of renal pelvis in most species, except non-human primates, where these receptors are sparse.

These mechanoreceptors frequently respond to changes in arterial or venous pressure and frequently a number of chemical mediators, including bradykinin, prostaglandins, histamine, adenosine, acetylcholine, and nicotine. The role of these mediators in stimulating these endings during conditions such as ischemia has not been determined. Two types of renal chemoreceptors have been described, including the  $CR_1$  receptor that responds to hypoxia, ischemia, or cyanide infusion, and the  $CR_2$  receptor that responds to ion movement, including back infusion of urine, NaCl, and

**FIGURE 36.16** Responses of a sympathetic afferent fiber to repeated myocardial ischemia before (A) and after (B) blockade of thromboxane  $A_2$  receptors in the heart with BM13177. This C-fiber afferent with a conduction velocity of 1.83 m/s innervating the posterior left ventricle ( $\star$ , inset) was excited biphasically during five minutes of regional ischemia (see ligature). Blockade of thromboxane's action reduced the increase in total discharge activity by ~50% from 214 to 103 imp/5 min, as demonstrated by actual responses in panels below histograms at indicated times.

KC1, but not urea or mannitol (Dietz and Gilmore, 1991; Kopp and DiBona, 1991).

Reflex cardiovascular activation commonly is observed during renal afferent stimulation. However, blood pressure is not tonically regulated by renal afferent input. Renorenal reflexes occur during stimulation of renal mechano- or chemoreceptors, leading to diuresis and natriuresis in association with decreased contralateral renal nerve activity. Renal afferents likely play a role in hypertension resulting from renal artery stenosis (Goldblatt kidney model) or coarctation involving the renal circulation (Oparil *et al.*, 1991).

### Interactions between Somatic and Visceral Reflexes

There are many examples of interactions between reflex systems. For example, low frequency, low intensity somatic afferent stimulation during electroacu-

puncture produces long-lasting reduction in visceral afferent-induced sympathoexcitatory increases in blood pressure by as much as 40% (Longhurst, 2004). *Acupuncture* stimulates group III and IV somatic afferents that provide input to both spinal and supraspinal centers in the CNS. During acupuncture polysynaptic input to the ventral hypothalamic arcuate nucleus, midbrain ventrolateral PAG and midline medullary (raphe) nuclei, causes prolonged inhibition of rVLM sympathoexcitatory cardiovascular premotor neuronal activity and sympathetic outflow. Visceral afferent-induced activity in rVLM bulbospinal glutaminergic neurons is inhibited by modulatory neuropeptides, including enkephalins and endorphins, nociceptin and GABA released during low level somatic stimulation. Ultimately these somatic-visceral interactions have the capability of lowering elevated blood pressure and reducing demand-induced myocardial ischemia.

## Summary

Reflex control of the cardiovascular system provides a unique advantage to mammalian species by allowing them to cope with the environment. The ability to respond rapidly to changes in blood pressure, regional blood flow, chemical composition of the blood and interstitial fluid, and adverse events such as pain, stress, and ischemia is managed by a set of sensory afferent systems that provide input into cardiovascular centers in the hypothalamus, midbrain, and brain stem with the end result of inducing both immediate and long-term changes in the autonomic and hormonal neuroeffector systems. Over the last century, an in-depth understanding of many neural mechanisms underlying these reflex events has been achieved. It is now known, for example, that even though these systems are largely responsible for beneficial short-term adaptations, they can play a role in a number of diseases that contribute to substantial morbidity and mortality. Recent insights suggest that it may be possible to activate these systems to more optimally regulate disease states like hypertension. Future challenges are to further define mechanisms underlying activation of sensory endings and central neural integrative functions, including interactions of multiple systems that add complexity to the behavior of interneurons in multiple regions concerned with conditioning reflex responses. Of particular interest are the new opportunities for investigation that are now present as a result of recently developed molecular and genetic approaches.

## Neural Control of Breathing

Organisms must constantly exchange various substances with the environment for homeostasis and ultimately, survival. Different physiological systems handle solid, liquid, and gaseous metabolic precursors and by-products. Aerobic metabolism consumes  $O_2$  and produces  $CO_2$ , the so-called blood gases. Organisms with large surface-to-volume ratios, such as bacteria, yeast, plants, and insects, rely on passive diffusion for gas exchange with the environment. However, vertebrates, with low external surface-to-volume ratios, actively pump gas using respiratory muscles to exchange air between the environment and the lungs (which in mammals have an exceptionally high surface-to-volume ratio) and the heart moves blood through and between the pulmonary and systemic circulations. The role of the brain in breathing is preeminent, as it generates the motor outflow driving the contraction and relaxation of skeletal muscles that pump the lung and modulates the tone of skeletal and smooth muscles in the upper airways and bronchi to control resistance to air flow.

Mammals that are neither diving nor hibernating, including humans, need a constant supply of  $O_2$  to support their high metabolic rate, and so must breathe continuously from birth until death without lapses of more than a few minutes. Breathing appropriate for the regulation of blood  $O_2$  and  $CO_2$  is adaptable over a 20-fold range in metabolism (in humans from 0.25 liter  $\times$  min<sup>-1</sup>  $O_2$  consumed at rest to ~3–6 liter  $\times$  min<sup>-1</sup>  $O_2$  consumed during maximal exercise). Respiratory muscles account for ~5% of the body's metabolism at rest, and need to be used efficiently because the metabolic cost adds up over time. Moreover, serious respiratory muscle fatigue must be avoided. During exercise, energy costs of breathing must be kept low when possible (the respiratory pump moves from 5 (at rest) up

to 200 (maximal performance in world-class athletes) liters  $\times$  min<sup>-1</sup> of air) to maximize the amount of  $O_2$  available to other working muscles.

The drive for continuous ventilation in humans is strong. Typically, breathing is the last consequential movement to disappear following generalized depression of higher function, such as during surgical anesthesia or following insults to the brain (e.g., hypoglycemic coma). Automatic, homeostatic breathing can remain in people who have lost cortical function, resulting in ethical and emotional dilemmas over people who are "brain dead."

Neuroscientists take advantage of this robustness of breathing to study synaptic, neural, and network mechanisms in anesthetized or decerebrate mammals that continue to breathe. These mechanisms are so robust and sufficiently self-contained that an *in vitro* tissue slice at an appropriate level in neonatal or late fetal rodent brain stem continues to generate respiratory-related patterns of motor nerve activity.

### EARLY NEUROSCIENCE AND THE BRAIN STEM

The persistent absence of breathing is the surest sign of death. Many ancient cultures associated life with breathing itself. Animation and animal are derived from the Latin *anima*, which means to breathe (and also soul). Taoism holds breathing sacred and a key to enlightenment: *immortality to the person who holds their breath for the time of 1000 respirations*. Buddhists believe that special states of enlightenment can be attained through effective modulation of breathing.

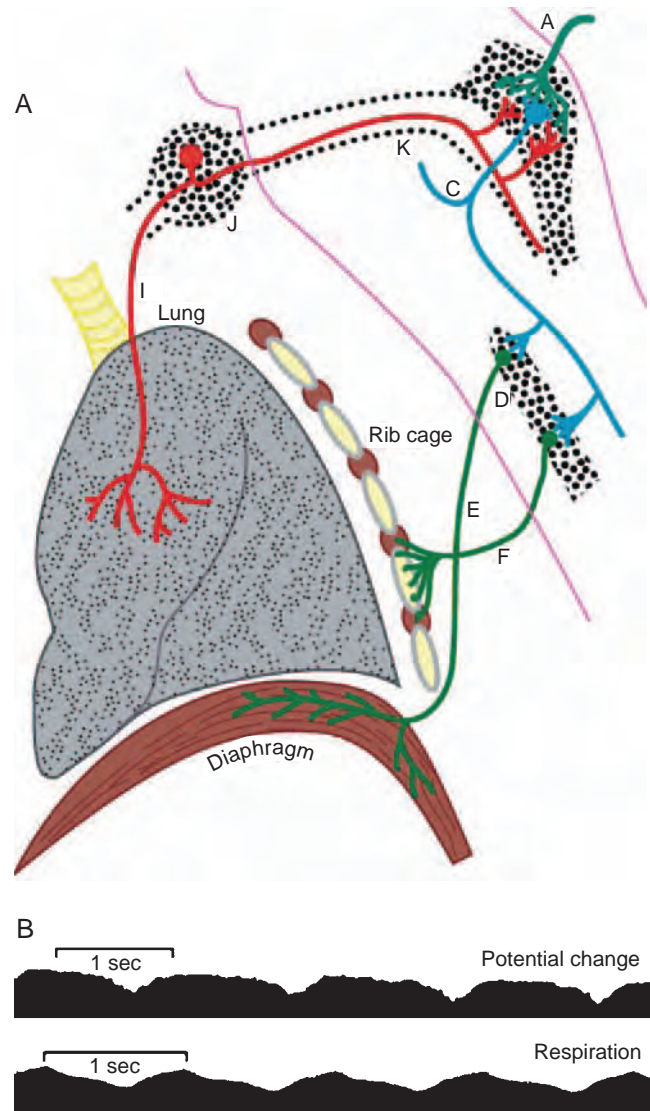

Although the purpose of breathing—to move air into and out of the lungs—was not established until the late eighteenth century, the underlying sites have been a constant source of speculation in Western culture. Perhaps the earliest suggestion that the brain was involved came from Galen (ca. 131–201 AD), who observed that gladiators and animals injured below the neck continued to breathe, but those injured in the neck stopped. Lorry (1760), who showed that cerebellectomized rabbits continued to breathe, concluded that the critical circuits lay within the brainstem and upper spinal cord, essentially the contemporary view. Legallois (1813) “extracted” brain tissue to determine what was necessary for breathing; he localized sites to the rostral ventrolateral medulla close to key sites, including the preBötzing Complex (preBötC).

Ramon y Cajal (1909) provided an anatomic rationale for the critical role of the medulla in breathing. Examining the afferent and efferent projections of respiratory-related nerves, he suggested that three brainstem nuclei are important: the solitary tract (NTS) and commissural nuclei, primary targets of pulmonary afferents, and the nucleus ambiguus, which contains cranial motoneurons that innervate upper airway muscles. His network model for breathing is prescient (Fig. 37.1A): afferent containing information about lung volume and blood gases combined with intrinsic properties of brainstem neurons to produce a rhythmic outflow to spinal and cranial respiratory motoneurons. Adrian and Buytendijk (1931) recorded slow, rhythmic potentials in *in vitro* goldfish brainstems that were similar in timing to that of gill movements in intact goldfish (Fig. 37.1B), physiological evidence that the brainstem contained the critical circuits. Gesell and coworkers (1936) subsequently recorded individual medullary neurons discharging bursts of activity in phase with the breathing rhythm. This finding initiated a concerted effort to identify neurons that generate respiratory rhythm.

## CENTRAL NERVOUS SYSTEM AND BREATHING

Breathing, chewing, and locomotion are important behaviors that require rhythmic movements with periods ~seconds. The underlying neural networks are programmed genetically and develop *in utero* so that newborn mammals breathe, chew, and, in some cases, locomote. How does the brain generate the rhythmic movements underlying breathing?

Although functionally straightforward (air in, air out), breathing from the brain’s point of view is much

**FIGURE 37.1** A) Ramon Y Cajal’s model for respiratory control. Respiratory neurons in solitary tract (C) process signals from pulmonary afferents (K; cell bodies in nodose ganglion (J)) and some blood factor present in local capillaries (A). Descending control signals go to spinal motoneurons (D), innervating the diaphragm (E) or intercostal muscles (F). From Ramon y Cajal (1909). B) Oscillograph recordings of the gross electrical potential of an *in vitro* goldfish brain stem (top) compared to gill movement of an intact goldfish (bottom). From Adrian and Buytendijk (1931).

more than rhythm generation. Ventilation requires a patterned motor output with appropriate timing and magnitude of muscle contraction and relaxation with precise coordination among synergists and antagonists. A complex and mutable regulatory network composed of many distinct components, including forebrain, brainstem, and spinal cord circuitry, interacts to adjust breathing as necessary during life (Fig. 37.2).

FIGURE 37.2 Functional organization of central nervous system control of breathing (see text for details).

Appropriate adjustment of breathing to meet changing metabolic needs requires information on blood and brain chemistry and the mechanical state of the lung, airways, and respiratory muscles. Nevertheless, even if deprived of sensory information, the central nervous system can generate a basic rhythmic respiratory pattern.

## WHERE ARE THE NEURONS GENERATING RESPIRATORY PATTERN?

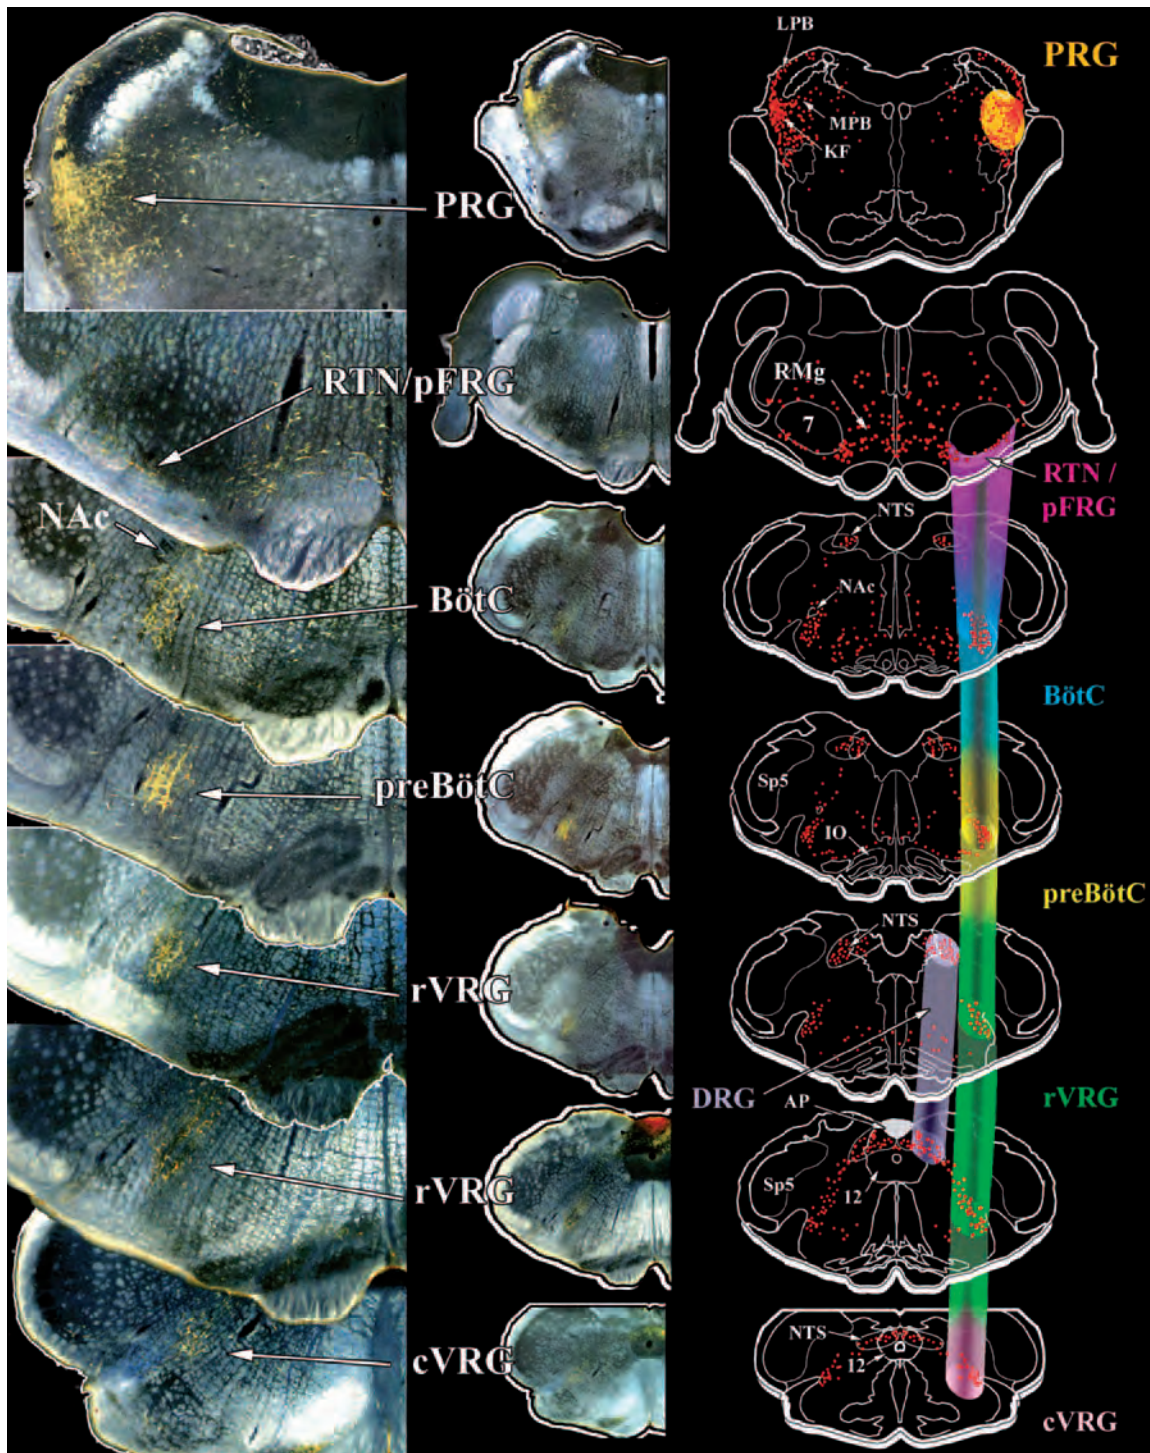

Three distinct functional classes of rhythmically active (respiratory) neurons underlie the generation of respiratory pattern: motoneurons innervating skeletal muscles of the respiratory pump and airways; rhythm generating neurons; and premotoneurons that link and coordinate rhythm generation to motoneurons. Nonrhythmic neurons that modulate the behavior of these respiratory neurons are also important. Brainstem respiratory neurons are concentrated within three regions (Fig. 37.3).

**Dorsal respiratory group (DRG).** The DRG is in the dorsomedial medulla caudal to mid-rostral portions of the NTS. The DRG is a source of input to spinal cord respiratory motoneurons in some species, but less so in others.

**Ventral respiratory column (VRC).** The VRC forms a continuous field in the ventrolateral medulla with five or more physiologically distinct subregions extending from around the facial nucleus to the spinomedullary junction. Distinct anatomical compartments within the VRC are inferred from clustering of similar types of respiratory neurons (e.g., inspiratory or expiratory neurons), presence or absence of spinal cord projections, and responses to chemical stimulation. Specific respiratory neuron types are not restricted to individual compartments, but overlap with the peak concentrations of particular neuron types centered within given compartments.

The caudal half of the VRC, termed the ventral respiratory group (VRG), contains bulbospinal respiratory premotoneurons that receive converging inputs from VRC rhythm generating neurons and neurons outside the VRC, sculpting the activity pattern distributed to various pools of respiratory motoneurons. The VRG is subdivided into rostral (rVRG) and caudal (cVRG) based on the peak concentrations of inspiratory (rVRG) versus expiratory (cVRG) bulbospinal neurons. Inspiratory bulbospinal neurons provide mainly excitatory input to spinal inspiratory motor pools, including monosynaptic input to phrenic motoneurons. Expiratory bulbospinal neurons in the cVRG are mainly excitatory and project to interneurons innervating thoracic and upper lumbar motoneurons that drive expiratory pump muscles (e.g., internal intercostal and abdominal muscles). Inhibitory expiratory neurons in the vicinity of the Bötzinger complex (BötC) and cVRG inhibit spinal inspiratory motor pools. Spinal cord injury that damages the axons of these bulbospinal neurons can cause life-threatening interference with the ability to breathe (Box 37.2)

Respiratory rhythm generation occurs mainly in the rostral VRC, which contains at least three functionally distinct compartments. The BötC is caudal to the facial nucleus, and contains mainly inhibitory glycinergic expiratory neurons. Further caudal is the preBötC an essential structure for rhythm generation (see later). The retrotrapezoid nucleus (RTN) is located at the rostral end of the VRC, ventral to the BötC and continues rostrally beneath the facial nucleus near the surface of the brain to just caudal to the trapezoid body. RTN neurons project to the pons and caudal VRC. The RTN is (part of) a region containing potential central chemosensory cells, an important source of respiratory drive and chemoreflexes. RTN

neuronal activity monotonically increases with extracellular acidity (associated with increased  $\text{CO}_2$ ). The parafacial respiratory group (pFRG) is ventral to the facial nucleus, at least in neonatal rats. The RTN/pFRG may play an important role in rhythm generation (see later).

**Pontine respiratory group (PRG).** The PRG is in the rostral dorsolateral pons and encompasses portions of the parabrachial complex and the ventrally adjacent Kölliker-Fuse nucleus.

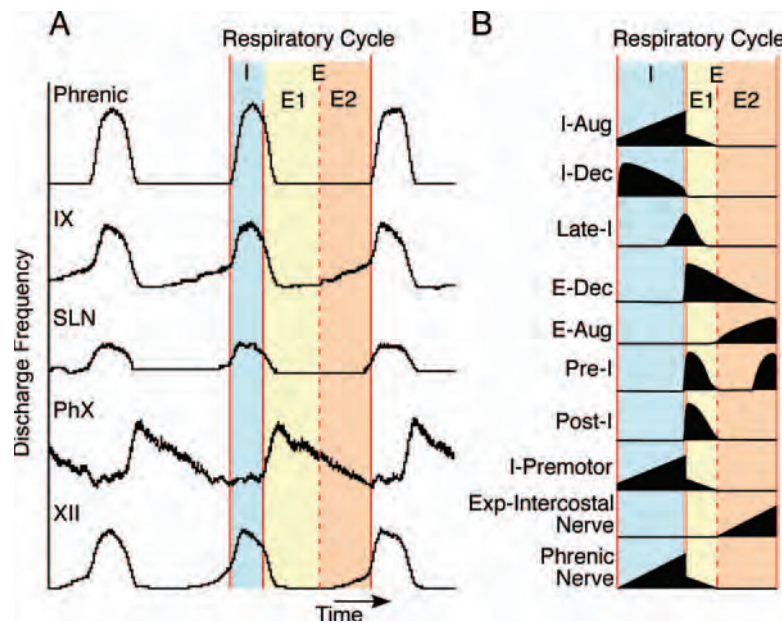

The PRG and VRC are at either end of an essentially continuous column of respiratory and

**FIGURE 37.3** Respiratory neuroanatomy of the rat brain stem. The three major brain stem clusters of neurons controlling respiration are depicted. On the left are medium- and low-magnification views of labeled neurons in representative transverse sections of the pons and medulla after a retrograde tracer injection (not shown) within the rostral part of the contralateral VRG. The sections were photographed using reflected light so that myelinated axons appear white, retrogradely labeled neurons (immunostained with diaminobenzidine) appear gold, whereas the remaining cellular areas appear gray. On the right, these retrogradely labeled cells are diagrammed (red dots) within outlines of the adjacent low-magnification photomicrographs. On the right side of the diagram, the columns of respiratory neurons are identified: cVRG, pink; rVRG, green; preBötC, yellow; BötC, blue; PRG, orange; RTN/pFRG, burgundy; DRG, purple. Not all the (red) retrogradely labeled neurons in the medulla are included within the respiratory regions; some of these presumably represent extrinsic neuronal relays that can modulate respiration in relation to other behavioral or metabolic demands. 4V, fourth ventricle; 7, facial nucleus; 12, hypoglossal nucleus; AP, area postrema; BötC, Bötzing Complex; cVRG, caudal VRG; DRG, dorsal respiratory group; IO, inferior olive; KF, Kölliker–Fuse nucleus; LPB, lateral parabrachial nucleus; MPB, medial parabrachial nucleus; NAc, ambiguus nucleus, compact division; NTS, nucleus of the solitary tract; preBötC, pre-Bötzinger complex; PRG, pontine respiratory group; RMg, raphe magnus; RTN, retrotrapezoid nucleus; rVRG, rostral VRG Sp5, spinal trigeminal nucleus; VRG, ventral respiratory group. respiratory-related neurons in the lateral pons and medulla that extends rostrally from the medulla, essentially surrounds the facial nucleus, traverses the ventrolateral pons and regions adjacent to both the motor trigeminal and principal sensory trigeminal nuclei before merging dorsally with the PRG.

## DISCHARGE PATTERNS OF RESPIRATORY NEURONS

One consideration that has impacted the classification of respiratory neurons is the number of phases that constitute the mammalian respiratory cycle, and whether the parcellation of motor output into multiple phases requires that rhythm generation *per se* be equivalently multiphasic. Inspiration and expiration constitute two obvious phases. However, a close examination of the discharge patterns of inspiratory (e.g., diaphragm) and expiratory (e.g., internal intercostal) muscle activity shows that there can be three (or more) phases of motor output (Fig. 37.4). Expiration can

**FIGURE 37.4** A) Diverse pattern of respiratory motor activity is exhibited on spinal (phrenic) and cranial nerves innervating the diaphragm and airways in an anesthetized rat. (A) Low-pass filtered trace of activity showing overall pattern of discharge. Red vertical lines indicate phase transitions between inspiration (I) and expiration (E). Note that the onset of inspiratory activity on cranial nerves precedes the onset of activity on the phrenic nerve. IX, glossopharyngeal nerve; PhX, pharyngeal branch of vagus nerve; SLN, superior laryngeal nerve XII, hypoglossal nerve. Adapted from Hayashi and McCrimmon (1996). Traces depict activity in a rat, but activity is similar in other mammals although respiratory frequency varies from greater than  $100 \times \text{min}^{-1}$  in mice to about  $3 \times \text{min}^{-1}$  in giraffes. B) Discharge patterns of respiratory neurons. For this classification, expiration is divided into E1, early expiration (or post-inspiration), and E2 or late expiration. The transition from inspiration to expiration is marked by a rapid decline in phrenic nerve activity illustrated in the bottom trace. Residual, declining phrenic nerve activity (when present) marks the E1 phase. Augmenting (Aug) activity occurs on the internal intercostal nerve (second trace from bottom) and Aug-E neurons largely during the E2 phase. The ordinate for each trace is discharge frequency with higher levels representing higher frequencies. Aug, augmenting neurons; Dec, decrementing neurons; E, expiratory; I, inspiratory.

consist of at least two phases. The onset of exhalation marks the onset of the first expiratory (E1), or post-inspiratory, phase. During this phase, the diaphragm often exhibits a low level of “postinspiratory” activity that brakes diaphragmatic relaxation and slows exhalation that declines rapidly, frequently ending by mid-expiration (Fig. 37.4B). At this point, an augmenting pattern of expiratory muscle activity begins, marking the onset of the second (E2) phase, characterized by active expiratory muscle contraction. Are these two phases separate components of rhythm generation, or a premotor division of a single expiratory phase? The rationale that the bursts reflect motor output patterns rather than rhythm is that the transition between the two expiratory phases is often ambiguous. For example, in Figure 37.4A, a declining postinspiratory output of the pharyngeal branch of the vagus nerve, which controls upper airway caliber, overlaps with the E2 pattern of activity in other nerves that affect the diameter of the upper airway, such as the glossopharyngeal and hypoglossal nerves.

The naming of respiratory neurons follows from the phase(s) in which their bursting activity occurs. Thus, neurons are designated inspiratory (I), postinspiratory (post-I), or expiratory (E). Neurons that have activity in more than one phase are termed phase-spanning. In addition, neurons that discharge only during inspiration or only during expiration can have distinctly different patterns of discharge. Investigators have interpreted these diverse patterns as evidence of different roles for each group of neurons in respiratory control and have used the discharge patterns to define subgroups of inspiratory and expiratory neurons. Although the total number of subgroups is relatively small, investigators have measured neuronal activities under various experimental conditions—for example, different species, different anesthesia, or decerebration—and have used slightly different criteria to name them. The result is a confusing array of population names, even to experts.

Representative patterns of discharge are shown in Figure 37.4B with the most common names of the predominant neuronal subgroups. Given this array of neuron types, the quandary is how they form a network. In particular, how do rhythm generating neurons in the preBötC, RTN/pFRG and perhaps elsewhere, interact with the rest of the network, including premotor and motoneurons, to produce the appropriate motor pattern? Investigators have produced working models that begin to address plausible mechanisms, however considerably more information on intrinsic membrane properties and synaptic interactions is required before this goal can be fully realized.

## Synaptic Excitation and Inhibition Shape the Respiratory Motor Pattern

Two factors determine the firing patterns of motoneurons and premotoneurons: rhythmic synaptic drive (Box 37.1) and intrinsic excitability. Typically, respiratory neurons (other than pacemaker neurons) fire when they receive phasic excitatory drive, and they are silent during the pauses in phasic excitatory drive; during these pauses they typically receive phasic inhibitory drive. Fast excitatory drive is probably similar throughout the respiratory control system. Application of antagonists of excitatory amino acid receptors reduces the phasic activity of brainstem respiratory neurons, including those in the preBötC and in the VRC (Feldman *et al.*, 2003), indicating that most of their excitatory synaptic input is via glutamatergic neurotransmission. The inhibitory drive is a bit more complex. Three types of synaptically mediated inhibition must be considered (Fig. 37.5).

**Reciprocal Inhibition.** Between phases of excitatory inputs (e.g., during expiration in inspiratory neurons), most respiratory motoneurons and premotoneurons are actively inhibited. Because these neurons are not spontaneously active, why is it necessary to inhibit them when they are not receiving excitatory input? Most likely, reciprocal inhibition prevents their spurious activation from unexpected afferent inputs that would cause inappropriate muscle contraction. Except for motoneurons that control jaw opening, which must be activated rapidly when a hard object is unexpectedly bitten during chewing, all motor and premotoneurons involved in periodic movements appear subject to reciprocal inhibition.

**Recurrent Inhibition.** There is a push–pull control of neuronal firing during a burst, that is, excitation and inhibition are concurrent, with the net balance determining the firing pattern. Reduction of inhibition (e.g., by the administration of inhibitory receptor blockers to motoneurons) results in increased burst amplitudes.

**Phase-Transition Inhibition.** Inhibition is postulated in many network models for breathing to arrest the activity of neurons producing one phase, thereby allowing transition into the next phase, as the neurons of the next phase become active.

Fast synaptic inhibition in brainstem respiratory networks is associated with an increase in permeability to  $\text{Cl}^-$ , mediated by GABA and glycine. Blocking GABA<sub>A</sub> receptors increases discharge of all VRG neurons. GABA appears to participate in reciprocal and phase-transition inhibitions to help maintain

## BOX 37.1

## EXPERIMENTAL ANALYSIS OF VENTILATION

Neuroscientists are constrained by what they can measure. Noninvasive experiments in humans reveal the phenomenology of breathing; for example, the relationship between ventilation and blood CO<sub>2</sub> levels. Brain imaging may reveal which regions are involved, but at present, spatiotemporal resolution is too coarse to show networks, much less neurons or synapses. Respiration lends itself to study because mammals suitable for experimentation breathe much like humans. Breathing continues following anesthesia or decerebration, and the neural patterns remain following paralysis (and mechanical ventilation), making possible experimental procedures requiring highly invasive techniques, such as single neuron recording. Compared to studies of neurons in culture or in tissue slices, experiments in whole mammals have serious limitations. For example, movements of the heart and lungs make certain types of single neuron recording difficult in the brain stem and spinal cord. Moreover, in live animals, the blood–brain barrier is intact, making precise control of brain extracellular fluid impossible. Finally, experiments are expensive and can

last 36h or more, requiring the dedicated and concurrent efforts of several investigators. Fortunately, the robust features of breathing that allow it to persist when other behaviors are suppressed by anesthesia or decerebration permit further reduction in the experimental preparation that removes these limitations. For example, a respiratory-related rhythm persists in the brainstem and spinal cord removed from a neonatal rodent. In addition, the rhythm persists in a particular slice of brain stem isolated from this preparation (Fig. 37.7). Using such slices, one can correlate exquisite measures of a neuron's intrinsic and synaptic properties and projections with measures of endogenous behavior, such as its firing pattern. With many common and otherwise useful *in vitro* preparations, such as the hippocampal slice, such correlations cannot be made because no endogenous behavior *in vitro* relates to known behavior *in vivo*. In general, *en bloc in vitro*, or slice, preparations play an important role in the study of basic cellular, synaptic, and integrative mechanisms underlying motor behavior.

**FIGURE 37.5** Membrane potential and discharge pattern of an augmenting inspiratory (or expiratory) neuron. The timing of three distinct types of inhibition is indicated.

appropriate timing of discharges in (pre)motor networks. GABA also appears to play a key role in regulating the baseline discharge frequency of VRG respiratory neurons, as antagonism of GABA<sub>A</sub> receptors with bicuculline amplifies the discharge pattern.

In inspiratory neurons, glycinergic transmission appears to mediate the rapid inhibition at the begin-

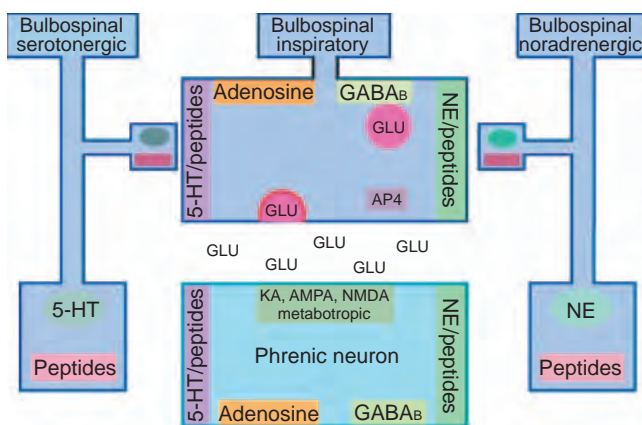

ning of expiration. Despite the clear role of synaptic inhibition in maintaining appropriate patterns of activity within the premotor circuitry, respiratory rhythms can be generated in the absence of phasic synaptic inhibition, at least in *in vitro* slices (see later).

### Neurotransmitters Contribute to the Modulation of Breathing

The waxing and waning membrane potential underlying the periodic bursting of motoneurons can be ascribed simply to the alternating release of glutamate, GABA, and glycine. Given the straightforward task of these motoneurons, especially for muscle as specialized as the diaphragm, one might presume that little more is required to control their excitability. Yet the picture is much richer and provides some insight into possible roles for the diversity of transmitters.

For all respiratory neurons including motoneurons, neuromodulators affect their discharge pattern. Modulators that alter respiratory rhythm and pattern include serotonin, catecholamines (norepinephrine, epinephrine, and dopamine), acetylcholine, adenosine, and numerous peptides (typically colocalized with the

amines), including substance P, neuropeptide Y, galanin, met-enkephalin, cholecystokinin, and thyrotropin-releasing hormone (Fig. 37.6). Many of these modulators are present in the phrenic nucleus. Why are so many present at such a simple relay to a muscle with a limited repertoire of functions? Multiple transmitters and receptors may be necessary to control neuronal excitability over the broad time scales important in breathing, from the millisecond scale of synaptic currents, to the seconds required to alter ventilation in response to changes in blood gases, to the hours or days for acclimatization to altitude or adjustment to disease, development, pregnancy, and aging. Multiple transmitters may allow coarse and fine control of  $P_{O_2}$ ,  $P_{CO_2}$ , and pH and may also ensure that breathing is not compromised by changes in state, especially during sleep when global changes in amine levels can affect motoneuronal excitability. During rapid eye movement (REM) sleep, motoneuronal excitability produces a widespread muscle atonia, yet respiratory motoneurons must continue to drive respiratory muscles. Some of these modulators, particularly 5-HT and NE, may underlie persistent changes in excitability (see later). Finally, multiple neurotransmitters may be needed to prevent respiratory muscle fatigue. A strong inspiratory drive will sufficiently elevate glutamate in the synaptic cleft to act via a presynaptic metabotropic receptor to reduce further release. This governor of maximal phrenic motoneuronal activity would limit the likelihood of diaphragmatic fatigue during periods of sustained high ventilatory demand (e.g., fleeing a predator).

**FIGURE 37.6** The diversity of synaptic control of phrenic motoneurons is essential for their proper function. The challenge is to understand how these mechanisms act in an integrated manner. Isolating and studying them one by one or out of context, e.g., in culture, may fail to reveal key properties. AMPA (see text), GLU, glutamate; 5-HT, serotonin; KA, kainate; NE, norepinephrine.

## WHERE ARE THE NEURONS THAT GENERATE THE BREATHING RHYTHM?

Although it has been known since the late eighteenth century that the brainstem is responsible for respiratory rhythm generation, precise localization of neurons involved required the development of novel *in vitro* preparations (Box 37.1). In the 1980s, Suzue and colleagues (Ballanyi *et al.*, 1999) noted that the isolated neonatal rat brain stem and spinal cord, termed the *en bloc* preparation, generated a respiratory rhythmic motor output in spinal nerves that innervate muscles of the respiratory pump, as well as in cranial nerves innervating the airways, which control airway resistance. This *in vitro* preparation permitted a refinement of the “blunt spatula” brainstem transection approach used almost 200 years earlier by Legallois (1813) to identify structures critical for respiratory rhythm generation. In the contemporary case, removing thin (50–75  $\mu\text{m}$ ) sections from either rostral or caudal ends of the *en bloc* preparation while recording respiratory activity from spinal or cranial nerves resulted in the isolation of a small, ventral medullary region as an essential component in the rhythm generating circuitry (Smith *et al.*, 1991). Lacking an anatomical designation, this region was named the preBötzinger Complex. Confirmation that neurons within this region provide a minimum essential circuitry for respiratory rhythm generation follows from the observations that a thin transverse slice that contains the preBötC can generate a respiratory-related rhythm (Fig. 37.7). In addition, the necessary role of preBötC neurons for rhythm generation is suggested by the observation that local blockade of excitatory, glutamatergic neurotransmission abolishes respiratory rhythm.

Further demonstration of the essential role of the preBötC in respiratory rhythm generation follows from the observation that local activation of receptors for substance P or for opioids, which are expressed on restricted subsets of neurons within the preBötC, change respiratory frequency. Targeted destruction of preBötC neurokinin-1 (NK1) receptor-expressing neurons with the toxin saporin (a ribosomal toxin that interferes with the synthesis of new proteins) conjugated to substance P disrupts breathing. By itself, saporin is not taken up appreciably by neurons. However, when substance P binds to the NK1 receptor, the ligand–receptor is internalized, and when substance P is conjugated to saporin, the toxin is dragged along into the neuron. The result is that neurons expressing the NK1 receptor in the region of the injection die after several days. This delayed effect permits injected rats to fully recover from surgery

## BOX 37.2

## SPINAL CORD INJURY CAN DIMINISH VENTILATION

Spinal injuries that affect the long axons of bulbospinal premotoneurons, which transmit respiratory drive to spinal motoneurons, can be life-threatening. With respect to the control of breathing, the severity of the injury depends on the spinal cord level at which the injury occurs. Damage between T1 and S1, in addition to causing sensory and motor deficits in the legs (see Chapters 25 and 29, this volume), can produce loss of control of intercostal muscles, leading to a diminished ability to generate inspiratory or expiratory movements. Injury between C4 and C8 can cause quadriplegia and loss of control of all intercostal

musculature. Although innervation of the diaphragm may remain (with low cervical damage), the lack of chest wall control means the diaphragm must do more work; these patients frequently experience an alarming sense of difficulty breathing (dyspnea). Injuries between the lower brain stem and C4 result in pentaplegia, in which there are motor and sensory losses to the legs, arms, diaphragm, and neck. Such injuries require immediate artificial support of ventilation to maintain life. This type of cervical injury is common following dives into shallow pools.

**FIGURE 37.7** A respiratory rhythm generating slice preparation from a rodent brain stem exhibits endogenous respiratory rhythm in cranial nerve XII with patch-clamp recordings from a preBötC neuron. Diagram of a transverse slice. Patch-clamp recordings can be made from XII or preBötC cells while drugs (or different solutions) are supplied in a bath or applied locally. The rhythm is generated in preBötC and transmitted to the XII nucleus so it appears in motor axons of the XII nerve. (Right) A recording from a preBötC inspiratory neuron that shows periodic, inspiration modulated depolarizations and associated action potentials (current-clamp) (upper tracing). Lower tracing is a XII nerve recording; bursts of activity correspond to inspiration.

prior to determining the impact of the toxin on breathing. During the initial postinjection period, rats breathe normally, even during sleep. However, after several days, rats continue to breathe normally during wakefulness but have sleep disordered breathing. After a few more days, with substantial bilateral destruction of the NK1 preBötC neurons, rats develop a highly abnormal breathing pattern during wakefulness and are essentially unable to breathe during sleep; they are unable to maintain normal levels of blood  $O_2$  and  $CO_2$ , and have pathological responses to hypoxia and hyperoxia. Nevertheless, the rats maintain sufficient ventilation to survive. These results suggest that preBötC neurons are required for normal breathing, but in their absence, other neurons can generate an ataxic

breathing pattern sufficient to maintain life. The identity of the neurons generating this remaining rhythm is unknown but could include preBötC neurons lacking NK1 receptors or even neurons that normally generate volitional breathing movements.

Taken together, these experiments underlie the now widely accepted view that the preBötC is an essential component of the circuitry generating breathing rhythm.

### A Second Respiratory Rhythm Generator Is Unveiled

Another collection of neurons, near the ventral medullary surface, rostral to the preBötC, may also be

essential for rhythmogenesis. They are proximal to the facial nucleus in the pFRG; they may also be coextensive with the RTN, and we will refer to them as the RTN/pFRG (Fig. 37.3). Several factors point to their involvement in generating breathing pattern:

1. RTN/pFRG neurons are rhythmically active neurons in *en bloc* preparations.
2. When isolated from the preBötC by intramedullary transection in these preparations,

3. When exposed to  $\mu$ -opiates, inspiratory activity in slices (which contain the preBötC but not the RTN/pFRG) slow down continuously, whereas inspiratory activity in *en bloc* preparations and *in vivo* slows discontinuously, a phenomena referred to as quantal slowing (Fig. 37.8); in similar conditions *in vivo*, rhythmic expiratory activity remains unaffected (Fig. 37.8).

**FIGURE 37.8** Inspiratory and expiratory rhythm generators in juvenile rat *in vivo*. **Top.** Left: Typical recording with normal cycles (1, 3, 6) interspersed with cycles without inspiratory activity (2,4,5) Traces from top: integrated genioglossus muscle EMG; integrated abdominal muscle EMG, tidal volume ( $V_T$ ); and air flow (inspiratory air flow is up). Right: Superposition of  $\int EMG_{GG}$  and  $\int EMG_{ABD}$  in a normal cycle (black) compared to an inspiratory skipped cycle (red). Note the marked differences, especially in the  $\int EMG_{ABD}$  burst. **Bottom.** Alternating inspiratory and active expiratory activity is evident in EMG GG and EMG ABD following complete brainstem transection in the plane marked rostral-t. Following a more caudal transection (caudal-t), effectively removing the RTN/pFRG, only active inspiratory activity is present. From Janczewski and Feldman, *J. Physiol.* (2006).

So, it appears that the preBötC and RTN/pFRG each have the intrinsic capacity to generate a respiratory rhythm, but normally are entrained to produce a single rhythm.

Thus, although many structures can modulate respiratory pattern, the working hypothesis of many in the field is that there are (at least) two coupled oscillators, the preBötC and the RTN/pFRG. An additional hypothesis is that inspiratory rhythm is generated by the preBötC and active expiration by the RTN/pFRG (Feldman and Del Negro, 2006).

Why two oscillators? Breathing in mammals is the end result of an evolutionary lineage of rhythmic movements that are closely driving rhythmic activity in gills of fish and adaptations related to the transformation of the swim bladder into the lung. Tadpoles have two distinct breathing patterns that can act separately or in tandem, with the “lung” rhythm opiate-sensitive whereas the “buccal” rhythm is not. The relative role of the two oscillators may differ between mammals and nonmammals, since the power stroke for breathing is primarily inspiratory and diaphragm-driven in mammals, whereas in most reptiles and amphibians, the power stroke is dominated more by expiratory effort.

Opiate-sensitivity clearly has consequences at birth, when there is a significant surge of maternally-derived opiates in the newborn mammal. This opiate surge should depress the opiate-sensitive preBötC; the unaffected RTN-pFRG may play an essential role in providing the necessary respiratory drive during the early postnatal period.

### Do Pacemaker Neurons Contribute to Rhythm Generation?

Almost every successful explanation of brain processes underlying complex behavior is based on a combination of cellular, synaptic, and network properties. It is easy to build computational models of simple oscillatory behavior using only network (e.g., reciprocal inhibition) or only cellular (e.g., pacemaker) properties. For several decades neuroscientists speculated that respiratory rhythm was driven by the same kinds of cellular properties that drive heart rhythm, which is generated by the pacemaker activity of specialized cells. The simplest explanation for generation of respiratory rhythm is that it is driven by pacemaker neurons, presumably located in the preBötC and/or RTN/pFRG. The compelling, but now intensely debated, evidence that pacemaker neurons were critical came from the observation that rhythm in slices continues after blockade of postsynaptic inhibition. *In vitro*, neurons with bursting-pacemaker properties repre-

sent a subpopulation (5–25%) of preBötC neurons. There are two types: voltage-dependent and driven by a persistent Na conductance ( $I_{NaP}$ ), present at birth; and those dependent on  $Ca^{2+}$  and/or a  $Ca^{2+}$ -activated non-specific cation current ( $I_{CAN}$ ), sparse before postnatal day 5.

Since the previous edition of this book, the pacemaker hypothesis has been challenged. Now, there are data that such activity is not essential (Feldman and Del Negro, 2006). While an obligatory role of pacemaker activity is disputed, there is a critical role in rhythmogenesis for intrinsic  $I_{NaP}$  and  $I_{CAN}$  currents that appear to be present in all preBötC neurons, pacemaker or otherwise, and contribute to burst generation in the context of amplifying inspiratory-related synaptic input.

### Summary

At the heart of breathing is rhythm generation. The site for automatic generation of this rhythm is within the brainstem. The consensus hypothesis is that the critical circuits lie within the preBötC and may also include the RTN/pFRG.

## SENSORY INPUTS AND ALTERED BREATHING

### O<sub>2</sub> and CO<sub>2</sub> Are Measured by Chemoreceptors

The principal homeostatic goal of breathing is the maintenance, within narrow limits, of arterial blood O<sub>2</sub> and CO<sub>2</sub> levels; that is, arterial Po<sub>2</sub> = 80–100 mmHg and Pco<sub>2</sub> = 35–45 mmHg. Changes in Po<sub>2</sub>, Pco<sub>2</sub>, and pH alter chemoreceptor activity, inducing reflex alterations in breathing that restore them toward regulated levels. Decreases in either Po<sub>2</sub> or pH or an increase in Pco<sub>2</sub> stimulates breathing, whereas increases in Po<sub>2</sub> or pH or a decrease in Pco<sub>2</sub> depress breathing.

The consequences of anoxia are catastrophic (particularly for the brain), but the effects of modestly depressed or elevated Po<sub>2</sub> are benign. In contrast, small changes in Pco<sub>2</sub> can profoundly affect cellular metabolism (due in large part to consequent changes in pH). Thus, at rest and in health, ventilation is controlled mostly to regulate CO<sub>2</sub>; however, in severe hypoxia, everything else is ignored. For example, the exceptionally low ambient Po<sub>2</sub> at the top of Mount Everest (~40 mmHg) results in such a strong ventilatory drive that Pco<sub>2</sub> in climbers without supplemental O<sub>2</sub> is exceptionally low (~7 mmHg compared with normal ~40 mmHg; see Box 37.3).

## BOX 37.3

## DISORDERS OF THE CHEMICAL CONTROL OF BREATHING ARE WIDESPREAD AND SERIOUS

Breathing is normally tightly controlled to maintain arterial  $P_{CO_2}$  within a narrow range close to 40 mmHg. However, cardiopulmonary pathology can increase  $P_{CO_2}$  markedly. When  $P_{CO_2}$  exceeds 90–120 mmHg, respiratory depression ensues. With further increases in  $P_{CO_2}$ , central nervous system function can be impaired severely; a life-threatening positive feedback loop can develop in which depression of breathing elevates  $P_{CO_2}$ , which further depresses breathing. In some patients with advanced chronic lung disease, and consequently elevated  $P_{CO_2}$ , any acute lung disease, such as bronchitis or pneumonia, can cause a further increase in  $P_{CO_2}$  and exacerbate respiratory depression. In these patients, the drive to breathe comes from hypoxemia (low blood  $P_{O_2}$ ) sensed by peripheral chemoreceptors. If these patients breathe  $O_2$  without medical monitoring, the hypoxemia may disappear, and without this stimulus these patients' breathing may stop.

Drug abuse is another cause of respiratory depression sufficient to elevate  $P_{CO_2}$  to produce further respiratory depression. Narcotics, barbiturates, and most general anesthetics depress breathing and reduce the sensitivity of the chemoreceptors to elevations in  $P_{CO_2}$  or reductions in  $P_{O_2}$ . Therefore, at high doses these drugs can cause death by respiratory failure.

*Sleep apnea.* Sleep is associated with a modest decrease in ventilation and a reduced responsiveness to deviations in  $P_{CO_2}$  and  $P_{O_2}$ . As a result, during sleep, arterial  $P_{CO_2}$  increases a few mm Hg and  $P_{O_2}$  decreases. This change in respiratory control is associated with the loss of a wakefulness-related excitatory drive. The source of this wakefulness stimulus is not known, but it may derive from corollary activity originating in the brain stem reticular-activating system.

With the onset of sleep, the breathing pattern can become unstable, and apnea (defined as at least 10 s without breathing) can occur. Two major types of apnea have been defined (White, 1990). The most common, *obstructive* sleep apnea occurs when inspiratory airflow reduces airway pressure (via the Bernoulli effect), pulling in on the walls of the upper airway and causing airway obstruction. During wakefulness, the activity of airway muscles counteracts this collapsing force. However, during sleep the reduction of airway muscle tone can result in vibration of the walls of the oropharynx (i.e., snoring). In more severe cases, the loss of activity in the glossopharyngeal nerve, which innervates the tongue, can cause the airway to become obstructed. Obstruction

reduces or abolishes ventilation, raising  $CO_2$  and lowering  $O_2$ . This in turn can cause arousal, or waking, and restoration of airway muscle tone and airway patency. In serious cases, the cycle of sleep, airway obstruction, and hypoxia-induced waking repeats hundreds of times every night. The marked disruption of sleep can cause debilitating hypersomnolence, and severe obstructive sleep apnea can also have other sequelae, such as hypertension.

In the less common *central* sleep apnea, pauses in breathing result from the failure of the central pattern generator for breathing to generate a rhythmic motor command. Mechanisms underlying central apneas are not understood, but the problem is associated with a variety of neurodegenerative diseases, including amyotrophic lateral sclerosis, Parkinson's disease, and multiple systems atrophy (where there is evidence of loss of preBötC neurons).

*Sudden infant death syndrome* (SIDS; Martin, 1990). SIDS is defined as the unexpected sudden death of an infant or young child that cannot be explained by a postmortem examination. SIDS is the leading cause of death of infants between 1 month and 1 year of age in the United States. Although a number of etiologies are likely to contribute to SIDS, current hypotheses tend to focus on abnormalities of cardiorespiratory control. The apnea hypothesis of SIDS attributes apnea to disorders of both the chemical control of breathing and the arousal response to insufficient ventilation. Infants who later succumb to SIDS have been described as exhibiting irregular breathing patterns, including periods of apnea, and depressed arousal responses to hypoxia or hypercapnia. Epidemiologically, SIDS has been associated with infants sleeping face down, where pillows, blankets, and mattress can limit the diffusion of expired air, resulting in elevated  $CO_2$  and lower  $O_2$  in inspired air and, consequently, in arterial blood. This in turn could depress breathing sufficiently to cause respiratory arrest and death.

## O<sub>2</sub>

The mammalian brain is extremely sensitive to O<sub>2</sub> deprivation. Several minutes of anoxia can initiate a cascade leading to neuronal (and, if sufficiently widespread, brain) death. Brain hypoxia can cause loss of consciousness. Accordingly, the principal O<sub>2</sub> sensors for breathing for the entire body, the carotid bodies, are in the bifurcation of the common carotid artery, the main portal through which O<sub>2</sub> enters the brain. The transduction of O<sub>2</sub> levels has been intensely studied since Corneille Heyman's Nobel Prize winning discovery (1938) of the physiological function of the carotid bodies. O<sub>2</sub>-related signals enter the brain via the glossopharyngeal nerve and terminate in the NTS.

O<sub>2</sub> sensors account for only a small part of the chemical drive to breathe during wakefulness, as breathing 100% O<sub>2</sub> reduces chemoreceptor discharge to near zero but only decreases ventilation by about 15% in awake mammals (Bisgard and Neubauer, 1995). Decreasing P<sub>O<sub>2</sub></sub> has relatively little influence on chemoreceptor activity and ventilation until it falls at or below 60 mmHg. With further reductions in P<sub>O<sub>2</sub></sub>, chemoreceptor discharge and ventilation increase exponentially.

## CO<sub>2</sub>

Ventilation is very sensitive to small changes in P<sub>CO<sub>2</sub></sub>. In an adult human, a 1 mmHg increase in P<sub>CO<sub>2</sub></sub> leads to a 2 liter × min<sup>-1</sup> increase in ventilation at rest (which is ~5 liter × min<sup>-1</sup>). In other words, a 2.5% increase in P<sub>CO<sub>2</sub></sub> at rest leads to a 40% increase in ventilation!

The sites and mechanisms of CO<sub>2</sub> chemoreception are the subject of intense scrutiny (Feldman *et al.*, 2003). Although the carotid bodies are sensitive to changes in P<sub>CO<sub>2</sub></sub>, a robust CO<sub>2</sub> response remains in peripherally chemodenervated, vagotomized mammals, indicating the existence of intracranial sensors for CO<sub>2</sub> or related variables (pH, HCO<sub>3</sub><sup>-</sup>). A number of structures are implicated in intracranial chemotransduction (Feldman *et al.*, 2003), including:

- RTN
- Serotonergic neurons in the medullary raphe nuclei
- NTS
- Noradrenergic neurons in the locus coeruleus
- Cerebellar fastigial nucleus
- PreBötC

For example, neurons within the RTN and raphe robustly respond to changes in CO<sub>2</sub>/pH within the physiological range and project to respiratory nuclei (Mulkey *et al.*, 2004; Richerson, 2004).

## MECHANORECEPTORS IN THE LUNGS ADJUST BREATHING PATTERN AND INITIATE PROTECTIVE REFLEXES

Many different patterns of muscle activity can produce appropriate ventilation; however, the specific pattern should minimize energy expenditure. Mechanical efficiency, in turn, depends on factors such as posture, and lung and chest wall mechanics; for example, a fibrotic (stiff) lung is harder to inflate to a given tidal volume than a normal lung, and thus for this condition, rapid, shallow breathing is more efficient. Feedback about the mechanical status of the lungs and chest wall is provided by mechanoreceptors.

Because the airways must be patent for airflow, airway receptors produce three of the most powerful and compelling of *all* reflexes: gagging, coughing, and sneezing. Another powerful reflex that occurs at birth is stimulated by pulmonary receptors, when the transition from the liquid uterine to an air environment requires powerful inspiratory efforts (sighs) to overcome surface forces resisting the initial lung inflation. Additional nonspecific reflex stimuli, typically mechanical or thermal, further facilitate the first inspiratory sighs. Special respiratory reflexes, such as sneezing and yawning, are also generated by pulmonary receptors.

Mechanosensory signals are critical in adapting, adjusting, and integrating breathing with other acts of brain and body. Many movements impact directly on breathing, either by using the same muscles—for example, phonation, posture, defecation, and emesis—or through mechanical linkages, such as locomotion.

### Lung Afferents

There are three distinct groups of lung afferents, all in the vagus nerve and terminating in the NTS (see Table 37.1; Kubin *et al.*, 2006). Two groups consist of large, myelinated A fibers, with receptors in the airways, and include slowly adapting and rapidly adapting pulmonary stretch receptors. The third group gives rise to small, unmyelinated C fibers and responds to inhaled irritants such as smoke. Most natural stimuli (e.g., pulmonary edema or alveolar collapse) probably activate multiple receptor types.

### Slowly Adapting Pulmonary Stretch Receptors (SARs)

Located in airway smooth muscle, SARs are activated when the airways stretch during lung inflation (Kubin *et al.*, 2006). Their activation drives reflexes by

TABLE 37.1 Pulmonary Vagal Afferents and Their Associated Reflexes

Receptor (fiber type)	Location	Stimulus	Reflex Response
Slowly adapting pulmonary stretch receptors (myelinated, A- $\beta$ )	Airway smooth muscle	Lung inflation (distension of airways)	Breuer–Hering (a) inspiratory termination (b) expiratory prolongation, airway dilation
Rapidly adapting pulmonary stretch receptors (myelinated, A- $\beta$ )	Airway epithelium and subepithelial layers of mucosa	Rapid lung inflation or deflation, edema in walls of large airways, chemical irritants	Augmented inspiration (sigh), shortened expiration, airway constriction, may contribute to cough
Cough receptors (myelinated, A- $\delta$ )	Mucosa of extra-pulmonary airways	Punctate mechanical stimuli, acid	Cough
Broncho-pulmonary C fibers (unmyelinated, C)	Throughout airways and alveolar wall	Chemical irritants, edema	Apnea (cessation of breathing), rapid shallow breathing, airway constriction, mucus secretion, may contribute to cough

which lung inflation shortens inspiration and prolongs expiration (Breuer–Hering reflex), which is an important determinant of inspiratory duration during normal relaxed breathing in most mammalian species, with the notable exception of humans. The activation of these receptors shortens inspiration and increases breathing frequency. In humans, activation of SARs by normal breaths only modestly alters inspiratory timing. Their activation also relaxes airway smooth muscle, dilating the airways to make breathing easier.

### Higher Order Neurons in the Breuer–Hering Reflex

The Breuer–Hering reflex is one of the most intensely studied vagal reflexes. Because its activation changes respiratory frequency, the underlying mechanisms illuminate aspects of the central rhythm generator for breathing. SAR afferents monosynaptically activate “pump” neurons in the NTS. Many pump cells are GABAergic and, in some cases, glycinergic and project widely within the VRC as well as to the PRG.

### Rapidly Adapting Pulmonary Stretch Receptors (RARs)

Located in airways, RARs initiate protective reflexes, including coughs, in response to a variety of stimuli, including large or rapid lung inflation or deflation, inhaled irritants, and, possibly, airway edema (see Table 37.1; Kubin *et al.*, 2006). Smoke activates RARs and elicits a cough to rid the airway of the offending material. RARs elicit a larger than normal inspiration (sigh) in response to alveolar collapse (atelectasis), inflating the lung and popping open the alveoli. Also contributing to cough is a recently identified group of airway receptors, termed cough receptors, with small myelinated fibers (A- $\delta$  fibers; Canning, 2006).

### Bronchopulmonary C Fibers

C fiber afferent activation elicits apnea followed by rapid shallow breathing. Like RARs, C fibers are polymodal, activated by chemical and mechanical stimuli. Their activation also enhances airway mucus secretion. Inhaled particles are trapped in the mucus and removed from the airways by the action of cilia, which continuously (in the nonsmoker) move the mucus and trapped particles toward the mouth to be swallowed or expectorated.

### Summary

Chemoreceptors in the carotid bodies and in the brain provide sensory input to the central circuits controlling breathing to tightly regulate  $P_{CO_2}$  and  $P_{O_2}$  within narrow limits, matching a wide range of metabolic demands. Carotid body chemoreceptors are especially sensitive to decreases in arterial  $P_{O_2}$ , while also sensing increases in arterial  $P_{CO_2}$  and decreases in arterial pH. Central chemoreceptors are exquisitely sensitive to increases in  $P_{CO_2}$  and decreases in pH, but respond little to changes in  $P_{O_2}$ . Mechanoreceptors, especially those in the lungs, are essential for the precise regulation of the timing and amplitude of breathing, and also participate in reflexes, such as coughing, that protect the airways and lungs from compromises in airflow.

## MODULATION AND PLASTICITY OF RESPIRATORY MOTOR OUTPUT

The spatiotemporal pattern of motor outputs for breathing must constantly adjust over short-time scales (e.g., due to changes in posture), medium-time scales

(e.g., during exercise), and much longer time scales (e.g., to adapt to changes in lung and chest wall mechanics that accompany postnatal development, normal aging, and pulmonary disease). A good example is adaptation to hypoxia, which increases ventilation by multiple mechanisms acting in time domains lasting seconds, minutes, and hours to days (Mitchell *et al.*, 2001). Thus, a single 10–20 min episode of hypoxia increases ventilation and it remains elevated for several minutes after return to breathing room air. This slow posthypoxic decline back to normal ventilation is referred to as *short-term potentiation* (Fig. 37.9) that may be important in smoothly changing respiratory responses during rapid or large changes in afferent input, since abrupt changes can result in an unstable breathing (e.g., Cheyne–Stokes respiration; Fig. 37.10).

A longer-lasting mechanism is revealed following repetitive brief episodes of hypoxia (three episodes of 5 min duration). As illustrated in Figure 37.9, following the decline in short-term potentiation after the third hypoxic episode, ventilation transiently returns toward control levels, but is followed by a slow, progressive augmentation that lasts for several hours; this postepisodic hypoxic response is known as *respiratory long-term facilitation*.

The mechanism of respiratory long-term facilitation has been investigated extensively (Feldman *et al.*, 2003). This form of plasticity requires episodic rather than continuous stimulation. The episodic and repetitive nature of activation of serotonergic and noradrenergic receptors appears necessary for its initiation but not its maintenance. Activation of serotonergic and noradrenergic receptors on respiratory motoneurons is hypothesized to initiate an intracellular signaling cascade, resulting in the synthesis of new proteins, including BDNF, that amplify the synaptic currents associated with descending, glutamatergic synaptic inputs from respiratory premotoneurons (Fig. 37.6). Thus, in many respects, respiratory long-term facilitation has similarities with other forms of synaptic plasticity in its stimulus pattern sensitivity and requirement for protein synthesis. The requirement for episodic serotonin receptor activation is similar to serotonin-dependent plasticity at the sensorimotor synapse of *Aplysia*.

Long-term facilitation could underlie some of the adaptive changes to pathophysiological conditions associated with repeating episodes of hypoxia. For example, it may stabilize respiration during repeated periods of sleep apnea that consequently result in episodic hypoxia. During sleep, the activity of

**FIGURE 37.9** Respiration-related neural activity in an anesthetized and artificially ventilated rat exhibits *respiratory long-term facilitation*. On the left in each trace, electrical activity in the phrenic nerve (the main nerve innervating the diaphragm) is integrated such that each peak represents the magnitude of a “fictive inspiration” that the artificially ventilated rat had intended to make. Under normal conditions of arterial oxygen and carbon dioxide (baseline), the phrenic bursts are rhythmic and consistent. When the rats are exposed to different patterns of decreased arterial oxygen (intermittent, upper trace; continuous, lower trace), phrenic bursts increase in amplitude, reflecting the drive to take deeper breaths when hypoxia-sensitive chemoreceptors are activated. In both types of low oxygen exposure, phrenic nerve activity slowly returns nearly to baseline over a period of several minutes in a process termed short-term potentiation (STP; open arrowheads). Following STP, in the case of intermittent but not continuous hypoxia, phrenic burst amplitude increases slowly and progressively over an hour, even though arterial oxygen and carbon dioxide are at baseline levels. This slow increase reflects a sort of “respiratory memory” that is elicited by intermittent hypoxia, or respiratory long-term facilitation (LTF). Respiratory LTF appears to result from serotonin-dependent plasticity (see text). Courtesy of T. L. Baker and G. S. Mitchell.

serotonergic raphe and noradrenergic neurons is reduced dramatically. Repeated activation of these neurons secondary to apnea-induced chemoreceptor activation could increase ventilatory drive and reduce the incidence and/or severity of subsequent apneas.

An example of unstable breathing is seen in a subset of patients in whom the central network controlling breathing responds to a change in activity of the chemoreceptors by causing too large or too rapid a change in breathing, as is the case in many individuals with congestive heart failure, who often exhibit Cheyne–Stokes respiration, especially during sleep (Fig. 37.10). Marked derangements of breathing can also occur in response to pathology within a variety of other brain regions that contain projections to respiratory neurons (Box 37.4).

### Summary

As metabolism, posture, and sleep–wake state change, the breathing pattern must adjust rapidly to ensure appropriate and efficient ventilation. Development and disease, as well as adaptation to changes in altitude, are processes that require slower adaptations in breathing. Amino acids, amines, peptides, and other neurotransmitters coordinate circuits generating and modulating respiratory pattern to ensure that adaptations proceed smoothly and precisely by mechanisms that remain to be determined.

## SUPRAPONTINE STRUCTURES AND BREATHING

We have focused on the roles of the pons, medulla, and spinal cord in the control of breathing. With respect to breathing, emotional and overt behavioral responses serve respiratory homeostasis. For example, although lung irritants such as smoke can elicit a cough as a protective reflex, mammals will avoid approaching environments where lung irritants are present, based on learned or unlearned sensory cues. Escape from environments inhospitable to respiratory homeostasis is also readily evoked and engages a broad range of higher order brain functions. It is interesting to note, however, that many organisms may voluntarily temporarily suspend breathing altogether to serve competing behavioral demands, such as mammals diving to catch prey under water.

Breathing also serves other behaviors. Speech, for example, requires the coordination of jaw and facial muscles, precise tongue, upper airway, and laryngeal control, and coordinated activity of breathing muscles to produce controlled modulation of expiratory airflow. The anterior limbic cortex (including the rostral anterior cingulate gyrus), midbrain periaqueductal gray, parabrachial region, ventrolateral pons, brain stem respiratory nuclei, and cranial and spinal motoneurons contribute to speech.

Sustained or repetitive movement of large muscles involved in such basic behaviors as fleeing predators,

## BOX 37.4

## CNS LESIONS PRODUCE ABNORMAL BREATHING PATTERNS

Many brain injuries and diseases produce abnormal breathing patterns (Plum and Posner, 1980). Because many brain regions provide afferent input to the neurons generating the breathing rhythm, pathology in regions not normally associated with the generation of breathing can produce abnormal breathing patterns. Despite the diffuse nature of many pathologies that give rise to abnormal breathing patterns, Fred Plum and colleagues systematically characterized several breathing disorders (Fig. 37.10) arising from specific CNS pathologies.

*Apneustic breathing* is marked by prolonged inspiratory periods. In humans, the most frequent pattern is inspirations lasting 2–3s alternating with prolonged expiratory pauses. In cats, the prolonged inspiratory periods are associated with plateaus in inspiratory drive that can last minutes (leading to death in the absence of mechanical ventilation). Apneusis is observed in people with lesions of the pons, including, or just ventral to, the pontine respiratory group. In experimental animals, apneusis requires not only lesions of the pontine respiratory group, but also interruption of vagal afferent input.

Lesions of the corticobulbar or corticospinal tracts can lead to *Cheyne–Stokes respiration*, a rhythmic waxing and waning of the depth of breathing. Periods of no breathing (apnea) follow each period of waning inspiratory depth. Lesions of the corticobulbar and corticospinal tracts can

also result in loss of voluntary control of breathing. In pseudobulbar palsy, for example, voluntary control of breathing and of cranial motoneuron function is lost secondary to a lesion often located dorsomedially in the base of the pons.

Extensive bilateral damage to the medullary respiratory groups can severely disrupt or abolish respiratory rhythm, resulting in death unless artificial ventilation is initiated immediately. Fortunately, unilateral damage does not appear to be sufficient to cause severe disruption of respiratory rhythm- and pattern-generating mechanisms. Because two vertebral arteries supply blood to the medulla, bilateral damage from an infarct or embolism is unlikely.

Less extensive damage to medullary respiratory structures can produce *ataxic breathing*, an irregular pattern of breathing with apparent randomly occurring large and small breaths and periods of apnea. Breathing frequency tends to be low.

chasing prey, and exercising also involves higher CNS functions. During exercise the metabolic production of CO<sub>2</sub> increases. However, arterial PCO<sub>2</sub> and PO<sub>2</sub> change little during moderate exercise because of an increase in breathing proportional to the demand for gas exchange. This increase may be produced by a feed-forward descending command from higher brain systems and sensory input from joint and muscle receptors. The latter inputs provide feedback about limb and muscle mechanics, but can be considered feed-forward with respect to the control of arterial blood gases because they may provide cues for adjusting the magnitude of the descending command. Any inadequacy in the feed-forward mechanisms to produce appropriate ventilation is immediately met by chemoreceptor feedback (mostly relevant to PCO<sub>2</sub>). Thus arterial blood gases are tightly regulated during moderate exercise.

The volitional initiation of exercise, signaled by suprapontine structures, likely involves parallel acti-

vation of spinal locomotor pathways and brainstem mechanisms controlling breathing and cardiovascular function so that pulmonary ventilation and gas transport change appropriately. Commands for the activation of pulmonary and locomotor muscles presumably arise in similar ways in the motor cortex, thalamus, and basal ganglia. Once the motor command has been initiated, respiratory and locomotor activities are likely coordinated at subcortical levels, including the hypothalamus. Electrical or chemical activation of the hypothalamus of an anesthetized, paralyzed cat elicits fictive locomotion paired with proportional increases in respiratory motor output (suggestive of exercise-related increases in ventilation or exercise hyperpnea) and redistribution of blood flow consistent with the induction of locomotion (Waldrop *et al.*, 1996). Because the animals are paralyzed, muscle activation does not occur, and thus the changes in breathing are the result of feed-forward control rather than sensory feedback from joint or muscle receptors.

## Summary

Breathing is a basic physiologic function that must be controlled vigilantly by the brain. This chapter has explored basic mechanisms underlying rhythm generation, sensory processing, and motor output. Given the broad range of experimental systems available to study these mechanisms, from *in vitro* rodent brain stem slices to intact awake and sleeping humans, all levels of neurobiological analysis have considerable potential to unravel integrative mechanisms of brain function that may be of general importance.

## Food Intake and Metabolism

Eating is a familiar behavior. In humans, it is strongly influenced by cultural, social, and experiential factors. Consequently, eating has been a subject of considerable interest to social and behavioral scientists. In mammals, including humans, food intake is also a regulatory behavior with the primary function of supporting the continuous energy demands of body tissues. When considered from this biological perspective, food intake is influenced by hunger, satiety, and the physiological mechanisms that couple eating with internal caloric supplies and a stable body weight. This chapter discusses the signals important for the central nervous system to control food intake and also describes mechanisms thought to integrate those signals.

Despite decades of investigation, considerable differences of opinion still exist about how food intake is controlled. The multiple views follow one of two principles. The first considers eating to be a consequence of depleted energy stores in adipose tissue, reduced use of energy-rich *metabolic fuel* (glucose or lipid) in some critical tissue, or both. In this schema, the purpose of eating is to restore energy reserves in adipose tissue or to increase fuel utilization to some desired level, thereby eliminating the signal to eat. This traditional “depletion–repletion” model is not the approach taken in this chapter. Rather, we subscribe to a second principle, in which hunger is thought to be initiated in part by the gradual disappearance of inhibitory satiety stimuli that were generated by the previous meal. In addition, meal initiation may occur based on learning, habits, and various social and other situations, which allow animals to take maximal advantage of their environment. According to this view, *caloric homeostasis* influences meals, albeit indirectly, and eating contrib-

utes to caloric homeostasis by providing nutrients. The storage and use of those nutrients are regulated independently by physiological mechanisms described later. We describe the properties of caloric homeostasis before we consider the control of food intake.

### CALORIC HOMEOSTASIS

#### Homeostatic Mechanisms Provide a Continuous Supply of Metabolic Fuels to Cells

The purpose of caloric homeostasis is to preserve cellular metabolism. Cells oxidize metabolic fuels to drive all cellular processes; thus, the higher the cellular activity, the greater the demand for energy. Because most cells have limited amounts of stored energy, they rely on a steady supply of calories and oxygen from the blood stream. Oxygen is dependably and instantaneously available via the respiratory system and is not stored in the body. In contrast, food calories can be scarce and require time after ingestion to become available to cells in significant quantities. One consequence of this functional organization is the capacity of animals to store sufficient energy to bridge long intervals during which no food is eaten.

Three categories of macronutrients—carbohydrates, lipids, and proteins—provide usable energy, but the use of specific macronutrients by the body varies depending on the tissue. Most tissues can oxidize carbohydrates in the form of *glucose* or lipids in the form of *free fatty acids*, depending on the availability of these nutrients and the levels of certain hormones in the blood. Notable exceptions are the liver, which requires

lipids for proper functioning, and the brain, which has a large, continuous need for glucose despite the ability to oxidize lipids in the form of *ketone bodies*. When the supply of glucose to the brain is compromised, neurons cease to function and in a few minutes consciousness is lost. Death will ensue unless glucose delivery to the brain is restored. Therefore, maintenance of circulating glucose in sufficient amounts to support normal brain function is a critical goal of caloric homeostasis.

Two distinct metabolic states are defined by the availability of recently consumed food to cells. The *prandial*, or fed, state is characterized by an abundance of newly ingested and absorbed nutrients in the blood. These molecules are sequestered rapidly in tissues to prevent them from being excreted wastefully in urine. The *postabsorptive*, or fasted, state is characterized by the absence of calories entering the circulation from the gastrointestinal tract and a consequent reliance on energy from metabolic fuels less recently consumed and stored. These stores are released gradually into the blood during a fast. In both states, tissues take nutrients from the blood as needed for cellular metabolism.

Many tissues store carbohydrates in the form of *glycogen*, a polymer of glucose; the liver and skeletal muscles have the largest depots. Energy is stored more efficiently, mainly in adipose tissue, as *triglyceride*, each molecule of which consists of glycerol with three attached fatty acids. During the prandial period, newly ingested food is used immediately by the body or is stored as glycogen or triglyceride. Excess carbohydrate is largely converted to lipid (*lipogenesis*) because glycogen storage capacity is limited, and triglyceride is a more efficient form of stored energy. During the fasting period, liver glycogen is converted back to glucose (*glycogenolysis*), which enters the blood and is available to all tissues. Similarly, stored triglycerides are mobilized from adipose tissue (*lipolysis*) and enter the circulation as fatty acids and glycerol. The fatty acids are used by tissues as needed or are converted to ketone bodies (*ketogenesis*), whereas glycerol is converted to glucose (*gluconeogenesis*) (Fig. 38.1).

The liver is the key organ in the traffic of energy. Lipogenesis (which also occurs in adipose tissue) and glycogen formation occur in the liver during the prandial period, and glycogenolysis, ketogenesis, and gluconeogenesis occur during the fasting period. These processes are regulated (discussed later), as are delivery of metabolic fuels (from the small intestine into the circulation), storage of excess fuels, and mobilization of stored energy. The control system involves interplay among several hormones and the sympathetic and parasympathetic divisions of the autonomic nervous system.

**FIGURE 38.1** Schematic diagram of the fluxes of metabolic fuels in the (A) prandial and (B) postabsorptive states. Note the absence of insulin in the postabsorptive state, which greatly facilitates the mobilization of energy stores from the liver and adipose tissue. The adult human liver stores sufficient fuel to support metabolism during fasting for about 7h, whereas the adipose mass has a far greater capacity.

### Insulin Is the Key Hormone Affecting Caloric Homeostasis

Secretion of the peptide hormone *insulin* from B cells of the pancreatic islets is influenced by several factors, among which interstitial glucose is critical. Insulin secretion increases in direct proportion to the concentration of glucose in the blood and does not occur in the absence of glucose. Other substrates, such as amino acids and ketone bodies, also stimulate insulin secretion. In addition, autonomic nerves innervate the pancreatic islets: Cholinergic parasympathetic activity stimulates secretion of insulin, and  $\alpha$ -adrenergic sympathetic activity inhibits it.

When a hungry person anticipates a meal, the aroma and, subsequently, the taste of food initiate insulin secretion via neural activity. Neural signals descend from the forebrain (where the smell and taste of food are recognized) through the hypothalamus to the dorsal motor nucleus of the vagus in the caudal brain stem and then to the pancreas by way of cholinergic fibers of the vagus nerve. This *cephalic phase* of insulin secretion helps reverse the mobilization of fuels that occurs during fasting and prepares the body for the

entry of fuels from the gut. As ingested food enters the stomach and duodenum, several gastrointestinal hormones, which also are important in digestion, stimulate B cells to secrete more insulin. This *gastrointestinal phase* of insulin secretion ensures that the level of insulin in the circulation is high by the time digested nutrients first appear in the bloodstream. Finally, nutrients absorbed from the small intestine cause even greater stimulation of insulin secretion by their direct effect on the pancreas. This *substrate phase* of insulin secretion increases insulin levels further, and this effect lasts well beyond the cessation of eating. As a result of these coordinated meal-related events, prandial insulin secretion is rapid and appropriate to the caloric load, and ingested fuels are efficiently used and stored (Fig. 38.2).

Neural and endocrine factors control the ebb and flow of metabolic fuels from body stores. Circulating insulin is the most important factor that promotes storage. Insulin enables most tissues to take up glucose from the blood for immediate oxidation or for storage

during the prandial period. Conversely, the most important factor for fuel mobilization is the near disappearance of insulin from the circulation during the postprandial, postabsorptive period, when fuel delivery from the small intestine has ended and parasympathetic activity to the pancreas is no longer elevated. Insulin secretion at this time is reduced greatly but is not inhibited and therefore can be stimulated immediately if necessary. For example, when more than the needed amount of stored fuels is mobilized, substrates directly stimulate the pancreas to secrete insulin, thereby slowing substrate mobilization to a rate appropriate to need. Thus, insulin is pivotal for storing calories in the fed state and for allowing stored calories to be mobilized in measured amounts during the postabsorptive state.

The amount of body fat (*adiposity*) is superimposed on other factors that influence insulin secretion. People with low adiposity have a relatively large number of active insulin receptors on adipose tissue and skeletal muscle. Obese individuals have fewer active insulin receptors. Consequently, in response to a given stimulus, secretion of insulin is lower in people who are lean than in those who are obese, but its net effects on adipose tissue are comparable. In healthy, nondiabetic people, this reciprocal relationship between the secretion of insulin and the sensitivity of most tissues to insulin ensures efficient storage and use of fuels independent of body weight. In these individuals, plasma insulin levels in the prandial and the postprandial periods are reliable correlates of adiposity.

**FIGURE 38.2** The three phases of meal-related insulin secretion. The cephalic phase, during which parasympathetic vagal activity stimulates the pancreas, is initiated when food is seen, smelled, and tasted. The gastrointestinal phase is mediated by the direct action of digestive hormones on the insulin-secreting B cells. The prolonged substrate phase is caused by metabolic fuels (mainly glucose) directly stimulating pancreatic B cells. When meals are prolonged, the three stimuli operate simultaneously and have additive effects.

## Summary

All cells require continuous supplies of metabolic fuels to support ongoing activity. The fuels enter the circulation from the small intestine during the prandial period and from storage depots during fasting. The availability of fuels to tissues is controlled primarily by the liver and by the hormone insulin. Hepatic function and insulin secretion are in turn controlled in large part by the autonomic nervous system.

## ROLE OF CALORIC HOMEOSTASIS IN CONTROL OF FOOD INTAKE

### Meals Generate Biological Satiety Signals

The traditional view of caloric homeostasis is that animals eat when they need calories. However, as discussed earlier, the delivery of metabolic fuels to cells is continuous, and animals experience urgent needs for calories to support cellular metabolism

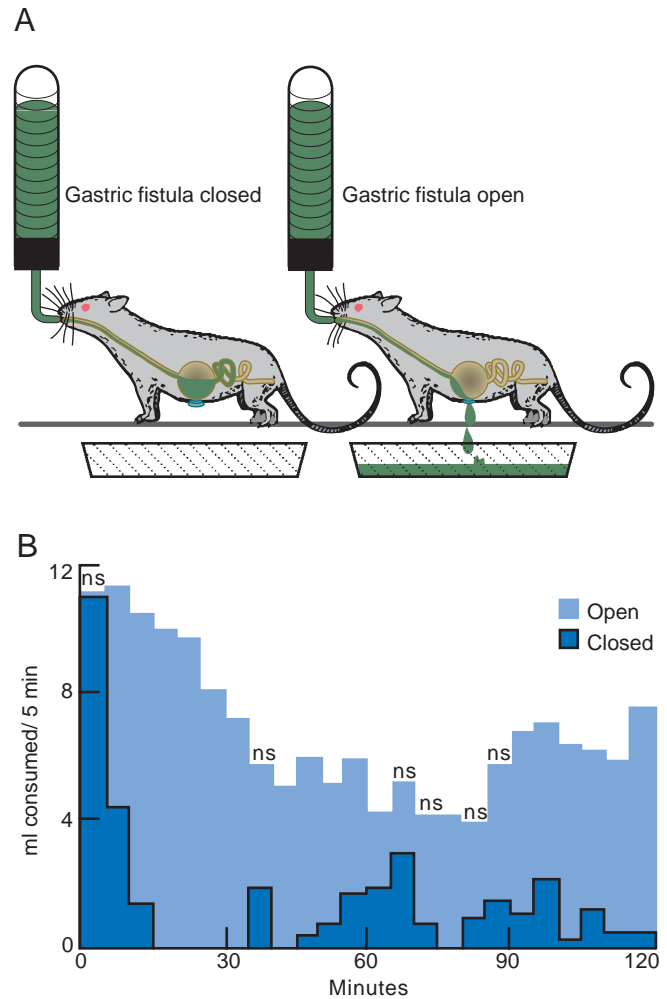

only infrequently. Instead, caloric homeostasis can be related to the control of food intake in ways that are unrelated to acute cellular needs.

Animals consume food in distinct bouts (i.e., meals); therefore, daily food intake reflects the cumulative intake of multiple meals. Control factors influence the time when each meal is initiated and the amount of food consumed before the meal is terminated. The first comprehensive study of meals was reported in 1966 by Le Magnen and Tallon. They maintained laboratory rats in cages and allowed them to eat *ad libitum* for weeks, during which time photosensors and electronic relays recorded intake. They obtained a full record of when meals were initiated, how much was eaten during each meal, how much time passed before the next meal, and so on. No relationship was found between how much a rat ate in a meal and how much time had passed since it had last eaten; in other words, meal sizes were unpredictable. However, the larger the meal, the longer the interval before the next meal, and the relationship was strongest during the night, when rats ate the largest meals. Thus, eating appeared to be inhibited by a satiety signal generated in proportion to the size of a meal, and eating resumed when that signal disappeared. Similar observations have since been made in many laboratories.

### Gastric Distension and Cholecystokinin Provide Satiety Signals

Several meal-related factors might plausibly provide satiety signals. These include factors based on the smell, taste, and texture of food. Factors arising from the stomach could also play a role, as could intestinal and postabsorptive factors that arise after ingested food has left the stomach. In studies of rats, pregastric factors have been ruled out because little satiety is achieved when ingested food is immediately drained out through an esophageal or gastric fistula; these animals eat continuously, as if they had no satiety despite the passage of very large amounts of food through the oropharynx (Fig. 38.3). Because meals end long before significant digestion and absorption occur, gastric factors have been considered a likely source of satiety signals. Gastric volume is an obvious possibility, and, in fact, meals are known to end when substantial *gastric distension* occurs. The stomach wall is richly endowed with stretch receptors whose activity increases in proportion to the volume of the stomach. Those signals are communicated by way of the vagus nerve to the *nucleus of the solitary tract* (NST) and adjacent *area postrema* in the brain stem. The signals travel to the hypothalamus and, ultimately, to the cortex, where gastric distension is perceived.

**FIGURE 38.3** (A) Rats consuming liquid diet, with gastric fistula closed (real eating) or open (“sham eating”). When the gastric fistula is closed, food passes through the stomach and into the small intestine normally. When the gastric fistula is open, ingested food drains out the open fistula instead of accumulating in the stomach to distend it, and no food enters the small intestine. (B) Mean consumption of liquid diet (ml/5 min) by rats with a gastric fistula after 17 h of food deprivation. The rats consumed food in discrete meals when the fistula was closed. When the fistula was open, they ate continuously throughout the test period and never displayed satiety. Thus, rats consumed significantly more food during the 2-h test period when their fistulas were open than when they were closed. ns, intervals in which the amount of food consumed did not differ significantly between open and closed fistulas. From Smith *et al.* (1974).

Gastric stretch that accompanies meals presumably interacts with other signals to produce satiety. For example, aside from directly affecting digestion, the intestinal peptide *cholecystokinin* (CCK), which is secreted during meals, acts on receptors located on vagal afferent fibers that carry gastric stretch signals from the pyloric region of the stomach to the brain stem. Thus, relatively small amounts of CCK can inhibit feeding in rats by acting synergistically with

gastric distension. When given in larger doses, CCK can inhibit food intake even when the stomach is empty (Gibbs *et al.*, 1973). As might be expected, total or selective gastric *vagotomy* (or ablation of brain stem areas to which the gastric vagus projects) decreases the ability of gastric volume and peripherally administered CCK to reduce meal size. Conversely, systemic administration of CCK receptor antagonists increases the size of meals (Box 38.1).

Gastric distension is one of the factors that control suckling in neonatal rats. The dam controls the timing

of meals, and at each meal pups consume as much milk as their stomachs allow; gastric volume, not caloric content, provides the signal to stop. Consistent with the importance of gastric distension to suckling, pups are particularly sensitive to the inhibitory effects of CCK on food intake, suggesting that a combination of gastric distension and CCK may be the principal signals that inhibit the initiation of spontaneous meals in suckling rats.

As rat pups mature, signals related to the caloric content of food begin to participate in the control of

### BOX 38.1

## SATIATION FACTORS

Several metabolically important peptides, including CCK, insulin, leptin, and *glucagon*, reduce food intake when administered systemically to laboratory animals. By themselves, these findings do not prove that the peptides normally function as endogenous satiation agents; blood levels of an administered agent must be within the physiological range. In addition, the behavioral effects of the agent must be specific to the inhibition of food intake and cannot merely reflect a secondary consequence of illness, behavioral depression, or motor incapacitation. Because investigators cannot be certain what animals sense, they must infer whether animals experience satiation in association with an observed reduction in food intake.

One common approach is to determine whether the agent can cause a *learned flavor aversion* in animals. People learn readily to avoid food or drink that, when ingested, produces nausea due to the unsuspected presence of some toxic contaminant. Rats and other animals seem to respond in the same way; moreover, when a toxin is administered systemically soon after consumption of an uncontaminated drink with a novel flavor, the animals subsequently avoid fluids of that flavor and behave as if the drink had contained the toxic agent that made them sick. In addition, electrophysiological recording from the first gustatory relay nucleus in the brain stem, the nucleus of the solitary tract, shows that the response elicited by a taste that has been associated with a toxin is similar to the pattern of activity typical of naturally aversive flavor. Nausea is critical to the process; damage to the "emetic center" in the area postrema eliminates the sensation of nausea and prevents the formation of the learned taste aversion.

Another approach to distinguishing nausea from satiation is to monitor biological variables that occur in asso-

ciation with nausea but not satiation, or vice versa. One such variable is neurohypophyseal hormone secretion. For example, administration of lithium chloride causes nausea in humans and vomiting in monkeys, and stimulates vasopressin secretion in both species. In this example, because elevated plasma vasopressin does not itself cause nausea or vomiting, it can be considered a biological marker of nausea. Curiously, rats secrete the other neurohypophyseal peptide, oxytocin (and not vasopressin), in response to large doses of lithium chloride and other nauseants. Control experiments have shown that following an ordinary meal, vasopressin is not secreted in primates nor is oxytocin secreted in rats. Thus, when rats are administered a chemical agent that stimulates pituitary oxytocin secretion, nausea, rather than satiation, is the suspected basis of the reduction in food intake.

Such experiments are helpful for interpreting the anorexia that occurs when a hormone or neurotransmitter is administered exogenously, but insight into the normal effects of endogenously secreted chemical signals requires an alternative experimental approach. For example, a drug that blocks the effect of an endogenous hormone or neurotransmitter on its receptors could be administered. If the hormone normally functions to reduce food intake, then the blocking agent should increase the size of meals. Such drugs are not yet available for all compounds suspected of being endogenous satiation factors, but experiments using drugs to reduce the activity of CCK, insulin, leptin, and glucagon at their respective receptors found increases in meal size. These observations strongly suggest that these compounds normally function as endogenous satiation factors.

*Stephen C. Woods and Edward M. Stricker*

meal size and become integrated with CCK, gastric distension, and other factors as satiation signals. This developmental change allows adults to ingest, assess, and respond to foods whose caloric density is not as constant as that of milk. For example, when liquid food is diluted with water, adult rats compensate by increasing the volume consumed in each meal, allowing daily caloric intake to remain stable. This observation reveals that gastric distension is but one of several possible satiation signals in adult rats and that greater distension can be accommodated in circumstances in which the calorie-related satiation signals have diminished.

The mechanism by which caloric signals are monitored remains unknown. Although early reports suggested that the stomach monitored caloric nutrients, more recent findings have not supported this hypothesis. For example, when hungry rats were equipped with closed pyloric cuffs to prevent ingested food from entering their small intestine, the rats decreased their food intake in proportion to the volume, and not the caloric content, of intragastric infusions (Phillips and Powley, 1996). In contrast, when the cuff was open so that gastric contents could empty into the duodenum, caloric nutrients were much more effective in reducing food intake than calorie-free loads of equal volume. These observations suggest that the stomach does not detect caloric nutrients but instead contributes primarily inhibitory signals related to gastric distension.

### Postgastric Effects of Meals Provide Additional Satiation Signals

Normally, some ingested food enters the small intestine and is absorbed during the course of a meal, thus allowing postgastric signals to contribute to satiation. In this regard, small amounts of specific nutrients infused directly into the duodenum produce a robust suppression of eating that cannot be attributed to gastric factors. It is not clear whether the upper small intestine or a postabsorptive site, or both, is responsible for detecting the administered calories and generating the signals that limit meal size. As discussed earlier, the liver plays a critical role in caloric homeostasis, and the delivery of nutrients absorbed from the small intestine to the liver may be monitored to provide an important postgastric signal for the inhibition of food intake. Consistent with this hypothesis are findings that infusion of glucose or lipids into the hepatic portal vein reduces food intake. Furthermore, such infusions have been found to increase the activity in hepatic vagal afferent fibers, whereas infusion of fructose into the general circulation no longer reduces

food intake in rats after hepatic vagotomy. Collectively, these findings suggest that the liver provides a satiation signal. That signal would disappear as absorption slows, which is when satiety diminishes as well.

Intravenously administered glucose reduces food intake but not by as much as the caloric content of the glucose. In contrast, when glucose solution is fed through a tube directly into the stomach, the compensatory reduction in food (calorie) intake is equivalent to the caloric load. In this case, gastric or intestinal signals might contribute to the increased satiety. Note that more insulin is secreted in response to infusion of glucose into the stomach than into a vein, which might contribute to the observed reduction in appetite. In fact, intravenously infused glucose reduces food intake by an equivalent caloric amount when insulin is added to the infusate. Together, these observations suggest that insulin contributes to the satiety effect of glucose whether given by gavage or ingested during a meal. Consistent with this possibility, rats made diabetic by destruction of their pancreatic B cells eat discrete meals more frequently as if they experienced less postprandial satiety (Box 38.2).

In addition to providing useful nutrients, consumption of food increases *plasma osmolality*, yet another factor influencing the size of a meal. Increased plasma osmolality stimulates thirst, and for this reason water intake usually accompanies eating. The important point, however, is that food intake is lower during meals when drinking water is not available, a phenomenon known as “dehydration anorexia.” Similarly, increased plasma osmolality caused by systemic injection of hypertonic saline reduces food intake in proportion to the administered osmotic load. The well-described osmoreceptors that cause thirst and influence vasopressin secretion (Chapter 39) apparently do not mediate this inhibitory effect on food intake, which persists after those forebrain osmoreceptors have been destroyed surgically. Instead, osmoreceptors in the caudal brainstem might mediate the inhibitory effect of increased plasma osmolality on food intake.

### Body Weight Influences Food Intake

The control of food intake also is associated with the maintenance of body weight. For example, after a period of food deprivation and forced loss of body weight, animals (including humans) eat larger meals than normal until adiposity returns to pretreatment levels. Conversely, after a period of force feeding, during which the increased daily intake of calories causes weight gain, animals eat smaller meals than

## BOX 38.2

## THE GLUCOSTATIC HYPOTHESIS

Almost half a century ago, Mayer (1955) proposed that the onset and termination of meals are determined by changes in the amounts of glucose used by certain areas of the brain. Critical to Mayer's hypothesis was the observation that food intake was reliably increased by systemic injections of insulin, which reduced delivery of glucose to the brain. Thus, Mayer hypothesized that food intake was controlled by a region of the ventral hypothalamus whose glucose utilization, unlike the rest of the brain, was sensitive to insulin. In diabetic rats, the presence of hyperphagia despite elevated blood glucose emphasized the point that diminished glucose utilization in these insulin-dependent cells (as opposed to a reduction of blood glucose levels *per se*) was the critical factor in removing satiety and stimulating food intake.

At first widely accepted, the glucostatic theory fell into disfavor for several reasons. For one, although eating can be induced by low availability of glucose to the brain, no evidence supports suppression of eating by high glucose availability. In addition, concentrations of blood glucose after administration of large doses of insulin are now known to be far lower than what occurs during a fast or at the normal onset of a meal. Thus, eating in response to insulin-induced hypoglycemia is now considered an "emergency" response that is not relevant to normal feeding. (A similar emergency response occurs after a systemic injection of 2-deoxyglucose induces an acute decrease in cellular glycolysis.) Finally, the prevailing view of the ventromedial hypothalamus as a satiety center has changed considerably since the original formulation of the glucostatic hypothesis. This region of the brain is

better regarded as a regulatory control center that influences many aspects of hormonal and autonomic function. Diabetic hyperphagia may therefore represent the loss of satiety promoted by insulin or leptin that activates neural systems to inhibit food intake. In contrast, the earlier glucostatic hypothesis would have explained diabetic hyperphagia as a consequence of the loss of insulin's effect on special hypothalamic neurons that mediate satiety.

In recent years, evidence has emerged that neurons in the hypothalamic arcuate nucleus are sensitive to fluctuations of glucose as well as to certain fatty acids (especially oleic acid) and amino acids (especially leucine). Neurons in the same area are also sensitive to the adiposity signals leptin and insulin, and manipulations of either nutrients or adiposity signals locally influence both food intake and the release of glucose from the liver (Obici *et al.*, 2002). Hence, the view is emerging that the arcuate nucleus integrates long-term stores (body fat) with acute availability of nutrients to control several aspects of energy homeostasis.

normal (or no meals at all) until normal adiposity is restored. Long-term stability of adiposity in adult animals is attributed in part to these compensatory responses to weight fluctuations that are caused by acute changes in food intake or energy expenditure.

Adiposity may indirectly influence food intake by modulating how quickly food passes through the gastrointestinal tract, how long nutrients remain in the circulation, or how nutrients interact with the liver. For example, after fasting, less prolonged gastric distension or more rapid absorption and storage of ingested calories would diminish the duration of satiety signals, thereby increasing the frequency of meals. These effects would promote the *hyperphagia* (overeating) associated with the restoration of body

weight in animals that have fasted. Similarly, the satiating properties of ingested food would be reduced by diversions of ingested food calories to the fetus during pregnancy, to milk during lactation, or to skeletal muscle during exposure to cold temperatures, thereby contributing to the hyperphagia associated with each of these conditions.

Alternatively, adipose tissue may directly signal the brain to modulate food intake. Although afferent nerves from adipose tissue to brain have been described, most communication from adipose tissue is thought to be mediated by a humoral (circulating) factor. *Parabionts*, created by surgically joining two animals at the flank muscles and skin, support this hypothesis. Vascular interconnection within a

parabiont is demonstrated when a dye injected into one animal appears in the blood of its partner. Because the nervous systems of the two animals remain independent, any physiologic communication between the animals must occur through the vascular system. When two lean rats were joined parabiotically, each consumed its normal amount of food and maintained its usual body weight. Similar results were obtained when two obese rats with lesions in the *ventromedial hypothalamus* (see later) were joined together. However, when a lean animal was joined to an obese animal, the result was striking: The lean animal reduced its food intake markedly and consequently lost a considerable amount of weight. These experiments have been interpreted to mean that a circulating factor, secreted in large amounts (proportional to adiposity) by the obese animal, enters the blood of the lean animal and reduces food intake, as if the lean animal was receiving a signal that it was too fat (Coleman and Hummel, 1969).

Investigations have identified *leptin*, the hormone synthesized by adipose tissue, as a key circulating adiposity signal that regulates food intake and body weight. Leptin concentration in plasma is directly proportional to adiposity, and a receptor-mediated transport process passes it into the brain. Animals that lack the gene for synthesizing leptin (*ob/ob* mice) are hyperphagic and obese, and administering leptin to *ob/ob* mice, or to normal animals, causes them to eat less and lose weight. Because lower doses of leptin have this action when administered into the ventricles of the brain than when administered systemically, leptin is believed to reduce food intake and body weight via a central site of action. Consistent with this hypothesis, the receptor for leptin has been identified and found to be located within the hypothalamus. Like *ob/ob* mice, animals with mutated leptin receptors (*db/db* mice and fatty Zucker rats) are obese (see Box 38.3), but unlike *ob/ob* mice, they do not respond to exogenous leptin. Hence, leptin appears to function as a negative feedback signal to the brain. When fat stores increase in adipose tissue, more leptin is secreted and enters the brain, causing a greater inhibition of food intake and loss of body fat. When circulating leptin levels are low, feeding and other anabolic responses are disinhibited. In this way, leptin acts to promote the maintenance of a relatively stable body weight over long intervals. The neural circuitry through which leptin inhibits food intake and influences caloric homeostasis is discussed later.

Insulin provides a second circulating signal that informs the brain of body fat levels. Plasma levels of insulin are directly correlated with adiposity, and, like leptin, insulin is transported through the blood-brain

barrier where it can act on insulin receptors in the hypothalamus and other sites. Insulin administered into the brain reduces food intake and body weight, whereas animals that do not secrete insulin are hyperphagic. Of course, severe diabetics do not become obese because their adipocytes cannot store fat in the absence of insulin. Mice lacking insulin receptors on brain cells are both hyperphagic and obese. In short, both leptin and insulin provide blood-borne signals that enter the brain and act on their respective receptors to reduce food intake and body fat.

Obesity, the accumulation of greater than normal fat in the body, is increasing throughout the world and creating a major public health problem, in part because it increases the risk for developing cardiovascular disorders, several cancers, type-2 diabetes mellitus, and other metabolic problems, and increases mortality. Obese individuals have both leptin resistance and insulin resistance; that is, although they secrete large amounts of both leptin and insulin in proportion to their adiposity, these signals are relatively ineffective at controlling metabolic parameters. Consequently, considerably more insulin is required to maintain plasma glucose within normal limits, and the brain is insensitive to the catabolic action of both leptin and insulin. The latter is thought to be due to a combination of reduced passage of these hormones through the blood-brain barrier as well as fewer leptin and insulin receptors within the brain itself.

Obesity often is defined in terms of the *body mass index* (BMI), which is weight in kilograms divided by height in meters squared. A BMI of 18.5 to 24.9 is considered normal, with <18.5 being underweight, 25 to 29.9 being overweight, and >30 being obese. A BMI over 40 is morbid obesity. However, the calculation of BMI does not consider the distribution of fat within the body, yet this is recognized as a major determinant of health risk. Abdominal fat (mainly around the viscera) is more metabolically active, more highly vascularized and innervated, and more likely to be a site of inflammation in the body than subcutaneous fat; abdominal fat (typified by the “pot belly” or “apple” stereotype) therefore carries a much higher health risk than subcutaneous fat (characterized as a “pear” shape). Because of this, assessment of the circumference of the waist (abdomen) at the top of the iliac crest is thought to be a better predictor of health risk than the BMI. By this determination, obesity is defined as a waist circumference of >102 cm in men and >88 cm in women.

Hypotheses as to why the incidence of obesity has been increasing so dramatically in recent years abound, and often presume some combination of increased availability of energy-dense palatable foods

## BOX 38.3

## VARIATIONS OF STRUCTURE AND FUNCTION AMONG LEPTIN RECEPTORS

Leptin, the peptide hormone secreted by adipose cells, enters the brain through a receptor-mediated transport system in the brain capillary endothelium. Within the brain, it binds to specific leptin receptors that are expressed in discrete populations of neurons. The leptin receptor, termed Ob-R, is a member of the class I cytokine receptor family, a group of structurally similar receptors that act through JAK and STAT intracellular signaling proteins. There is only a single gene for Ob-R, and it is processed differentially by different cells such that many isoforms of the receptor are known. As depicted in Figure 38.4, Ob-R has an extracellular segment that is over 800 amino acids long, which binds selectively to leptin. Variations in function of the different isoforms are conferred by the length of the intracellular segment, with longer segments having more sites where intracellular signaling molecules can interact. Hence, longer isoforms have a greater potential to interact with the greatest number of such signaling molecules. The longest isoform, termed Ob-Rb, has an intracellular component of over 300 amino acids and is the only form capable of initiating the full complement of JAK and STAT proteins and of stimulating transcription at the nucleus of the cell. For these reasons, Ob-Rb is known as the signal-transducing form of the leptin receptor.

Within the brain, Ob-Rb is synthesized in high quantities in various nuclei in the ventral hypothalamus,

including the arcuate, ventromedial, and paraventricular nuclei. Ob-Rb is recognized as the receptor that stimulates the synthesis and secretion of  $\alpha$ -MSH and inhibits the synthesis and secretion of neuropeptide Y and agouti-related peptide in the arcuate nucleus. Other isoforms, with shorter intracellular segments, are localized in other brain areas and in the choroid plexus. They are thought to mediate activities locally at the cell membrane such as the movement of molecules through the membrane.

Many spontaneously occurring mutations of the leptin receptor have been identified (Fig. 38.4), and all result in an animal that is obese and hyperphagic. In the mouse, where the leptin receptor gene is called DB, at least four mutations are known. All have shortened intracellular segments and are called db/db mice. All are also extremely obese. The fatty Zucker rat (fa/fa) has a mutation resulting in a single amino acid substitution in the extracellular segment. As its name implies, this animal is also extremely obese. The Koletsky rat has a truncated extracellular segment and lacks all leptin signaling and it is also obese. A small number of hyperphagic, obese humans recently have been identified with mutations of the leptin receptor.

Stephen C. Woods and Edward M. Stricker

**FIGURE 38.4** There are many isoforms of the leptin receptor (Ob-R). All have the same extracellular segment that binds with leptin, such that variations are in the length of the intracellular segment. Most tissues synthesize one or another “short” isoform that binds leptin and initiates cellular events locally near the cell membrane. Only the long form (Ob-Rb) is capable of triggering intracellular signaling cascades that can alter nuclear transcription. Several mutations that shorten the Ob-R occur in mice. These mice, called db/db, are all hyperphagic and obese. Two mutations of the Ob-R also have been identified in rats, and both also result in obesity. Fatty Zucker (fa/fa) rats have single amino acid substitution in the extracellular segment of Ob-R, whereas Koletsky rats have a truncated receptor.

and/or decreased average energy expenditure. One intriguing possibility is that the bacteria in the gastrointestinal (GI) system, termed the *microbiota*, are an important factor. Among other actions, these bacteria determine the proportion of ingested nutrients that actually are absorbed into the body. Recent reports indicate that the GI tracts of some obese humans and obese mice have a higher proportion of bacteria of the phylum *Firmucites* than the GI tracts of lean individuals; those bacteria express enzymes that break down certain complex carbohydrates, enabling the obese individuals to extract and absorb more calories from what they have eaten. Importantly, inoculation of the guts of lean mice with the microbiota from obese mice resulted in the lean mice losing fewer calories in their feces and gaining slightly more weight than controls inoculated with microbiota from lean mice (Turnbaugh *et al.*, 2006), and mice lacking gut bacteria have been found to be resistant to diet-induced obesity (Backhed *et al.*, 2007). Although these observations are preliminary, they suggest that manipulation of the microbiota might provide a novel therapeutic approach to obesity.

### Summary

Three effects of eating limit the size of an ongoing meal: gastric distension (potentiated by CCK), post-gastric detection of calories (via satiety signals such as CCK, perhaps potentiated in the liver by insulin), and increased plasma osmolality. These signals reach the brain through visceral afferent fibers (especially those traveling in the vagus nerve) and the circulatory system. Meal size invariably increases after the inhibitory effects are experimentally removed by blocking the detection of gastric stretch or of CCK, diluting the food with noncaloric material, or rehydrating the animal. Inhibition appears to be integrated so that as one effect diminishes (e.g., the signal associated with gastric distension), another increases (e.g., the signal associated with the postabsorptive delivery of calories and insulin to the liver), thereby maintaining satiety and prolonging the interval between meals. When the satiety signals disappear, hunger emerges and stimulates initiation of another meal.

Food intake is also normally linked closely with body weight. In experimental animals, periods of starvation or forced feeding are followed by self-regulated compensatory changes in eating patterns until prior body size is regained. Links between body weight and food intake can be mediated indirectly by altered gastrointestinal motility and absorption as well as by the blood-borne, centrally active hormones, leptin and insulin.

## CENTRAL CONTROL OF FOOD INTAKE

Early theories of the control of food intake focused on signals derived from stomach and blood. Peripheral factors, such as the concentration of glucose in the blood, were plausibly associated with food intake and were accessible to experimentation. Theories involving the brain emerged after development of a stereotaxic instrument that enabled discrete lesions of the cerebrum to be made in laboratory animals, permitting evaluation of ideas about brain function (Fig. 38.5). The first findings from such experiments were striking: Bilateral electrolytic lesions of the ventromedial hypothalamus (VMH) caused marked hyperphagia and obesity in rats. This observation was interpreted to mean that the animals had become less sensitive to incoming signals of satiety and that they therefore overate and became fat. Bilateral lesions in the adjacent *ventrolateral hypothalamus* (VLH) were later found to cause *aphagia* (absence of eating), which led to death by starvation. This finding was interpreted to mean that these rats no longer detected hunger signals, and thus they starved to death while unaware of their internal state. Collectively, these results provided the foundation of a *dual center hypothesis*, in which a satiety center in the VMH was thought to suppress activity in a hunger center in the VLH. Both the syndrome of hyperphagia and obesity and the syndrome of aphagia and weight loss that result from focal hypothalamic

**FIGURE 38.5** Coronal section through an adult rat brain at the level where the optic tract enters the two hemispheres. The lateral ventricle and third cerebral ventricle (V) are shaded, and selected fiber tracts are outlined for reference (OT, optic tract; CC, corpus callosum; FX, fornix). Key hypothalamic sites important in caloric homeostasis, present in each hemisphere, are paraventricular nuclei (PVN), ventromedial nuclei (VMN), arcuate nuclei (ARC), and the lateral hypothalamic area (LHA).

lesions have been reproduced in multiple laboratories and in multiple species. However, additional observations have caused reinterpretation of these familiar and reliable findings, and they now have a very different meaning.

### Food Intake Is Not Controlled by Hypothalamic Hunger and Satiety Centers

The strength of the traditional dual center model, in which one center mediates hunger and the other satiety, was that it provided a simple answer to the question of how the brain controls intake of food. The principal limitation of the model, however, was that it could not answer the next level of questions: What signals control individual meals? How are these signals integrated with physiological aspects of caloric homeostasis, including long-term maintenance of body weight? What is the influence of other neural sites and systems in the brain? How are excitatory and inhibitory influences on eating integrated? How are behaviors, such as motivation and reinforcement, explained? Investigators are addressing these and related questions, but they now usually take a perspective that does not presume the existence of brain centers mediating hunger and satiety.

In addition to causing hyperphagia, VMH lesions profoundly reduce sympathetic tone and increase parasympathetic tone and vagal reflexes. For example, the high concentration of insulin in animals with VMH lesions is not simply a secondary consequence of hyperphagia but occurs even when food intake is limited. Because of the change in autonomic tone, caloric equilibrium in adipose tissue shifts away from lipolysis and toward lipogenesis, thereby allowing more rapid storage of ingested calories after a meal. Increased parasympathetic activity also allows faster gastric emptying. Importantly, VMH lesions do not cause loss of satiety. Meal sizes continue to correlate with postmeal intervals, but the interval after a meal of any size is shorter in animals with VMH lesions than in control animals.

Because the duration of their postprandial satiety signals is shorter than normal, rats with VMH lesions eat more frequent meals. They remain hyperphagic until the equilibrium between lipogenesis and lipolysis is reestablished in adipocytes. For this to happen, triglyceride stores must accumulate in the cells to levels sufficient to create insulin resistance, whereupon lipogenesis subsides. Meals are eaten less frequently, and daily food intake is reduced. The animal maintains its obese state as if it had a new "set point" for body weight. Thus, after obese rats with VMH lesions have been deprived of food and forced to lose

weight, hyperphagia reoccurs until high adiposity is reattained. Similarly, when neurologically normal rats are overfed and become obese prior to receiving a lesion of the VMH, they are not hyperphagic after the lesion but rather eat to maintain their elevated weight.

In sum, rats gain body fat after VMH lesions, and as fat accumulates the duration of satiety after meals increases. This explanation contrasts with early hypotheses that body weight increased after VMH lesions because animals became obligatorily hyperphagic. The primary phenomenon is now recognized as a change in autonomic tone to promote vagal reflexes and fat storage. Because the change in autonomic tone is observed even when increased food intake is prevented, hyperphagia cannot be the primary phenomenon. The key element appears to be the chronic, neurally stimulated increase in insulin secretion. When the increased insulin secretion is prevented by denervating the pancreas, obesity does not develop and hyperphagia is attenuated greatly.

In contrast to VMH lesions, rats with large VLH lesions do not eat (to the point of starvation). However, they also do not drink water when dehydrated, move about in their cages, or respond to diverse stimulation. In other words, the most prominent abnormalities in these rats are akinesia and sensory neglect. In this respect, rats with VLH lesions resemble human patients with Parkinson's disease, a neurological disorder that has been attributed to the degeneration of dopamine-containing neurons of the nigrostriatal bundle (see Chapters 30 and 31). Dopaminergic fibers course through the internal capsule just lateral to the VLH as they ascend from the ventral mesencephalon to the striatum along the medial forebrain bundle (Chapter 43). Large electrolytic lesions of the VLH area interrupt these dopaminergic fibers. More selective damage to the dopaminergic neurons by intracerebral administration of the neurotoxin 6-hydroxydopamine also produces akinesia and sensory neglect in association with loss of food intake, and it does so without disturbing parasympathetic reflexes. Thus, the aphagia induced by large VLH lesions does not result from damage to a putative hunger center in the brain but instead reflects a more general disruption of movement and sensorimotor integration (Ungerstedt, 1971), at least in part (see later).

### Summary

The ability of brain circuitry to control food intake initially was based on the consequences of stereotaxic lesions of ventromedial and ventrolateral hypothalamic nuclei leading to hyperphagia or aphagia,

respectively. Subsequent studies revealed that each lesion also induces changes in gastrointestinal function and in the equilibrium between lipolysis and lipogenesis in adipocytes. In addition, these nuclei help regulate body weight through influences on spontaneous mobility and sensory responsiveness to food-derived stimuli. The nucleus of the solitary tract also relays important visceral sensory cues on gastrointestinal fill that can further influence food intake.

## NEUROPEPTIDES AND THE CONTROL OF FOOD INTAKE

Although the details of the central control of food intake are incompletely understood, many neuropeptides have been implicated. To simplify the discussion,

we focus on two broad categories of neuropeptides: those that are mainly anabolic and those that are mainly catabolic. Both of these subgroups in turn are modified by multiple influences, including satiety signals, adiposity signals, experience, habit, emotional state, the social situation, and so on. Anabolic peptides cause increased eating, decreased energy expenditure, and, when chronically elevated, increased body fat accumulation. Catabolic peptides reduce food intake, increase energy expenditure, and lead to loss of body fat. Figure 38.6 presents a simplified model of some of the better-known components of this control system. An interesting feature of the model is that major efferent outputs from the hypothalamus to autonomic nuclei and to motor nuclei controlling ingestion *per se* emanate from the VMH and VLH, the central neural sites that were the main focus of attention over a half-century ago.

**FIGURE 38.6** Schematic diagram of the signals that control caloric homeostasis. Satiety signals arising in the periphery such as gastric distension and CCK are relayed to the nucleus of the solitary tract (NTS) in the brain stem. Leptin and insulin, the two circulating adiposity signals, enter the brain and interact with receptors in the arcuate nucleus (ARC) and other brain areas. These adiposity signals inhibit ARC neurons that synthesize NPY and AgRP (NPY cells in the diagram) and stimulate neurons that synthesize proopiomelanocortin (POMC), the precursor of  $\alpha$ -MSH, and CART. These ARC neurons in turn project to other hypothalamic areas, including paraventricular nuclei (PVN) and the lateral hypothalamic area (LHA). Catabolic signals from the PVN and anabolic signals from the LHA are thought to interact with the satiety signals in the brain stem to determine when meals will end. From Schwartz *et al.* (2000).

## The Hypothalamic Arcuate Nucleus Mediates the Effect of Adiposity on Food Intake and Body Weight

The amount of body fat is signaled to the brain by leptin and insulin. Receptors for both peptides are located (among other sites) in the hypothalamic arcuate nucleus on two distinct groups of neurons. The first group of arcuate neurons synthesizes the neuropeptides,  $\alpha$ -melanocyte-stimulating hormone ( $\alpha$ -MSH) and cocaine-amphetamine-related transcript (CART); these neurons are activated by leptin and insulin.  $\alpha$ -MSH and CART are potent catabolic peptides, and when either is administered locally into the third cerebral ventricle, animals eat less food, have increased energy expenditure, and lose weight (Cone, 1999).  $\alpha$ -MSH is in the melanocortin family of peptides, a group that also includes adrenocorticotrophic hormone (ACTH). These peptides act on melanocortin (MC) receptors, and two of these receptors, termed MC3 and MC4, are expressed in several nuclei of the hypothalamus, including the paraventricular nucleus (PVN), VMH, and VLH, where  $\alpha$ -MSH-containing axons project from the arcuate nucleus and where  $\alpha$ -MSH acts as an agonist. Animals that lack either MC3 or MC4 receptors become obese; animals with no MC3 receptors gain weight gradually over their lifetime without overeating, whereas animals without MC4 receptors are hyperphagic and become much fatter. The administration of selective MC4 antagonists causes normal animals to overeat and, if prolonged, to become obese. Hence, hypothalamic melanocortins, exemplified by  $\alpha$ -MSH, exert a tonic catabolic effect to keep body weight from increasing (Cone, 1999). Importantly, the ability of exogenous leptin to reduce food intake and body weight is completely attenuated in the presence of an antagonist to MC3 and MC4 receptors, suggesting that the "downstream" pathway by which adiposity influences caloric homeostasis is via melanocortin signaling (Seeley *et al.*, 1997).

The other type of arcuate neuron influenced by adiposity signals synthesizes the neuropeptides, neuropeptide Y (NPY) and agouti-related protein (AgRP). Both peptides are potent anabolic compounds in that the administration of either into the third ventricle results in hyperphagia, reduced energy expenditure, and weight gain. Although NPY is synthesized in many areas of the brain, AgRP synthesis is limited to the arcuate nucleus. Neurons containing NPY and AgRP express receptors for both leptin and insulin, and the local administration of either insulin or leptin near the arcuate nucleus reduces the synthesis of both NPY and AgRP. Hence, adiposity signals exert net catabolic effects through the joint mechanisms of stimulating

$\alpha$ -MSH/CART neurons and simultaneously inhibiting NPY/AgRP neurons. For all these reasons, the arcuate nucleus can be considered to be the brain's sense organ that detects body adiposity by monitoring the levels of leptin and insulin. In turn, axons from these two groups of arcuate neurons innervate many other hypothalamic nuclei as they modulate aspects of caloric homeostasis.

A particularly important tract includes NPY-containing axons that project from the arcuate nucleus to the PVN. The PVN expresses receptors for NPY, and careful mapping studies have identified the PVN as the most sensitive site to the orexigenic effect of exogenously administered NPY. Consistent with this finding, when antisense oligonucleotides to NPY receptors are given locally within the PVN, rats that have been deprived of food eat less than they usually would. Among the numerous sites that synthesize NPY within the brain, only those in the arcuate nucleus are sensitive to changes of food intake as signaled by leptin and insulin (Schwartz *et al.*, 2000). NPY mRNA is increased in the arcuate nucleus when animals are fasted and returns to baseline upon refeeding. Fasting also increases the levels of NPY in axon terminals in the PVN and increases secretion of NPY within the PVN. Hence, the fasted animal is primed to eat more food due in part to the action of elevated NPY in the area of the PVN. Circulating insulin and leptin are decreased during fasting, and local administration of either into the brain of a fasted rat lowers the elevation of NPY mRNA in the arcuate nucleus and lowers the amount of food eaten by food-deprived rats (Schwartz *et al.*, 2000). Hence, the metabolic state, as reflected by leptin and insulin, has a marked influence on arcuate NPY-containing neurons and consequently on neural pathways that influence energy intake and expenditure. Endogenous levels of NPY in the arcuate-PVN system normally peak when daylight ends and nocturnal activity begins (Leibowitz, 1990), which is also the time when rats typically eat their largest meal of the day. Hence, NPY activity in the PVN appears to be a key mediator of anabolic activity.

The other neuropeptide synthesized in NPY neurons in the arcuate nucleus, AgRP, is an endogenous antagonist of MC3 and MC4 receptors (Cone, 1999). AgRP therefore promotes food intake by acting at MC receptors in the PVN and other areas to block the action of  $\alpha$ -MSH. When exogenous AgRP is administered into the third cerebral ventricle, the resultant hyperphagia lasts for up to six days (Hagan *et al.*, 2000). In contrast, the hyperphagia elicited by NPY lasts only a few hours. Hence, activation of the arcuate NPY/AgRP neurons results in an acute but robust increase of food intake caused by the actions of NPY and a steady and more

prolonged increase caused by the actions of AgRP. Furthermore, the two peptides act in different ways. NPY acts through its receptors to stimulate anabolic pathways directly, whereas AgRP acts through a different receptor by antagonizing tonically active catabolic peptides. It is not known whether NPY and AgRP from the arcuate neurons act on the same or different target cells in the PVN, VLH, and elsewhere.

In sum, the arcuate nucleus appears to be a chemosensor in the brain that detects body adiposity by means of insulin and leptin receptors. One type of arcuate neuron synthesizes peptide transmitters ( $\alpha$ -MSH and CART) having a net catabolic effect, whereas another type synthesizes peptide transmitters (NPY and AgRP) with a net anabolic effect. Both types of neuron project to other hypothalamic areas where they influence specific aspects of caloric homeostasis.

### Other Hypothalamic Peptides Also Influence Food Intake

Several newly discovered neuropeptides important in the control of caloric homeostasis are synthesized in the VLH, including *orexin A* and *melanin-concentrating hormone* (MCH) (Shimada *et al.*, 1998). Administration of either of these peptides into the brain stimulates food intake, whereas mice that lack the gene for MCH are lean and obesity resistant. It appears likely that the aphagia exhibited by animals with VLH lesions is due in part to reduced levels of these peptides and that the hyperphagia caused by electrical stimulation of the VLH is due in part to release of these peptides.

Oxytocin is a peptide synthesized in the PVN and supraoptic nuclei of the hypothalamus and is secreted from the posterior lobe of the pituitary. In the systemic circulation of female mammals, this hormone is well known for stimulating uterine contractions for parturition and stimulating milk let-down in mammary glands during lactation. However, the hypothalamus and pituitary of males contain as much oxytocin as those of females; therefore, the peptide has long been suspected of being secreted in other circumstances and having additional functions. In fact, research has revealed that gastric distension, CCK administration, and plasma hyperosmolality, treatments that decrease food intake in rats, elicit pituitary oxytocin secretion in male and female rats. In addition, increases in plasma concentrations of oxytocin correlate highly with observed decreases in food intake.

Although observations were consistent with oxytocin being an appetite suppressant, later experiments showed that this was not the case: Systemic administration of oxytocin does not affect food intake. Instead, the reduced food intake seen after treatment with CCK

or hypertonic saline appears to be mediated by oxytocin secreted from neurons whose cell bodies are located in the hypothalamic PVN but whose axons project within the central nervous system rather than to the pituitary gland. Consistent with this hypothesis, central injection of oxytocin into the cerebral ventricles (icv) decreases food intake in rats, an effect that is blocked by icv pretreatment of the animals with an oxytocin receptor antagonist. More to the point, the effects of exogenous CCK and hypertonic saline on food intake are blunted by icv pretreatment with an oxytocin receptor antagonist. A summary of some of the hypothalamic peptides that modulate food intake is depicted in Figure 38.7.

Stress is also well known to decrease food intake in animals, and various stressors activate the hypothalamic–pituitary–adrenal axis. A key mediator of this effect is *corticotropin-releasing hormone* (CRH), which is synthesized and secreted from the PVN. CRH stimulates the secretion of ACTH from the anterior pituitary, and ACTH in turn elicits steroid hormone secretion from the adrenal cortex (see Chapter 40). In rats, icv injection of CRH decreases food intake in the absence of stress and in association with oxytocin secretion from the posterior pituitary. In addition, icv pretreatment with an oxytocin receptor antagonist eliminates CRH-induced inhibition of food intake. These findings are consistent with central oxytocinergic neurons mediating the inhibition of food intake that occurs during stress. Such inhibitory effects on eating would complement the known inhibitory effects of central oxytocin on gastric motility and emptying.

**FIGURE 38.7** Hypothalamic neuropeptides that influence caloric homeostasis. The adiposity hormones, leptin and insulin, are transported through the blood–brain barrier and influence neurons in the arcuate nucleus (ARC). ARC neurons that synthesize and release NPY and AgRP are inhibited by adiposity signals, whereas ARC neurons that synthesize and release  $\alpha$ -MSH and CART are stimulated by adiposity signals. NPY/AgRP neurons are inhibitory to the PVN and stimulatory to the LHA, whereas  $\alpha$ -MSH/CART neurons are stimulatory of the PVN and inhibitory of the LHA. The PVN in turn has a net catabolic action, whereas the LHA has a net anabolic action.

Two additional features of these findings deserve note. First, despite prominent pituitary oxytocin secretion, central oxytocinergic pathways are not stimulated by suckling. Therefore, nursing does not inevitably reduce food intake in dams; in fact, lactating rats are hyperphagic in association with the substantial loss of calories through milk. Second, because the various stimuli for oxytocin release are not related to caloric homeostasis, oxytocin is not a factor in the termination of normal meals; in fact, oxytocin is not secreted by rats during meals taken *ad libitum*.

### The Brain Stem Plays an Important Role in the Control of Food Intake

The NST and the adjacent area postrema in the brain stem receive sensory fibers from gustatory receptors in the mouth and throat (see Chapter 24), as well as afferent information from the stomach, small intestine, pancreas, and liver. In the central control of food intake, these linked brain stem sites likely are where sensory input from the viscera is first integrated with input from taste buds. This sensory information is relayed along prominent neural projections from the brain stem to the hypothalamus, amygdala, and other portions of the limbic system, as well as to the thalamus and gustatory cortex. Reciprocal neural connections to the brain stem from these rostral sites allow emotion and cognitive function to influence the control of eating. Complementary and linked efferent elements participate in the central control of the gastrointestinal tract and liver, and of autonomic function generally.

Evidence of the control of the brain stem over food intake comes from investigations of the chronic decerebrate rat in which all axonal connections between the caudal brain stem and the forebrain are severed at the midcollicular level of the midbrain (Grigson *et al.*, 1997). This animal does not seek food or initiate spontaneous meals, but, like an intact animal, will reflexively swallow liquid food put directly into its mouth via an oral fistula. The decerebrate rat will swallow a sucrose solution when its stomach is empty, such as after a period of food deprivation; however, it will not swallow water or saline when food deprived, nor will it swallow sucrose solution when its stomach is full or when it has received a systemic injection of CCK or hypertonic saline (but instead lets the administered fluid passively drip from its mouth). These experiments suggest that considerable control of food intake exists entirely within the caudal brain stem, which receives signals that arise when ingested food contacts peripheral sensory organs (i.e., taste buds, gastric stretch receptors, intestinal CCK-secreting cells). None-

theless, decerebrate animals are incapable of receiving input from forebrain sites that could modify intake based on learning or other experience, on body adiposity, or on time of day.

Other observations provide additional support for an important role of the brain stem in the control of meal size. When the area postrema is ablated, rats eat larger meals than normal, although total daily food intake is normal; that is, they compensate for their large meals by eating less frequently, indicating that long-term controls of food intake are not impaired. A similar effect is seen in rats pretreated with capsaicin, a neurotoxin that destroys most gastric afferent vagal axons, eliminating the food intake-reducing effects of CCK and presumably damaging the signal of gastric distension.

### Summary

To provide a biological context within which to consider the purpose of eating and the fate of ingested food, we began this chapter with a description of the physiology of caloric homeostasis. Two principles were emphasized. First, meal size is determined by the integrated effects of several acute stimuli. Delivery of calories to the stomach and small intestine upon food consumption and postabsorptive delivery of nutrients to the liver elicit sensory neural signals from the stomach and the liver, respectively, to the brain stem. Second, food intake is also influenced by chronic signals associated with body adiposity. Adiposity indirectly affects gastric and hepatic signals of satiety. In addition, humoral signals proportional to adiposity enter the brain and affect food intake. One signal emanates from adipose tissue itself (i.e., leptin), and the other comes from the pancreas (i.e., insulin). These two peptides appear to be important in the central control of food intake; they modulate the response of the brain to the acute neural signals that affect food intake.

These neural and humoral signals are related to caloric homeostasis and are inhibitory in nature. During meals, they combine to stop ongoing ingestion; later, when these signals disappear in the postabsorptive state, new meals begin. Other inhibitory signals are unrelated to caloric homeostasis yet can have a pronounced effect on the cessation of eating. These signals include gastric distension, toxins (in the food or body), and dehydration.

The central nervous system exerts control over eating at many levels. The spinal cord and brain stem influence all aspects of caloric homeostasis via the autonomic nervous system. The hypothalamus and limbic forebrain receive signals about ingested food and body adiposity and integrate them with

information about the taste of the food, the memory of that food, the experience of previous meals, the competition of other desires, and aspects of the environment. Thus, the central control of eating involves many areas of the central nervous system in the collective maintenance of caloric homeostasis. In short, food intake is a simple behavior influenced by a complex array of stimuli and situational variables, the details of which remain to be fully understood.

# Water Intake and Body Fluids

Body fluids are the watery matrix in which the biochemical reactions of cellular metabolism occur. The concentration of substrates in cellular fluid is a key factor in determining the rate at which those reactions take place. All tissues depend on circulating blood to deliver the nutrients needed to support cellular metabolism and to carry away unwanted metabolites for excretion. Thus, the maintenance of solute concentrations or osmolalities—*osmotic homeostasis*—and the regulation of plasma volume—*volume homeostasis*—are essential functions in the physiology of animals.

When normal body fluid osmolality or plasma volume is threatened, various physiological and behavioral responses are stimulated to maintain or restore the basal state adaptively. For example, during water deprivation, animals decrease water lost in urine to prevent dehydration from worsening and consume water to replace the fluid they have lost. Similarly, hemorrhage stimulates the urinary conservation of water and sodium, as well as the ingestion of water and NaCl. Water retention and sodium retention are accomplished through actions of the antidiuretic hormone *arginine vasopressin* (AVP) and the antinatriuretic hormone *aldosterone*, whereas water ingestion and NaCl ingestion are motivated by *thirst* and *salt appetite*. These complementary responses are mediated and coordinated by the brain.

This chapter describes the various mechanisms by which the signals for fluid homeostasis are detected and integrated by the central nervous system. However, we first present a brief overview of body fluid physiology to provide a context in which to consider the regulated functions.

## BODY FLUID PHYSIOLOGY

Water is the largest constituent of the body. It contributes 55 to 65% of the body weight of animals, including humans, varying mostly in relation to the amount of body fat. Total body water is distributed between *intracellular fluid* (ICF) and *extracellular fluid* (ECF) compartments, with approximately two-thirds in the former and one-third in the latter. The ECF can be further subdivided into the *interstitial fluid* surrounding the cells and the *intravascular fluid* within blood vessels. The intravascular fluid, the plasma (or serum) of blood, averages 7 to 8% of total body water, or 20 to 25% of the ECF.

Fluid compartments differ not only in their volumes, but also in the solutes they contain. Specifically, membrane-bound  $\text{Na}^+\text{-K}^+$  pumps move  $\text{Na}^+$  outside the cells and  $\text{K}^+$  inside. Despite the differences in solute composition, the *osmotic pressure*, which reflects the concentrations of all solutes in a fluid compartment, is equivalent between ECF and ICF compartments. This equilibrium occurs because water is driven across cell membranes by osmosis from a relatively dilute compartment into one with a higher solute concentration until the osmotic pressures are equivalent on both sides of the cell membrane.

### Multiple Mechanisms Help Maintain Blood Volume and Pressure

The distribution of fluid between intravascular and interstitial fluid compartments is determined by a

balance between the *hydrostatic pressure* of the blood, which is maintained by cardiac output and arteriolar vasoconstriction, and the opposing osmotic pressure contributed by plasma proteins. Although those proteins contribute only 1 to 2% to overall plasma osmolality, the permeability of capillary membranes to such large molecules is low; therefore, proteins exert a pressure differential (of approximately 15–20 mmHg), called the *colloid osmotic (oncotic) pressure*, that tends to pull interstitial fluid into the circulation. Figure 39.1 summarizes the forces governing transcapillary fluid transfer between the two extracellular compartments, a phenomenon first described by the English physiologist Starling (1896). Note that according to this arrangement, interstitial fluid acts as a reservoir for plasma. The Starling equilibrium is such that when blood pressure falls, as after hemorrhage, interstitial fluid moves into the circulation, thereby helping restore plasma volume. The reverse occurs when saline is added to the blood because plasma proteins are then diluted and the oncotic pressure they provide diminishes, allowing fluid to flow into the interstitial space.

Blood pressure also is maintained by two other mechanisms intrinsic to the cardiovascular system.

**FIGURE 39.1** Starling forces governing transcapillary fluid transfer. At the arteriolar end of the capillary, the difference between the intravascular hydrostatic pressure ( $P_c$ ) and the interstitial hydrostatic pressure ( $P_i$ ) exceeds the oppositely oriented difference between the intravascular oncotic pressure ( $\pi_c$ ) and the interstitial oncotic pressure ( $\pi_i$ ); the resultant pressure gradient drives capillary fluid into the interstitial space ( $J_{v1}$ ). As fluid leaves the capillary,  $P_c$  decreases due to fluid loss and  $\pi_c$  increases due to hemoconcentration. Consequently, at the venous end of the capillary, interstitial fluid is pulled back into the vascular space ( $J_{v2}$ ). Numerical values indicate approximate net pressure differences (in mmHg) between intravascular and interstitial spaces. Relative sizes of  $P$  and  $\pi$  are indicated by arrow length. Note that fluid accumulating in the interstitial space ultimately returns to the blood via the lymphatic system (not shown).

First, although the arteries that receive the cardiac output of blood have thick walls to preserve blood pressure, the veins are thin-walled, distensible vessels. After a moderate hemorrhage, veins collapse, redistributing blood to arteries that cannot collapse and thus remain full. Consequently, arterial blood pressure is not compromised, and the blood deficit occurs primarily on the venous side of the circulation. Conversely, fluid accumulates in the veins when blood volume is expanded, again without much effect on arterial blood pressure. This property is called the *capacitance* or *compliance* of the vascular system. Second, the filtration of blood in the glomeruli of the kidneys is determined in large part by blood pressure in the renal arteries. A drop in blood pressure reduces the *glomerular filtration rate* (GFR) and decreases urine formation, whereas a rise in blood pressure elevates GFR and promotes urinary fluid loss. This normal function of the kidneys is so efficient that the development of hypertension always implicates renal dysfunction as a contributing factor because the kidneys failed to adjust to the elevated blood pressure by increasing fluid excretion in urine.

## Summary

Body fluid homeostasis is directed at achieving stability in the osmolality of body fluids and the volume of plasma. Such homeostatic regulation is promoted by several mechanisms intrinsic to the physiology of body fluids and the cardiovascular system. Nevertheless, changes in body fluid osmolality and plasma volume may be so large that additional mechanisms must be recruited to maintain homeostasis. These other responses involve the central control of water and sodium excretion in urine through the actions of specific hormones, and the central control of water and NaCl consumption motivated by thirst and salt appetite.

## OSMOTIC HOMEOSTASIS

Osmolality is an expression of concentration—that is, a ratio of the total amount of solute dissolved in a given weight of water:

$$\frac{\text{solute (osmoles)}}{\text{water (kilograms)}}$$

Dehydration and the consequent need for water occur whenever this ratio is elevated, whether by a decrease in its denominator or by an increase in its numerator. In fact, both changes occur naturally and

often: Body water decreases as a result of water deprivation or the loss of dilute fluids to accomplish evaporative cooling (e.g., sweating) and increases as a result of solute load (e.g., the consumption of sodium as NaCl in foods).

The water loss associated with dehydration is borne by the ECF and the ICF in proportion to their sizes because the osmolality of fluid in the two compartments remains in equilibrium. In contrast, the increase in plasma osmolality that results from a solute load results only in cellular dehydration because the water leaving cells by osmosis expands ECF volume. Thus, a solute load is a more abrupt, less complex treatment than water deprivation for stimulating AVP secretion and thirst, the two main osmoregulatory responses of the brain.

### Arginine Vasopressin Is the Antidiuretic Hormone

AVP is a nine amino acid peptide that is synthesized in the magnocellular neurons in the supraoptic nucleus (SON) and the paraventricular nucleus (PVN) of the

hypothalamus. The peptide is cleaved enzymatically from its prohormone and transported along axons projecting from the hypothalamus to the nearby posterior lobe of the pituitary gland (*neurohypophysis*). There, AVP is stored within neurosecretory granules until specific stimuli, such as an increase in the effective osmolality of body fluids, activate its secretion into the bloodstream. The importance of AVP in maintaining water balance is underscored by the fact that its stores in the pituitary contain sufficient hormone to enable maximal antidiuresis when dehydration is sustained for more than a week.

The circulating hormone acts on a subset of AVP receptors (the  $V_2$  subtype) in the kidney to increase water permeability of the collecting ducts of nephrons through insertion of water channels, called *aquaporins*, into the apical membranes of tubular epithelial cells. Antidiuresis occurs when water moves out of the distal convoluted tubule and collecting duct by osmosis. As secondary responses to the increased net water reabsorption, urine flow decreases and urine osmolality increases. See Box 39.1 for more on renal water channels (Knepper, 1997).

#### BOX 39.1

### WATER CHANNELS

Water conservation by the kidney is dependent on its ability to concentrate the urine. Urine is concentrated through the combined actions of the loop of Henle and the collecting duct of the kidney. The loop of Henle generates a high osmolality in the renal medulla via a mechanism known as the countercurrent multiplier system. AVP acts in the collecting duct to increase water permeability, thereby allowing osmotic equilibration between the urine and the hypertonic interstitium of the renal medulla. The net effect of this process is to extract water from the urine into the medullary interstitial blood vessels, resulting in increased urine concentration and decreased urine volume.

AVP produces antidiuresis by virtue of its effects on the epithelial principal cells of the collecting duct in the kidney, which are endowed with AVP receptors of the  $V_2$  type. It has long been known that binding of AVP to G protein-coupled  $V_2$  receptors causes cAMP generation via activation of adenylate cyclase. However, the intracellular mechanisms responsible for the subsequent increased water reabsorption across the collecting duct cells have been elucidated only recently following the discovery of

*aquaporins*, which are a widely expressed family of water channels that facilitate rapid water transport across cell membranes.

Many different aquaporin water channels are expressed in various body tissues, including the brain. Several of these channels have been localized in the kidney. Aquaporin-1 is expressed constitutively in the proximal tubule and thin descending limb of the loop of Henle and is believed to be responsible for reabsorption of a large fraction of the water filtered by the glomerulus. The other three water channels, aquaporin-2, -3, and -4, are expressed in collecting duct principal cells, target cells for the action of AVP to regulate collecting duct water permeability. Aquaporin-2 is the only water channel known to be expressed in the apical membrane (i.e., the side bordering the tubular lumen, through which urine flows) of collecting duct principal cells and is also abundant in intracellular vesicles located below the apical membrane. Aquaporin-2 is the major AVP-regulated water channel and mediates water transport across the apical plasma membrane of the principal cells of the collecting ducts. In contrast, aquaporins-3 and -4 are

(continues)

## BOX 39.1 (cont'd)

expressed at high levels in the basolateral plasma membranes (i.e., the side bordering the blood) of principal cells and are responsible for the constitutively high water permeability of the basolateral plasma membrane.

There are at least two ways by which AVP regulates osmotic water permeability in the collecting duct: short-term and long-term regulation (Knepper, 1997). Short-term regulation is associated with increases in water permeability within a few minutes of AVP exposure, an effect that is rapidly reversible. AVP triggers this response by binding to the  $V_2$  receptor and increasing intracellular cyclic AMP levels by activating adenylate cyclase. Studies have demonstrated that the increase in collecting duct water permeability is a consequence of fusion of aquaporin-2-containing intracytoplasmic vesicles with the apical plasma membranes of the principal cells, a process that increases apical water permeability by markedly increasing the number of water-conducting pores in the apical plasma membrane. Dissociation of AVP from the  $V_2$  receptor allows intracellular cAMP levels to decrease, and the water channels are reinternalized into the intracytoplasmic vesicles, thereby terminating the increased water permeability. By virtue of the subapical membrane

localization of the aquaporin-containing vesicles, they can be quickly shuttled into and out of the membrane in response to changes in intracellular cAMP levels. This mechanism therefore allows minute-to-minute regulation of renal water excretion through changes in ambient plasma AVP levels. Long-term regulation of collecting duct water permeability represents a sustained increase in collecting duct water permeability in response to prolonged high levels of circulating AVP. This response requires at least 24h to elicit and is not as rapidly reversible. Studies have demonstrated that this conditioning effect is due largely to the ability of AVP to induce large increases in the abundance of aquaporin-2 and -3 water channels in the collecting duct principal cells. Greater total expression of the number of aquaporin-2 and -3 water channels, when combined with the short-term effect of AVP to shift aquaporin-2 into the apical plasma membrane, allows the collecting ducts to achieve extremely high water permeabilities during conditions of prolonged dehydration, thereby further enhancing the urine concentrating capacity in response to elevated levels of circulating AVP.

*Edward M. Stricker and Joseph G. Verbalis*

With refinement of radioimmunoassays for AVP, the unique sensitivity of the hormone to small changes in osmolality has become apparent, as has the remarkable sensitivity of the kidney to small changes in plasma AVP levels. Circulating AVP is linearly related to plasma osmolality above a threshold of 1 to 2%  $\text{pg ml}^{-1}$  (Fig. 39.2). Urine osmolality, in turn, is related linearly to AVP levels from 0.5 to 5–6  $\text{pg ml}^{-1}$ , in association with increases in plasma osmolality to only 4% above the threshold for AVP secretion. However, because urine volume is related inversely to urine osmolality, small increases in plasma AVP concentration (e.g., from 0.5 to 2  $\text{pg ml}^{-1}$ ) have the effect of decreasing urine flow much more than subsequent larger increases (e.g., from 2 to 5  $\text{pg ml}^{-1}$ ; Fig. 39.3). This relationship emphasizes the marked physiological effects of small initial changes in plasma AVP levels. The net result of these relations among plasma osmolality, AVP secretion, urine volume, and urine osmolality is a finely tuned regulatory system that adjusts the rate of free water excretion according to plasma osmolality via changes in pituitary hormone secretion.

**FIGURE 39.2** Plasma concentrations of AVP as a function of changes in plasma osmolality, blood volume, or blood pressure in humans. The arrow indicates the plasma AVP concentration at basal plasma osmolality, volume, and blood pressure. Modified with permission from Robertson (1986).

**FIGURE 39.3** Relationship of plasma osmolality, plasma AVP concentrations, urine osmolality, and urine volume in humans. Note that small changes in plasma AVP concentrations have larger effects on urine volume at low plasma AVP concentrations than at high plasma AVP concentrations. Modified with permission from Robinson (1985).

### Thirst Is Another Effective Osmoregulatory Response to Dehydration

Accompanying the excretion of concentrated urine is reabsorption of conserved water, which can considerably dilute remaining body fluids. Thirst, and the water intake it provokes, is a much more rapid and less limited response to dehydration than antidiuresis. Thirst may be defined as a strong motivation to seek, to obtain, and to consume water in response to deficits in body fluids. Like AVP secretion, thirst can be stimulated by cellular dehydration caused by increases in the effective osmolality of ECF (Gilman, 1937). Studies in animals consistently indicate that drinking behavior is elicited by 1 to 3% increases in plasma osmolality above basal levels, and analogous research in humans has revealed that similar thresholds must be reached to produce thirst (Robertson, 1986). This arrangement, in which the threshold for drinking is slightly higher than that for secretion of AVP (Fig. 39.3), ensures that ongoing behavior is not disrupted by thirst unless the buffering effects of osmosis and antidiuresis are insuf-

ficient to maintain osmoregulation. It also ensures that dehydration does not become severe before thirst is stimulated. See Box 39.2 for more on how the neurohypophysis controls the volume of water in the body.

Also like AVP secretion, water intake increases linearly in proportion to increases in the effective osmolality of ECF. The dilution of body fluids by ingested water complements the retention of water that occurs during antidiuresis, and both responses occur when drinking water is available. However, there may be marked individual differences in whether dehydrated subjects respond to their need for water promptly by drinking, or more slowly by increasing renal water conservation (Kanter, 1953). AVP secretion and urine osmolality are more elevated when an induced increase in plasma osmolality is not compensated for by water intake (e.g., because drinking water is not available). Conversely, water intake in response to a solute load increases in animals after their kidneys are removed or their capability to secrete AVP is compromised, thereby precluding rapid excretion of the load in concentrated urine. See Box 39.3 on the rapid inhibitory feedback control of drinking.

### Osmoreceptor Cells Stimulate AVP Secretion and Thirst

All body cells lose water by osmosis when the effective osmolality of ECF is increased. Thus, cells that provoke AVP secretion and thirst do not have unique osmosensitive properties (unlike retinal photoreceptor cells, e.g., which are uniquely responsive to light). Instead, the exceptional feature of osmoreceptor cells is thought to be their neural circuitry, which activates the central systems for AVP secretion and thirst when the cells are dehydrated.

Destruction of osmoreceptor neurons should eliminate detection of increased plasma osmolality and thus the AVP secretion and thirst responses that are elicited by dehydration. In fact, ample research has confirmed that certain brain lesions eliminate AVP secretion and thirst responses. Such studies also have revealed that osmoreceptor cells (Johnson and Buggy, 1978; Thrasher *et al.*, 1982) appear to be located in the vascular organ of the lamina terminalis (OVLT) and areas of the adjacent anterior hypothalamus, near the anterior wall of the third cerebral ventricle (Fig. 39.4). Surgical destruction of that area of the brain in animals abolishes the AVP secretion and thirst responses to hyperosmolality but not their responses to other stimuli. The same conclusion was drawn after a study of people who were unable to osmoregulate when water deprived or when given a NaCl load; these patients were found to have

## BOX 39.2

## DIABETES INSIPIDUS

The disease *diabetes insipidus* (DI), in which the secretion of AVP is impaired or absent, illustrates the crucial role of AVP in controlling the volume of water in the body. An eighteenth century English physician, Thomas Willis, named the disease diabetes insipidus, or insipid urine, to distinguish it from *diabetes mellitus*, or sweet urine, in which abnormally high concentrations of glucose in the blood result in glucose appearing in the urine.

AVP is the only known antidiuretic substance in the body. In its absence, the kidney is unable to concentrate urine maximally to conserve water. The result is a continued excretion of copious amounts of very dilute urine. Patients with severe cases of DI, in whom the ability to excrete AVP is completely lost, can excrete up to 25 liters of urine each day. Such patients urinate almost hourly, which renders the completion of even simple tasks and activities of daily living, including sleeping, exceedingly difficult.

Patients with DI can quickly become dehydrated if their urinary fluid losses are not replaced by drinking water. Fortunately, thirst remains intact in most patients with DI because lesions that destroy the magnocellular neurons in the SON and PVN that synthesize AVP generally leave intact the osmoreceptors in the anterior hypothalamus as well as the higher brain centers that control thirst. Consequently, extreme thirst is one of the hallmarks of this disease, leading to the characteristic symptoms of *polydipsia* (excessive drinking) and *polyuria* (excessive urination). If drinking water is unavailable, or

if a person with DI is unable to drink, then the unreplaced urinary water loss leads to dehydration and death in the absence of medical intervention.

DI can be caused when tumors and infiltrative diseases of the hypothalamus destroy the magnocellular neurons that produce AVP. Because four nuclei contain magnocellular neurons, and 10 to 20% of AVP-producing neurons are sufficient for normal urine concentration, brain lesions that cause DI are generally large. Less commonly, DI is idiopathic (of unknown cause), most likely from an autoimmune basis. DI can also be genetic, transmitted as an autosomal-dominant trait. Some patients with DI do not have any defect in AVP secretion but rather have defects in the V<sub>2</sub> AVP receptors in the kidney that respond to circulating AVP. These cases are called *nephrogenic* (of kidney origin) DI.

The treatment for DI, like that of other endocrine deficiency disorders, is replacement of the deficient hormone, in this case AVP. The short half-life of AVP in the circulation allows mammals to have minute-to-minute control of their urine output. However, longer acting synthetic analogs of AVP are more convenient for treatment because they need not be taken as frequently as short-acting drugs (Robinson, 1985). These agents can restore urinary concentration and allow a person with DI to lead a more normal life.

Edward M. Stricker and Joseph G. Verbalis

focal brain tumors that destroyed the region around the OVLT.

The location of osmoreceptor cells in the OVLT is consistent with the results of pioneering investigations in which hyperosmotic solutions injected into blood vessels perfusing the anterior hypothalamus stimulated AVP secretion in dogs (Verney, 1947). The OVLT and surrounding areas of the anterior hypothalamus were subsequently implicated by studies in rats. After systemic injections of hypertonic NaCl solution, modern immunocytochemical techniques were used to detect early gene products in cells associated with the production of new protein. Dense staining in the OVLT (and in AVP-secreting cells in the hypothalamus) indicated that it had been strongly stimulated by

the experimentally induced dehydration. See Box 39.4 on the use of cFos immunocytochemistry in studies of brain function.

The neural pathways connecting the OVLT with magnocellular AVP-secreting cells in the hypothalamic SON and PVN have been identified, whereas the neural circuits in the forebrain that control thirst are less well known. Early reports identified the lateral hypothalamus as a "thirst center" because its destruction in rats eliminated the drinking response, but not the associated AVP secretion, to increased osmolality of body fluids. However, later investigations showed that the critical damage was not to hypothalamic cells but to dopamine-containing fibers that coursed through the area. The induced disruption of behavior was not

## BOX 39.3

## RAPID INHIBITORY FEEDBACK CONTROL OF DRINKING

Water deprivation and systemic administration of hypertonic saline each increases the effective osmolality of circulating plasma and thereby activates forebrain osmoreceptor cells. Animals drink water, but 10 to 20 min elapse before ingested water is absorbed into the circulation and affects plasma osmolality. However, many species (e.g., dogs, humans) drink water very quickly, stopping long before the ingested water actually rehydrates them. What are the biological mechanisms that mediate this anticipatory satiety?

One possibility is that a neural message is communicated from the oropharynx to the brain in association with the act of swallowing. Thus, the more animals drink and swallow, the greater the inhibition of thirst, even before the water is absorbed. In fact, evidence is consistent with metered fluid consumption providing a preliminary signal of satiety. The main experiments were done in dogs with implanted gastric fistulas (Thrasher *et al.*, 1981). When the fistula was closed, ingested water flowed normally from the stomach into the intestine and was absorbed; water-deprived dogs drank rapidly, stopped 15 min before their plasma osmolalities began to decrease, and did not resume drinking as their stomach emptied. In contrast, when the fistula was left open, ingested water drained out from the stomach, never entering the intestine and thus never being absorbed; the dogs drank normal amounts, stopped drinking, and after 10 to 20 min resumed drinking. When the dogs were not allowed to drink but water was introduced into the stomach through the fistula, thus bypassing the oropharynx, the gastric load did not affect water intake until it had been absorbed.

These observations are consistent with a temporary satiety being produced by the act of water consumption, with a more long-lasting satiety occurring only after absorption of the ingested water and rehydration of the dog. AVP secretion is affected in parallel, showing that physiological and behavioral components of osmoregulation are influenced similarly. Ingestion of a concentrated NaCl solution instead of water produces the same temporary satiety and inhibition of AVP secretion, but after the saline is absorbed, the increase in plasma osmolality stimulates more drinking and AVP secretion than occurred at first. In similar experiments, people respond the same way.

Animals drink appropriate amounts perhaps because they have learned from previous experiences how much to drink to relieve their thirst. After all, when we are thirsty, we fill a glass to a volume that, based on previous experience, we think will be sufficient for satiety. No doubt animals behave equivalently. Alternatively, this drinking response may not be learned, and instead appropriate neural circuits linking the act of swallowing with satiety may be present at birth.

Research indicates that rats also obtain early feedback from drinking but do so by a different mechanism. In one study, rats were infused intravenously with a hypertonic NaCl solution to stimulate AVP secretion (Huang *et al.*, 2000). Water intake for 5 min was found to cause a rapid decrease in plasma levels of AVP without noticeable changes in plasma osmolality. These effects were not associated simply with the act of drinking because intake of the same volume of isotonic saline had no effect on plasma AVP levels. Thus, the animals appeared to be responding to the composition of the ingested fluid, not its volume. These and other observations suggest the existence of osmo- or Na<sup>+</sup>-receptor cells that detect ingested water, located somewhere after the fluid leaves the stomach and before it enters the general circulation. The small intestines, hepatic portal vein, and liver all are potential sites for such receptors. Moreover, distension of the stomach and small intestine appears to provide an additional presystemic signal inhibiting thirst (but not AVP secretion) in dehydrated rats. After the destruction of vagal afferent neurons from these visceral loci, or the neural projection sites in the nucleus of the solitary tract and area postrema in the caudal brain stem (Curtis *et al.*, 1996), rats drank excessive amounts of water in response to thirst stimuli, especially in the early portion of the drinking test. These thirsty animals behaved as if they did not receive inhibitory feedback until the ingested water was absorbed and had reduced plasma osmolality. Thus, whether inhibitory signals arise from the oropharynx, the hepatic portal vein, or other peripheral sites, early messages modulate drinking and AVP secretion.

*Edward M. Stricker and Joseph G. Verbalis*

**FIGURE 39.4** Summary of the main anterior hypothalamic pathways that mediate secretion of arginine vasopressin (AVP) and oxytocin (OT). The vascular organ of the lamina terminalis (OVLT) is especially sensitive to hyperosmolality. Hyperosmolality also activates other neurons in the anterior hypothalamus, such as those in the subfornical organ (SFO) and median preoptic nucleus (MnPO), and magnocellular neurons, which are intrinsically osmosensitive. Circulating angiotensin II (AII) activates neurons of the SFO, an essential site of AII action, as well as cells throughout the lamina terminalis and MnPO. In response to hyperosmolality or AII, projections from the SFO and OVLT to the MnPO activate excitatory and inhibitory interneurons that project to the supraoptic nucleus (SON) and paraventricular nucleus (PVN) to modulate direct inputs to these areas from the circumventricular organs. Cholecystokinin (CCK) acts primarily on gastric vagal afferents that terminate in the nucleus of the solitary tract (NST), but at higher doses it can also act at the area postrema (AP). Although neurons apparently are activated in the ventrolateral medulla (VLM) and NST, most oxytocin secretion appears to be stimulated by monosynaptic projections from A2/C2 cells, and possibly also noncatecholaminergic somatostatin/inhibin b cells, of the NST. Baroreceptor-mediated stimuli, such as hypovolemia and hypotension, are more complex. The major projection to magnocellular AVP neurons appears to arise from A1 cells of the VLM that are activated by excitatory interneurons from the NST. Other areas, such as the parabrachial nucleus (PBN), may contribute multisynaptic projections. Cranial nerves IX and X, which terminate in the NST, also contribute input to magnocellular AVP neurons. It is unclear whether baroreceptor-mediated secretion of oxytocin results from projections from VLM neurons or from NST neurons. AC, anterior commissure; OC, optic chiasm; PIT, anterior pituitary.

specific to drinking but instead reflected a general inability of the brain-damaged animals to initiate movement (Stricker, 1976). Indeed, the syndrome of behavioral dysfunctions seen in these animals generally resembled that of Parkinson's disease, which has also been attributed to the loss of dopaminergic fibers in the brain. (See Chapter 38 for the same reinterpretation of the inability of rats to eat normally after dopamine-depleting lesions of the lateral hypothalamus.) More recent studies using functional magnetic resonance imaging of the brain have implicated the anterior cingulate cortex as a likely area involved in thirst perception (Egan *et al.*, 2003).

### Natriuresis and Inhibition of Solute Intake Also Promote Osmotic Homeostasis during Dehydration

When body fluid is hyperosmolar, adaptive behavior includes not only drinking and conserving water (thereby increasing the denominator in the ratio that represents body fluid osmolality), but also excreting NaCl and avoiding the consumption of additional osmolytes (thereby decreasing the numerator of that ratio). Endogenous natriuretic agents promote urinary sodium loss after an administered NaCl load or a period of imposed water deprivation. One such agent

## BOX 39.4

USE OF cFOS IMMUNOCYTOCHEMISTRY IN STUDIES OF  
BRAIN FUNCTION

cFos was named for its homology to an FBR osteogenic sarcoma virus protein, v-fos. The cFos protein is the product of the *c-fos* gene, which belongs to a family of genes whose products are involved in the regulation of gene transcription. The protein has a "leucine zipper" motif that promotes dimerization (pairing) with other regulatory proteins, most commonly with members of the Jun family. Genes encoding Jun and Fos are *immediate-early genes* (IEGs), the first genes expressed in response to activation of cells. Jun and Fos protein dimers bind specific DNA sequences (e.g., APS sites) to modulate the expression of genes expressed later.

The precise relationship between cFos expression and transcription of later gene products remains uncertain for most neural systems. However, many neurons are known to express cFos only on synaptic activation; therefore, the mRNA or protein product (cFos) of the *c-fos* gene can be used as a marker of neuronal activation in the brain. The protein product is especially useful because it is detected easily by antibodies directed against cFos. This immunohistochemical staining allows investigators to determine which neurons are activated in the brain in response to specific stimuli given to experimental animals.

Many of the initial studies simply localized the IEG expression to magnocellular neurons in the SON and PVN, but later studies used antibodies against proteins located in cytoplasm, along with the antibody against IEG

products, and showed that the IEG products were located in the nucleus (Hoffman *et al.*, 1993). Such studies have now confirmed that in response to these treatments, IEG expression in AVP- and oxytocin-secreting neurons closely parallels pituitary AVP and oxytocin secretion. Thus, in rats, hyperosmolality, hypovolemia, and administration of AII stimulate secretion of AVP and oxytocin and activate cFos expression in AVP and OT neurons; CCK, which stimulates secretion of oxytocin but not AVP, causes expression of cFos only in neurons that secrete oxytocin. Similarly, although severe hemorrhage stimulates secretion of AVP and oxytocin and activates cFos expression in both types of neurons, lower intensity hypovolemia predominantly causes peptide secretion and cFos expression only in AVP neurons. During CCK administration and during hemorrhage, plasma AVP and oxytocin correlate well with cFos expression. Consequently, IEG expression is now considered a specific and sensitive marker of magnocellular secretory activity in response to most acute stimuli.

Immunocytochemical detection of cFos expression, phenotypic characterization of activated cells, and standard techniques of tract tracing together have enabled investigators to map brain circuits activated by specific stimuli.

*Edward M. Stricker and Joseph G. Verbalis*

is the hormone *atrial natriuretic peptide* (ANP), which is synthesized in the atria of the heart and released when increased intravascular volume distends the atria. Another is the hormone *oxytocin*. Like AVP, oxytocin is synthesized in magnocellular neurons in the PVN and SON and secreted from the posterior pituitary in proportion to induced hyperosmolality (Stricker and Verbalis, 1986). In rats, oxytocin is as potent in stimulating natriuresis as AVP is in stimulating antidiuresis (Verbalis *et al.*, 1991).

Salt loads are also known to decrease the intake of osmolytes, whether in the form of NaCl solution or food, complementing the stimulation of thirst and the secretion of AVP and oxytocin. However, because destruction of the OVLT eliminates the two latter effects but not the dehydration-induced reduction in NaCl intake, osmo- or Na<sup>+</sup> receptors located outside

the basal forebrain must mediate the inhibition of NaCl and food intake. Possible sites for such cells include the *hepatic portal vein* and the *area postrema*, both of which have been suspected of having Na<sup>+</sup> receptor functions. In addition, cells in the hepatic portal vein are well situated to detect the sodium content of ingested food and to modulate its intake accordingly.

### Diuresis and Inhibition of Water Intake Promote Osmotic Homeostasis during Overhydration

Osmoregulation is required not only under conditions of dehydration, but also during periods of acute overhydration and hypoosmolality, as may result when beverages are consumed in excess of water

needs. Such consumption occurs not because of thirst but, for example, because of the palatability of or chemical substances in the beverages (e.g., caffeine, alcohol). Unlike excess food, which is stored as triglycerides in adipose tissue, excess water is not stored for later use but instead is excreted in urine. When plasma osmolality is below normal, circulating levels of AVP are reduced, and in consequence, the kidneys excrete dilute urine and thereby raise plasma osmolality. The major behavioral contribution of osmotic dilution to osmoregulation is inhibition of free water intake; the ingestion of osmolytes in food and NaCl is not stimulated by osmotic dilution.

## Summary

Osmoregulation in animals and humans is accomplished by a combination of physiological responses to dehydration, resulting in antidiuresis and natriuresis, and the behavioral response of increased water intake. Osmoreceptor cells critical for mediating these functions have been identified in the basal forebrain. These neurons respond to very small increases in plasma osmolality, and the effector systems they control correct any increase in plasma osmolality. In addition, an early stimulus must exist, generated by peripheral osmo- or Na<sup>+</sup> receptor cells, which signals the brain in anticipation of subsequent rehydration. Other osmo- or Na<sup>+</sup> receptor cells appear to mediate the inhibition of NaCl and food intake, which also contributes to osmoregulation during dehydration. Conversely, diuresis and inhibition of water intake promote osmoregulation during overhydration, whereas excitation of NaCl or food intake does not.

## VOLUME HOMEOSTASIS

Like osmotic dehydration, loss of blood volume (*hypovolemia*) stimulates several adaptive compensatory responses appropriate for restoring circulatory volume. The physiological contributions to volume regulation have been studied extensively in laboratory animals subjected to a controlled loss of blood. Because behavior is compromised by the anemia and hypotension that result from extensive hemorrhage, researchers studying thirst in rats may instead produce hypovolemia by subcutaneous injection of a colloidal solution. Such treatment disrupts the Starling equilibrium in capillaries near the injection site because the extravascular colloid opposes the oncotic effect of plasma proteins. Consequently, fluid leaches out of capillaries and remains in the interstitial space. Ingested

fluid is also drawn into the interstitial space by the colloid so the total fluid volume required to correct the plasma volume deficit may be substantial. Water does not move from the cells by osmosis, however, because the osmolality of the injected colloidal solutions actually is similar to that of cells.

After colloid injections, rats conserve water and Na<sup>+</sup> in urine and increase their consumption of water and saline solution (Stricker, 1981). When given an isotonic NaCl solution to drink, these rats ingest volumes appropriate to their needs. When given separate bottles of water and concentrated NaCl solution, remarkably the rats drink appropriate amounts of each to create an isotonic fluid mixture. These observations raise several questions: How do the hypovolemic rats detect their plasma volume depletion? How are their thirst and salt appetite coordinated so that they consume the desired isotonic mixture of fluid? How are these two behavioral responses integrated with the complementary physiological responses of water and Na<sup>+</sup> conservation in urine, as well as with the vasoconstrictor responses needed to support blood pressure? Research has provided answers to these and related questions, which are discussed in the following sections.

## Neural and Endocrine Signals of Hypovolemia Stimulate AVP Secretion

An appropriate physiological response to volume depletion should include water conservation and urine concentration. In fact, like plasma hyperosmolality, hypovolemia is an effective stimulus for AVP secretion (Robertson, 1986; Stricker and Verbalis, 1986). However, AVP secretion does not occur until blood loss exceeds 10% of total blood volume, meaning AVP secretion is much less sensitive to hypovolemia than to increases in ECF osmolality (Fig. 39.2). The effects of hypovolemia and osmotic dehydration are additive; that is, a given increase in osmolality causes greater secretion of AVP when animals are hypovolemic than when they are euvoletic (Fig. 39.5).

Loss of blood volume is first detected by stretch receptors in the great veins entering the right atrium of the heart. These stretch receptors provide an afferent vagal signal to the *nucleus of the solitary tract* (NST) in the brain stem (Chapter 36). Still larger decreases in blood volume may also lower arterial blood pressure and reduce the stretch of receptors in the walls of the carotid sinus and aortic arch. That information is integrated in the NST with neural messages from the low-pressure, venous side of the circulation. Note that these sensory neurons are not actually baroreceptors (literally, pressure receptors), although commonly they are referred to as such.

**FIGURE 39.5** The relationship between the osmolality of plasma and the concentration of vasopressin (AVP) in plasma depends on blood volume and pressure. The line labeled N shows plasma vasopressin concentration across a range of plasma osmolality in an adult with normal intravascular volume (euvoletic) and normal blood pressure (normotensive). Lines to the left of N show the relationship between plasma vasopressin concentration and plasma osmolality in adults whose low intravascular volume (hypovolemia) or blood pressure (hypotension) is 10, 15, and 20% below normal. Lines to the right of N are for volumes and blood pressures 10, 15, and 20% above normal. Modified with permission from Robertson (1986).

The ascending pathway between the NST in the brain stem and the SON and PVN in the hypothalamus includes noradrenergic fibers arising from A1 cells in the ventrolateral medulla. Volume depletion stimulates AVP secretion via other pathways as well. In addition, the kidneys secrete *renin* during hypovolemia, a response mediated in part by sympathetic neural input to  $\beta$ -adrenergic receptors on cells that secrete renin. Renin is an enzyme that initiates a cascade of biochemical steps that result in the formation of *angiotensin II* (AII) (Fig. 39.6), an extremely potent vasoconstrictor. AII stimulates AVP secretion by acting in the brain at the *subfornical organ* (SFO) (Ferguson and Renaud, 1986), which is located in the dorsal portion of the third cerebral ventricle. Because this circumventricular organ lacks a blood–brain barrier, the AII receptors can detect very small increases in the blood levels of AII. Neural pathways from the SFO to the SON and PVN in the hypothalamus mediate AVP secretion and may use AII as a neurotransmitter. A branch of this pathway goes first to the OVLT, perhaps providing an opportunity for the integration of information about volume states and osmotic concentration.

### Neural and Endocrine Signals of Hypovolemia Also Stimulate Thirst

In addition to the antidiuresis and vasoconstriction produced by the secretion of AVP and activation of the

renin–angiotensin system, colloid treatment increases water intake in rats (Fitzsimons, 1961). Once 5 to 10% of the normal plasma volume has been lost, the water intake elicited by hypovolemia increases linearly in relation to further deficits in plasma volume. This stimulus for water intake and the effect of a NaCl load on thirst are additive. The stimulus of thirst during hypovolemia appears to be the same as the signal for AVP secretion—that is, a combination of neural afferents from cardiovascular baroreceptors and endocrine stimulation by AII (Fitzsimons, 1969). Each signal can stimulate water intake in the absence of the other. For example, water intake by hypovolemic rats is not diminished by destruction of the NST and loss of neural input from baroreceptors, nor is it eliminated by the loss of AII resulting from bilateral removal of the kidneys (Fitzsimons, 1961). Presumably, colloid treatment would not elicit thirst in rats subjected concurrently to bilateral nephrectomy and NST lesions.

Intravenous infusion of AII strongly stimulates thirst in rats and most other animals studied in the laboratory (including humans). AII adds to the thirst stimulated by an osmotic load when the two treatments are combined. There had been considerable controversy about whether AII functions as a normal physiological stimulus of thirst because the doses of AII required to stimulate significant water intake produce blood levels of AII well above the physiological range. However, such doses also increase arterial blood pressure, and it has been shown that this acute hypertension inhibits thirst and limits the induced water intake. For example, drinking was enhanced considerably when the hypertensive effects of AII were blunted by a simultaneous administration of vasodilating agents (Robinson and Evered, 1987).

### Osmotic Dilution Inhibits Thirst and AVP Secretion during Hypovolemia

Hypovolemic rats need isotonic saline, not water alone, to repair their plasma volume deficits. When the rats drink only water, about two-thirds of the ingested volume moves into cells by osmosis, and much of what remains extracellular is captured by the colloid. Thus, most of the water that is consumed does not remain in the vascular compartment, and the volume deficit within the vascular compartment persists. This situation may be contrasted with the negative feedback control of osmoregulatory thirst in which the dehydration of osmoreceptor cells causes thirst and ingested water repairs dehydration, eliminating the stimulus for thirst.

Rather than repairing the volume deficit, the water consumed by hypovolemic rats causes a second serious

**FIGURE 39.6** The renin–angiotensin cascade. Baroreceptors in the aortic arch, carotid sinus, and renal afferent arterioles sense hypovolemia and then cause the kidneys to secrete the enzyme renin. Renin cleaves angiotensinogen, which is synthesized by the liver, to produce angiotensin I. The angiotensin-converting enzyme, primarily in the lungs, cleaves angiotensin I to produce angiotensin II (AII), a peptide made of eight amino acid residues. AII is a potent vasoconstrictor and one of several stimulants of aldosterone secretion. Stimulation of aldosterone secretion from the adrenal cortex, along with possible direct intrarenal effects of AII, promotes renal conservation of sodium ions, complementing the pressor effect of AII in stabilizing arterial pressure and volume. ACTH, adrenocorticotropic hormone; ANP, atrial natriuretic peptide; pOsm, plasma osmolality. Modified with permission from Stricker and Verbalis (1992).

challenge to body fluid homeostasis: osmotic dilution. The animals cannot readily eliminate this self-administered water load because hypovolemia reduces GFR and thereby diminishes urinary excretion independent of AVP. Therefore, when water is the only drinking fluid available, an appropriate response of colloid-treated rats would be to stop drinking and thereby limit the secondary problem of osmotic dilution. In experiments, colloid-treated rats actually do stop drinking water despite persistent hypovolemia, and

the stimulus for the inhibition of thirst has been found to be osmotic dilution of body fluids (Stricker, 1969). A mere 4 to 7% decrease in osmolality is sufficient to stop drinking that has been motivated by a 30 to 40% loss of plasma volume. Thus, the osmoregulatory system appears dominant in the control of thirst. Comparable data demonstrate the same to be true of AVP secretion in colloid-treated rats: osmotic dilution inhibits AVP secretion even in severely hypovolemic rats (Stricker and Verbalis, 1986).

## Hypovolemia Also Stimulates Aldosterone Secretion and Salt Appetite

As mentioned earlier, hypovolemic animals need to consume and retain water and NaCl, not just water. Appropriately, colloid-treated rats drink NaCl solution and conserve Na<sup>+</sup> in urine. Renal Na<sup>+</sup> retention is mediated largely by aldosterone secreted from the adrenal cortex, although Na<sup>+</sup> conservation also occurs in association with the decrease in GFR. The central nervous system does not innervate the adrenal cortex, as it does the adrenal medulla. However, a neural influence on aldosterone secretion is provided indirectly because AII is a very potent stimulus of aldosterone secretion, and renin secretion from the kidneys during hypovolemia is stimulated in part by the sympathetic nervous system (Fig. 39.6). The secretion of aldosterone is also stimulated by another peptide hormone, *adrenocorticotrophic hormone* (ACTH), which is secreted from the anterior lobe of the pituitary gland in response to *corticotrophic-releasing hormone* (CRH). The release of CRH from the PVN is triggered by various stressors, including activated cardiovascular baroreceptors. Yet another stimulus of aldosterone

secretion is increased plasma levels of K<sup>+</sup>, which can develop as a consequence of reduced GFR and an associated decrease in urinary K<sup>+</sup> excretion. The effects of these three independent stimuli of aldosterone secretion are additive. Aldosterone has also been found to stimulate salt appetite in animals, which therefore complements its renal effects to cause sodium conservation. (See Box 39.5 on salt appetite after adrenocortical dysfunction.)

The onset of salt appetite induced in rats by colloid treatment is curiously delayed relative to the appearance of thirst. That is, water intake increases within 1 to 2 h after colloid treatment, whereas the intake of NaCl solution does not increase until at least 5 h later (Stricker, 1981). Investigations showed that the delay is caused both by the gradual appearance of an excitatory stimulus of salt appetite (i.e., AII) and by the gradual disappearance of an inhibitory stimulus for NaCl intake. With regard to the latter, recall that during the delay, hypovolemic rats drank water and thereby caused an osmotic dilution of body fluids, which inhibits secretion of pituitary AVP and oxytocin. Either of these neurohypophyseal hormones might have provided an inhibitory stimulus for salt appetite that

### BOX 39.5

#### SALT APPETITE AFTER ADRENOCORTICAL DYSFUNCTION

Fifty years ago, a 4-year-old boy was brought to the Johns Hopkins University Hospital in Baltimore with the peculiar behavior of eating large amounts of table salt. The child heavily salted all his food, even juice, and often consumed salt directly from its container. His parents tried unsuccessfully to keep him from consuming salt and brought him to the hospital in the hope that his strange behavior could be understood and stopped. The physicians were able to prevent the boy from having access to NaCl, but they were shocked when he died a few days later. An autopsy revealed that the child had bilateral tumors in his adrenal glands. In retrospect, it seems clear that he could not secrete aldosterone and therefore lost Na<sup>+</sup> in urine uncontrollably. Like patients with diabetes insipidus, who excrete a copious amount of dilute urine and drink comparable volumes of water in compensation (see Box 39.2 on diabetes insipidus), this boy evidently was ingesting salt as an adaptive compensation to his recurrent need for sodium (Wilkins and Richter, 1940). He died when that response was prevented.

After surgical removal of their adrenal glands, rats increase their consumption of NaCl by amounts proportional to the sodium loss in urine (Richter, 1936). The stimulus for this salt appetite appears to be a combination of elevated circulating levels of AII and reduced activity in a central oxytocinergic inhibitory system. In humans, however, a comparable salt appetite is not as common in patients with Addison disease, whose adrenocortical dysfunction causes them to lose Na<sup>+</sup> in urine excessively. Nor is salt appetite usually stimulated in people who lose excessive amounts of Na<sup>+</sup> in perspiration. No explanation is available for why an adaptive salt appetite appears readily in laboratory animals but not in humans, but this appears to be related, in part, to factors associated with herbivorous versus carnivorous eating behaviors.

*Edward M. Stricker and Joseph G. Verbalis*

disappeared as the animals drank water. In other studies, however, rats showed a strong inverse relationship between intake of NaCl and plasma levels of oxytocin (but not AVP), suggesting that circulating oxytocin was an inhibitory stimulus of salt appetite.

### Central Oxytocin Inhibits Salt Appetite

However, in tests of the hypothesis that circulating oxytocin inhibits salt appetite, an intravenous infusion of physiological doses of oxytocin did not decrease NaCl intake in hypovolemic rats, nor did infusion of an oxytocin receptor blocker increase NaCl intake. These unexpected findings were clarified by the observation that, coincident with the secretion of oxytocin from magnocellular neurons, oxytocin was released from parvicellular neurons projecting centrally from the PVN. Thus, plasma oxytocin may have been a peripheral marker of the centrally acting oxytocin that mediated the inhibition of salt appetite in rats (Blackburn *et al.*, 1992). This hypothesis has been strongly supported by the results of a series of investigations. For example, salt appetite in hypovolemic rats was eliminated by a systemic injection of naloxone, an opioid receptor antagonist that disinhibits oxytocin secretion, and this effect was blocked by the prior injection of an oxytocin receptor antagonist directly into the cerebrospinal fluid. Conversely, NaCl ingestion in response to hypovolemia or AII was potentiated by diverse treatments that inhibit the secretion of oxytocin. In addition to osmotic dilution, these treatments included systemic injection of ethanol, maintenance on a sodium-deficient diet (instead of the standard laboratory diet rich in Na<sup>+</sup>), and peripheral administration of mineralocorticoid hormones such as aldosterone. Thus, excitatory and inhibitory components together regulate NaCl intake in a dual-control system in the brain.

Central oxytocinergic neurons can inhibit salt intake and food intake (Chapter 38). Thus, when osmotic dehydration activates oxytocinergic neurons, the intake of food and salt is inhibited and hyperosmolality is thereby prevented. From this perspective, food is a source of osmolytes (not just of calories) and NaCl solution provides osmolytes without calories. Inhibition of intake of osmolytes complements the natriuretic effect of pituitary oxytocin in supporting osmoregulation.

### Salt Appetite Is Also Inhibited by Atrial Natriuretic Peptide

The role of oxytocin in osmoregulation has become apparent only during the last decade, and the identi-

cation of other peptide hormones as important factors in the homeostasis of body fluids may be anticipated. One likely candidate is atrial natriuretic peptide. Like oxytocin, ANP promotes Na<sup>+</sup> loss in urine; in fact, ANP may mediate the natriuretic effects of OT. Also, like oxytocin, ANP is secreted by neurons within the brain, and when administered directly into the cerebrospinal fluid, it inhibits an experimentally induced salt appetite in rats. Moreover, destruction of ANP receptors in the brain eliminates the inhibition of salt appetite caused by a NaCl load (Blackburn *et al.*, 1995). Further work will be needed to understand the role of ANP-containing neurons in the central control of salt intake and the relationship of the neurons with other systems that participate in the regulation of water and NaCl intake.

### Summary

Regulation of blood volume, like osmoregulation, is accomplished by a combination of physiological responses to hypovolemia, resulting in antidiuresis and antinatriuresis, and the complementary behavioral responses of increased water and NaCl intake. Cardiovascular baroreceptor cells detect hypovolemia and send neural signals to the brain stem, which communicates to the hypothalamus and forebrain structures mediating neurohypophyseal AVP and oxytocin secretion, as well as thirst and salt appetite. AII also appears to stimulate these responses while additionally supporting blood pressure as a potent vasoconstrictor. However, AII and hypovolemia both increase central oxytocin secretion, which mediates inhibition of NaCl intake, so for salt appetite to emerge this effect must be inhibited (as by osmotic dilution of body fluids, resulting from the renal retention of ingested water). The integration of these stimuli ensures that behavioral and physiological responses occur simultaneously, and their redundancy allows these vital regulatory processes to occur even when one stimulus is lost due to injury or disease. More generally, studies of water and NaCl ingestion provide insights into how the brain controls motivation, and how peptide and steroid hormones interact with neural signals in the control of behavior.

## Neuroendocrine Systems

### THE HYPOTHALAMUS IS A NEUROENDOCRINE ORGAN

The hypothalamus, located at the most rostral region of the brain stem in the diencephalon, is a key center regulating numerous and diverse physiological functions, including growth, metabolism, stress responses, reproduction, osmoregulation, and circadian rhythms. All these functions are critically involved in maintaining the homeostasis of the organism and in coordinating the occurrence and timing of physiological functions with the appropriate environmental conditions. In order to accomplish this, the hypothalamus acts as an integrator, receiving converging inputs from virtually every sensory and autonomic system related to the internal and external environment of the organism. The hypothalamus responds rapidly to this convergent information by changing its output of neurotransmitters and neuropeptides, thereby affecting change at its targets within the central nervous system (CNS), the pituitary gland, and the bloodstream.

The hypothalamus contains several groups of cells that are defined as neuroendocrine, meaning that they have both neuronal and endocrine features. Neuroendocrine cells in the central nervous system have a neuronal phenotype, and release a peptide or neurotransmitter in response to a depolarizing stimulus. In this way, they are similar to other nonneuroendocrine neurons in the brain. However, neuroendocrine cells differ from other “traditional” neurons in their targets and modes of release. Instead of releasing their neuropeptide or neurotransmitter at another neuron, for example, via synaptic connections, these hypothalamic neuroendocrine cells release their neurotransmitter into a blood system. An endocrine gland is character-

ized by its direct release of a substance into a blood system. Thus, these neuroendocrine cells in the brain are true endocrine organs in the sense that their targets are a vascular system. Although the substances released by most neuroendocrine cells are peptides and neurotransmitters, they are also appropriately referred to as hormones because they are released into blood vessels to act remotely at a target organ. Thus, the molecules released by these hypothalamic neuroendocrine cells, to be discussed later in this chapter, often are referred to as neurohormones.

The primary target of hypothalamic neuroendocrine cells is the pituitary gland (Fig. 40.1). The pituitary gland comprises the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). Some species also possess an intermediate pituitary lobe. The hypothalamic cells that regulate the anterior pituitary are referred to as hypothalamic releasing or inhibiting cells, and are the major focus of this current chapter. These neurons have their cell somata in the hypothalamus, and they have a nerve process that extends to the median eminence at the base of the hypothalamus. The median eminence is highly vascularized by a blood system called the portal capillary plexus. Hypothalamic releasing/inhibiting hormones are released into the portal capillary vasculature, which then transports these neurohormones to the anterior pituitary gland.

The posterior pituitary gland also is regulated by hypothalamic cells, but the anatomical connectivity between the hypothalamus and the neurohypophysis differs from the hypothalamic-adenohypophysial system. Hypothalamic cells that regulate the neurohypophysis have their cell bodies in the hypothalamus, but their nerve terminals project directly into the posterior pituitary gland (Fig. 40.1). From there, the

**FIGURE 40.1** General features of brain-pituitary-target organ systems. For the five hypothalamic releasing/inhibiting hormonal systems that control reproduction, stress, metabolism, growth, and lactation, each system has a hypothalamic neurosecretory cell, a corresponding pituitary hormone, and a target organ and/or hormone. The hypothalamic-neurohypophysial hormones, AVP and OT, are shown at the right. Abbreviations: ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; DA, dopamine; FSH, follicle-stimulating hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor I; LH, luteinizing hormone; OT, oxytocin; PRL, prolactin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine.

neurohypophyseal hormones are released into the general circulatory system, and are transported to reach their targets elsewhere in the body.

The concept of a link between the hypothalamus and the pituitary gland was suggested and later demonstrated by Geoffrey Harris, who proved the existence of a tiny series of blood vessels leading from the median eminence at the base of the hypothalamus to the anterior pituitary gland (Harris, 1971). Harris proposed that the hypothalamus controls the release of anterior pituitary hormones via this vascular connection. Subsequent studies have shown that the hypothalamic–anterior pituitary connection is critical for maintaining numerous physiological functions involved in metabolism, growth, reproduction, stress responses, and lactation. The isolation and purification of the hypothalamic releasing hormones in the late 1960s by the laboratories of Roger Guillemin, Andrew Schally, and others led to an enormous increase in

knowledge of these molecules. Guillemin and Schally were awarded the Nobel prize in Physiology and Medicine in 1977 for these fundamental discoveries in neuroendocrinology.

## HYPOTHALAMIC RELEASING/ INHIBITING HORMONES AND THEIR TARGETS

### Overview of Hypothalamic–Anterior Pituitary–Target Organ Axis Systems

To date, five neuroendocrine systems have been identified involving hypothalamic–adenohypophysial–target organ regulation. These systems each are characterized by a primary hypothalamic hormone that either stimulates (“releasing” hormone) or inhibits (“inhibiting” hormone) and its corresponding

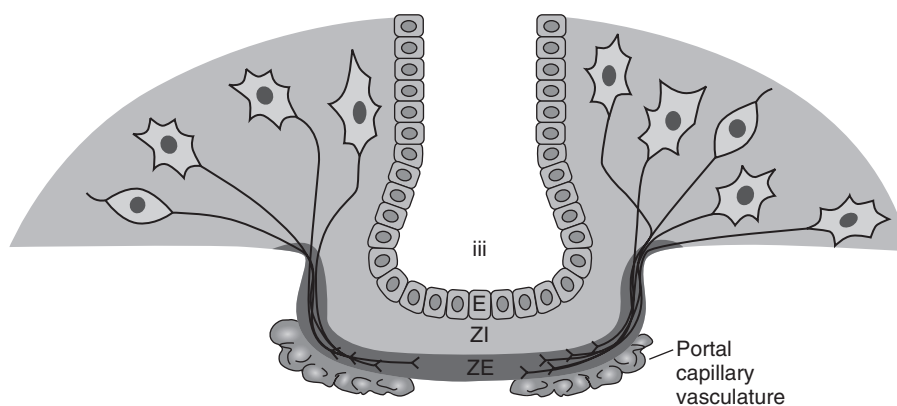

anterior pituitary hormone(s) (Fig. 40.1). The hypothalamic releasing hormones are gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and growth-hormone releasing hormone (GHRH), which stimulate the reproductive, stress, thyroid, and growth axes, respectively. The growth axis also has a hypothalamic inhibiting hormone, somatostatin, and the lactational axis has only a known inhibiting hormone, dopamine, as no unique releasing hormone has been identified for this latter axis. Each of the neuroendocrine axes also has in common a secondary anterior pituitary hormone, or hormones, that is/are released into the general circulatory system. These hormones are luteinizing hormone (LH) and follicle-stimulating hormone (FSH) for the reproductive axis; adrenocorticotropic hormone (ACTH) for the stress axis; thyroid-stimulating hormone (TSH) for the thyroid axis; growth hormone (GH; also called somatotropin) for the growth axis; and prolactin (PRL) for the lactational axis. Finally, four of the neuroendocrine systems (reproduction, stress, thyroid, growth) have a tertiary hormone or hormones, produced by a target organ in the body that expresses receptors for the specific anterior pituitary hormone (Fig. 40.1). The fifth system, lactation, has as its target the mammary gland, whose output is milk, rather than secretion of a hormone into the blood system.

At the hypothalamic level, neuronal perikarya are localized in hypothalamic or preoptic nuclei that vary depending upon the system. The preoptic areas of the brain, just rostral to the hypothalamus, are functionally and neurochemically related to the hypothalamus. Although the precise anatomical localization of the somata of neuroendocrine cells within the hypothala-

mus and preoptic area may differ, each system projects neuroterminals to a common target, the median eminence, located at the floor of the hypothalamus just above the anterior pituitary gland (Fig. 40.2). The external zone of the median eminence contains the portal blood vessels into which the hypothalamic hormone is released. These blood vessels then carry the hypothalamic hormone to the anterior pituitary gland.

The anterior pituitary contains a heterogeneous group of cells that respond to a specific releasing or inhibiting hormone. The anterior pituitary cells are specialized, and each has specific receptors that bind a specific hypothalamic hormone. Thus, although all anterior pituitary cells are exposed to the same "cocktail" of hypothalamic releasing hormones via the portal capillary vasculature, the only cells that will respond to a hypothalamic hormone are those that express the appropriate receptors. The binding of the hypothalamic hormone to its receptor triggers a cascade of biosynthetic and secretory events, stimulating (or inhibiting) the synthesis and release of the pituitary hormone into the general circulatory system. The anterior pituitary gland, like the hypothalamus, is an endocrine gland, in that it releases its hormones into the circulatory system. Anterior pituitary hormones are transported throughout the general circulation to act remotely at organs in the body that are specific to each neuroendocrine axis.

The target organs of the neuroendocrine axes have specific receptors that bind the corresponding pituitary hormone. These target organs respond to the binding of these pituitary hormones to their receptors by increasing (or decreasing) synthesis and secretion of tertiary hormone, such as sex steroid hormones

(from the gonads), thyroxine and triiodothyronine (from the thyroid), insulin-like growth factor-I (from the liver), and glucocorticoids (from the adrenal cortex). It is the actions of these hormones at somatic targets that cause the ultimate physiological effect on the body such as growth, metabolism, mediation of stress, and reproductive function. In addition, each of these tertiary hormones feeds back at the level of the brain, hypothalamus, and/or pituitary gland to regulate its neuroendocrine axis. In this way, the delicate hormonal balance is maintained for each system.

The hypothalamic–pituitary target organ axes are not an independent series of parallel regulatory systems. These axes have considerable crosstalk with one another and can interact at multiple levels. For example, reproductive and stress axes regulate each other at specific hypothalamic neurons, both through direct actions at the CNS, as well as through feedback from the target steroid hormones. During stressful situations, elevated adrenal glucocorticoids will feedback to the brain and have actions not only at the CRH neurons, but at the GnRH neurons as well, thereby suppressing reproduction at a time when it is not optimal. Therefore these hypothalamic neurons serve as integrators of multiple, complex pieces of information about the homeostasis and environment of the organism.

### The Hypothalamus Is Regulated by Inputs from the Central Nervous System and Feedback of Hormones from Target Organs

Hypothalamic-adenohypophysial axes often are referred to as hypothalamic–pituitary–target axes (the targets being the gonad, adrenal gland, thyroid gland, liver, mammary gland, and other somatic organs). However, although this description is accurate in that hypothalamic hormones are the primary regulators of each of these axes, the central nervous system plays a more complex role in the regulation of neuroendocrine function than simply the release of a hypothalamic hormone. For example, each hypothalamic releasing or inhibiting hormone neuron receives afferent inputs from other elements of the brain, such as neurons or glia, which regulate their functions. Additionally, feedback of hormones released by target organs may not occur directly or exclusively at the respective hypothalamic cells, and therefore feedback regulation of hypothalamic hormones may be mediated by other cells in the brain.

A good example is provided by the hypothalamic–pituitary–gonadal system that controls reproduction. Hypothalamic GnRH neurons are the primary activators of this axis. These cells stimulate the release of the

gonadotropins, LH and FSH, from the anterior pituitary, and these molecules in turn target the gonads to stimulate the synthesis and release of sex steroid hormones, particularly estrogens, progestins, and androgens. GnRH neurons express one type of sex steroid hormone receptor, the estrogen receptor  $\beta$  (ER $\beta$ ), but they are not believed to possess other types of sex steroid hormone receptors (Wintermantel *et al.*, 2006). The presence of ER $\beta$  within GnRH neurons is not sufficient to explain the ability of GnRH neurons to respond to positive and negative feedback from estrogens. Therefore at least some of the feedback regulation of GnRH cells by these steroid hormones is probably mediated indirectly by other central nervous system afferents to GnRH neurons. Some of these afferents may be localized in the hypothalamus, whereas others may lie in extrahypothalamic regions, that express sex steroid hormone receptors. Thus, many researchers have begun to refer to the hypothalamic–pituitary–gonadal axis as the *brain–pituitary–gonadal* axis. This concept can be extended to the other neuroendocrine axes as well, as each is regulated by extrahypothalamic inputs, and steroid hormone feedback may occur directly on the hypothalamic cells, but may also be mediated by indirect inputs to these cells.

### Characteristics of Neurohormone Release: Ultradian, Circadian/Diurnal, and Seasonal Rhythms

In considering the release of a hypothalamic hormone and its resulting effect on downstream targets, it is important to note the rhythmicity of this release. Hypothalamic hormones are released in a pulsatile manner, characterized by brief bursts of release, usually at intervals of 1–2 h. This rhythmic pattern also is referred to as ultradian (i.e., shorter than daily rhythms) or circoral (approximately hourly intervals of release). The corresponding anterior pituitary cells respond to each pulse of a hypothalamic hormone with a corresponding pulse of its pituitary hormone shortly thereafter (Fig. 40.3). It has been speculated that the pulsatile release of hypothalamic hormones is necessary to prevent the desensitization of their receptors in the anterior pituitary gland. Indeed, infusion of exogenous hypothalamic hormone analogs in a continuous manner may result in an initial activation of pituitary hormone release, but subsequent refractoriness of the pituitary cell and overall decreases in release. In contrast, infusion of exogenous hypothalamic hormones in a pulsatile manner maintains the maximal pituitary sensitivity to its corresponding hypothalamic hormone.

**FIGURE 40.3** Representation of pulsatile hormone release in a neuroendocrine system. A representative hypothalamic-releasing hormone is released in discrete pulses at 1- to 2-h intervals. This causes pulses of the corresponding anterior pituitary hormone to occur shortly thereafter. The release of the pituitary hormone stimulates the target organ to release its hormones.

Along with these ultradian pulses of hypothalamic pulses are the circadian or diurnal rhythms of hormonal release that are characteristic of the neuroendocrine system. These 24-h rhythms of hormone release, which can occur independently of the light/dark cycle (circadian) or are entrained to the light/dark cycle (diurnal), are characteristic of neuroendocrine systems (Gore, 1998). Circadian rhythms are driven by a part of the hypothalamus called the suprachiasmatic nucleus (SCN), and the SCN makes projections within the hypothalamus to regulate neuroendocrine release in a 24-h cycle.

Cycles of hormonal release longer than 24h can be observed for the reproductive axis. This is discussed in more detail later, but in brief, female vertebrates often exhibit reproductive cycles, such as the four-day estrous cycles of rats or the 28-day menstrual cycles of many primates, including humans. Reproductive hormones undergo substantial fluctuations across these cycles. Even longer cycles are observed in the cases of seasonal breeders that may be sexually active during certain periods of the year, and as infrequently as once per year or even less. This seasonality enables the females of the species to coordinate the energetically demanding process of pregnancy, lactation, and rearing of the offspring with the appropriate environmental conditions.

## THE HYPOTHALAMIC-ADENOHYPOPHYSIAL NEUROENDOCRINE SYSTEMS

Five neuroendocrine axes are involved in the control of metabolism, growth, reproduction, lactation, and stress. These systems are summarized in Figure 40.1, and each is discussed in detail next.

### Metabolism: The Brain-Pituitary-Thyroid Axis

#### Overview and Characteristics

The proper regulation of metabolism is critical for the development and survival of the organism. The brain-pituitary-thyroid axis plays a critical role in the control of metabolic activity, stimulating an increase in metabolic processes in target cells. The hypothalamic hormone involved in this function is thyrotropin-releasing hormone (TRH), produced by a group of cells in a specific nucleus in the hypothalamus, the paraventricular nucleus (Fig. 40.4). As is the case for all hypothalamic releasing hormones, TRH neurons have long axons that terminate in the external zone of the median eminence (Fig. 40.2). This region is highly vascularized by the portal capillary system, which transports TRH to the anterior pituitary gland. There, TRH targets receptors on thyrotropes, which are cells that, when stimulated, produce the thyroid-stimulating hormone (TSH; Fig. 40.4). Thyrotropes constitute approximately 10% of the cells in the anterior pituitary gland. TSH is released from the anterior pituitary gland into the general circulation and acts at receptors in the thyroid gland, located in the neck. These cells then produce the thyroid hormones, thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ), the latter being the more potent thyroid hormone, which are also released into the general circulation (Fig. 40.4).

Thyroid hormones act at target organs throughout the body to regulate cellular metabolism.  $T_3$  and  $T_4$  also feed back at the brain and anterior pituitary gland to regulate levels of TRH and TSH, respectively. The thyroid hormone axis is a classical negative feedback loop, as thyroid hormone feedback inhibits the secretion of these hypothalamic and pituitary hormones, thereby maintaining appropriate levels of free thyroid hormone in the bloodstream. Such precise regulation of thyroid hormone levels is critically important because elevated or depressed levels of this hormone can have substantial adverse consequences on the body, particularly during sensitive periods of development.

It is important to note the terminology of *free* versus *bound* hormone. When the thyroid hormones are

**FIGURE 40.4** Left: Schematic representation of the brain–pituitary–thyroid axis showing TRH neurons in the paraventricular nucleus projecting their neuroterminals to the external zone of the median eminence. This projection occurs bilaterally, although only a unilateral projection is shown. TRH travels through the portal vasculature to cause the synthesis and release of TSH from thyrotropes. This molecule acts at the thyroid gland to cause the biosynthesis and release of the thyroid hormones, T<sub>3</sub> and T<sub>4</sub>. These are released into the general circulation to affect metabolism. Negative feedback of T<sub>3</sub> and T<sub>4</sub> at the thyrotropes of the pituitary and at the TRH neurons of the PVN is indicated by the long arrows. Right: the pre-proTRH molecule of two representative species, mouse and human, is shown on top, with shaded bars indicating sites where multiple copies of the TRH tripeptide are cleaved from this precursor. Structural information about the TRH tripeptide sequence, the TSH protein, and T<sub>3</sub> and T<sub>4</sub> are provided. Abbreviations: PVN, paraventricular nucleus; iii, third ventricle; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; T<sub>3</sub>, triiodothyronine; T<sub>4</sub>, thyroxine.

released into the circulation from the thyroid gland, a large portion bind to binding globulins. The free (or not protein-bound) thyroid hormone constitutes only <1% of all thyroid hormone circulating in the bloodstream. It is the free thyroid hormone that is responsible for the negative feedback regulation of TRH neurons and thyrotropes, as well as for actions at target tissues. Bound hormone is not immediately bioavailable but may provide a reservoir for thyroid hormones when they are needed.

### Physiological Functions

**Thyroid Hormone Is Critical for Cellular Metabolism.** The brain–pituitary–thyroid axis is involved in metabolism, protein synthesis, and development of the brain. Thyroid hormone receptors are located throughout the brain, highlighting their importance in central nervous system development and function. They are also found in peripheral and autonomic nervous systems, pituitary gland, bone, muscle, liver, heart, testis, lung, placenta, and other tissues. The major function of the thyroid hormone is the regulation of basal metabolic rate and calorogenic responses. In the target cells, thyroid hormones regulate ATP levels produced by mitochondria and alter protein

synthesis. The maintenance of thyroid hormone levels is extremely important for adult metabolic activity, and thyroid hormone abnormalities in the developing organism can have catastrophic consequences. Thyroid hormone deprivation in the fetus causes permanent nervous system abnormalities and substantial effects on growth and bone development that may be reversed or mitigated only if the thyroid hormone is replaced.

### Pulsatile and Circadian Release of TRH and TSH.

The pituitary hormone TSH, and presumably the hypothalamic hormone TRH (which is much more difficult to measure due to the inaccessibility of the portal capillary system), is released in a pulsatile manner, with pulses occurring at approximately 90- to 180-min intervals in humans (Gore, 1998). Studies on the pulsatile release of TSH in humans demonstrate that its levels also change across the 24-h period, peaking from the evening through 0400h, decreasing through noon, and remaining low until the beginning of the next cycle in the evening. The increase in TSH release during the evening is referred to as the nocturnal TSH surge. This appears to be a true circadian rhythm, and it is driven by the suprachiasmatic nucleus of the hypothalamus (Chapter 41).

### **Structures and Properties of TRH, TSH, Thyroid Hormone, and Their Receptors**

**TRH and the TRH Receptor.** TRH is a tripeptide with the sequence pGlu-His-Pro-NH<sub>2</sub> (Fig. 40.4). This tiny peptide, when bound to its receptor on the pituitary thyrotrope, rapidly and potently stimulates the pulsatile release of TSH. As is true for other neurohormones (Chapter 7), TRH is cleaved and processed from a prohormone in which its sequence is expressed in multiple copies (Yamada *et al.*, 1990; Fig. 40.4). The resulting TRH tripeptide is released from the cell to act on its target, the TRH receptor.

The TRH receptor, localized in the anterior pituitary on thyrotropes, is a G-protein-coupled membrane receptor (Gershengorn, 1993). Binding of TRH to its receptor causes the activation of membrane-bound phospholipase C and the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP<sub>2</sub>) to inositol 1,4,5-trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). This results in calcium mobilization and the phosphorylation or changes in the concentrations of nuclear proteins that interact with the genes involved in the synthesis of TSH and causes an increase in TSH gene transcription.

**TSH and the TSH Receptor.** TSH is an ~30-kDa glycoprotein hormone, comprising an  $\alpha$  and  $\beta$  subunit, that are synthesized from two different genes (Fig. 40.4). The  $\alpha$  subunit of TSH is identical to that of the gonadotropins, LH and FSH (see later). The  $\beta$  subunit confers the unique identity and biological specificity to TSH, LH, and FSH. The common glycoprotein  $\alpha$  subunit is 92 amino acids in humans. The unique TSH  $\beta$  subunit gene encodes a 112 amino acid glycoprotein in humans (Szkudlinski *et al.*, 2000).

The TSH receptor is a seven-transmembrane domain G-protein coupled receptor located predominately in the thyroid gland (Graves and Davies, 2000). Binding of TSH to its receptor activates cAMP generation and stimulates the production and release of the thyroid hormone in the thyroid gland.

**Thyroid Hormones.** The two major thyroid hormones are T<sub>4</sub> and T<sub>3</sub>, of which T<sub>3</sub> has greater biological activity (Fig. 40.4). Thyroid hormones contain two phenolic rings, which make these molecules lipophilic, facilitating their transport through the lipophilic membranes of target cells. Some plasma membrane transport molecules assist with this process because the thyroid hormones possess a polar alanine side-chain that appears to impede the process of passive diffusion. Within the cell, thyroid hormones interact with the thyroid hormone receptor. The thyroid hormones contain three (T<sub>3</sub>) or four (T<sub>4</sub>) iodide molecules. T<sub>3</sub> binds to the thyroid hormone receptors in target

tissues and also mediates negative feedback effects on TRH cells in the hypothalamus and pituitary. Although T<sub>4</sub> is released from the thyroid gland in greater quantities than T<sub>3</sub>, most T<sub>4</sub> is converted to T<sub>3</sub>, as catalyzed by two enzymes, type I and type II deiodinases. Type I deiodinase is found mostly in peripheral tissues and the pituitary gland, and type II deiodinase is found in the brain, pituitary gland, and brown fat. Because an important component in the synthesis of thyroid hormones is iodine, an iodine-deficient diet results in the impairment of thyroid hormone metabolism, leading to developmental abnormalities.

With respect to the negative feedback regulation by thyroid hormone (Fig. 40.4), thyroid hormone receptors have been localized within TRH neurons in the paraventricular nucleus (Segerson *et al.*, 1987). Thus, these actions can be mediated directly on TRH neurons in the brain. In addition, the expression of the thyroid hormone receptor is abundant in the anterior pituitary gland, particularly thyrotrope cells, indicating direct feedback action of the thyroid hormone on this organ as well.

Along with its regulation by TSH, the thyroid gland also receives direct neuronal inputs from the autonomic nervous system. Fibers from the sympathetic and parasympathetic nervous systems penetrate the thyroid gland and terminate around arterioles, capillaries, and, less frequently, venules and near follicular cells, providing additional mechanisms for regulation of thyroid hormone output.

**The Thyroid Hormone Receptor Family.** The thyroid hormone receptor is a member of the nuclear hormone superfamily. These are nuclear transcription factors that bind to a regulatory element on the DNA to activate or inhibit gene transcription. Several thyroid hormone receptor isoforms have been identified. These are termed thyroid hormone receptors (TR)  $\alpha$  and  $\beta$ , which are derived from different genes and can be alternatively spliced. Thus, each TR subtype has a splice variant, termed  $\alpha 1$ ,  $\alpha 2$ ,  $\beta 1$ , and  $\beta 2$ .  $\alpha 1$  and  $\beta 2$  are most abundant in the hypothalamus and are found in more than 80% of TRH neurons in the PVN (Lechan *et al.*, 1994). As is the case for most nuclear hormone receptors, binding of the thyroid hormone to its receptor causes the heterodimerization of the receptors with another member of the nuclear receptor superfamily, RXR, and facilitates the binding of the dimerized receptor-ligand complex to the promoter of the target gene, thereby modulating gene transcription.

### **Neuroanatomy of the TRH System**

TRH neurons are concentrated in the paraventricular nucleus (PVN) of the hypothalamus (Fig. 40.4). This

hypothalamic nucleus is localized at the dorsal region of the third ventricle and can be divided into a magnocellular division (large neurons) and a parvocellular division (small- to medium-sized neurons). TRH neurons exist exclusively in the parvocellular region of the PVN and are concentrated particularly along the medial and periventricular parts of the parvocellular PVN. Other non-TRH neurons also are localized in this region, including corticotropin-releasing hormone, neurotensin, galanin, enkephalin, and vasoactive intestinal peptide. It has been reported that there are also nonneuroendocrine TRH cells localized outside the PVN that do not project to the median eminence. Because these play nonneuroendocrine roles in nervous system function they are beyond the scope of discussion of this chapter.

### *Disruptions in the Thyrotropic Axis*

Thyroid hormone excess or insufficiency can have profound effects on the central nervous system, particularly during development. Thus, a normal or euthyroid tone is necessary for the health and survival of the organism. Excessive thyroid hormone, or hyperthyroidism, can result in symptoms such as tremor, nervousness, tremulousness, insomnia and sleep disorders, and impairments in memory and concentration. More profound effects include neuropsychiatric syndromes, seizure, chorea, and even coma. Deficiencies of the thyroid hormone, called hypothyroidism, can cause problems such as sleep apnea, hypothermia, hypoventilation, neuropsychiatric syndromes, peripheral neuropathy, cerebellar ataxia, and coma. During chronic thyroid hormone deficiency, fluids can accumulate and result in puffiness of the hands, feet, face, and tongue and cause speech impairment. This is called myxedema. Hypothyroidism generally is treated by thyroid hormone replacement.

When an organism is exposed to insufficient thyroid hormone during fetal or early neonatal development, it can develop cretinism, characterized by severe deficits in mental, neurological, and physical development. Most of these deficiencies can be mitigated or even reversed by newborn infant screening and thyroid hormone replacement.

## **Growth: The Somatotropic Axis**

### *Overview and Characteristics*

Somatic growth is an obvious characteristic of the development of vertebrate organisms. The somatotropic axis has three levels: the primary hypothalamic hormones, of which there are two, growth hormone-releasing hormone (GHRH) and a growth hormone-

inhibiting hormone, called somatostatin; the secondary pituitary hormone, called growth hormone (GH) or somatotropin; and the tertiary target organ, in this case the liver, which produces insulin-like growth factor I (IGF-I) in response to the GH stimulus. A special characteristic of the somatotropic axis is that its pituitary hormone, GH, as well as its tertiary hormone, IGF-I, can exert growth-promoting effects alone or in combination. In fact, GH and IGF-I act synergistically with each other to affect somatic growth. However, both of these hormones play important roles, as mutations resulting in the absence of either GH or IGF-I result in dwarfism.

Unlike most other neuroendocrine systems, the somatotropic axis has two known hypothalamic hormones that play important but opposing roles (Fig. 40.5). One hormone, growth hormone-releasing hormone (GHRH), is stimulatory to the release of the pituitary GH. The other hypothalamic hormone, somatostatin, inhibits GH release. These hormones are both released into the portal capillary vasculature to affect the synthesis and release of GH, from specialized cells in the anterior pituitary gland called somatotropes, constituting approximately 30% of pituitary cells. The GH binds to its receptors in the liver to stimulate the release of the tertiary hormone, IGF-I. Both GH and IGF-I have somatotropic actions on target organs and tissues undergoing growth, regeneration, or metabolic homeostasis, such as bone and muscle.

Growth hormone and IGF-I both appear to be involved in the feedback regulation of the somatotropic axis (Fig. 40.5). In the case of GHRH, GH acts as a classical negative feedback molecule, down-regulating the synthesis and secretion of GHRH. By contrast, GH *stimulates* gene expression of the inhibitory hypothalamic hormone somatostatin. In the absence of GH, somatostatin mRNA levels are down-regulated. IGF-I also acts as a feedback regulator of the somatotropic axis, negatively regulating GHRH levels and stimulating somatostatin gene expression. As shown in Figure 40.5, this is a highly complicated and tightly regulated feedback loop.

### *Physiological Functions*

***The Somatotropic Axis Controls Somatic Growth and Development.*** GH plays its major role in neonatal and postnatal growth and is particularly important in the pubertal growth spurt. Its anabolic activities are critical for metabolic homeostasis. The growth hormone stimulates protein synthesis, increases lipolysis, influences carbohydrate metabolism, enhances glucose uptake and utilization, and has lipolytic effects. At the systems level, it stimulates the growth of organs, such as the heart and kidney, and plays a role in hormone

**FIGURE 40.5** Left: Schematic representation of the somatotrophic axis showing GHRH neurons in the arcuate nucleus and somatostatin neurons in the periventricular region of the anterior hypothalamus. Both sets of neurons project their neuroterminals to the external zone of the median eminence. This occurs bilaterally for both hypothalamic hormones, although only a unilateral projection is shown. GHRH and somatostatin travel through the portal vasculature to stimulate or inhibit, respectively, the synthesis and release of GH from somatotropes. This molecule acts at the liver to cause the biosynthesis and release of IGF-I. Both GH and IGF-I are released into the general circulation to affect somatic growth, and they both feed back in a negative manner at the somatotropes of the pituitary and the GHRH neurons of the arcuate nucleus. IGF-I and growth hormone also feed back to stimulate somatostatin, which in turn negatively regulates the somatotrophic axis. Right: The amino acid sequences for GHRH and somatostatin are shown, and structural information about GH and IGF-I is provided. Abbreviations: AH, anterior hypothalamus; ARC, arcuate nucleus; GH, growth hormone; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor I; iii, third ventricle.

production, skeletal growth and maturation, and immune function. Many of its effects are sexually dimorphic, as are the distribution of its receptors and other proteins involved in this axis.

**Pulsatile and Diurnal Release of GHRH and Somatostatin.** Both GHRH and somatostatin are released from hypothalamic nerve terminals into the portal circulation in a pulsatile manner, similar to other neurohormones. It might be predicted that these neurohormones might be released out of phase, but in fact, their release often is coordinated. Pulses of GHRH appear to drive pulses of growth hormone, which occur at intervals of about 1–3 h.

The growth hormone is released in a diurnal pattern. The 24-h cycle of GH release is strongly associated with sleep, with highest levels occurring shortly after the onset of slow-wave sleep, and most GH secretion occurring at night in humans. Thus, this is not a true circadian rhythm but rather a diurnal pattern of release (Gore, 1998).

### **Structures and Properties of GHRH, Somatostatin, Growth Hormone, IGF-I, and Their Receptors**

**Growth Hormone-Releasing Hormone and Somatostatin.** GHRH is derived from a 108 amino acid precursor protein, called preproGHRH. Following a multistep processing procedure involving cleavage by endopeptidases, mature GHRH molecules are produced (Fig. 40.5). In some species, there are two GHRHs with similar biological activity; other species have a single GHRH peptide. In humans, the active GHRH is 44 amino acids (Clynen *et al.*, 2004).

GHRH binds to its receptor on somatotropes in the anterior pituitary gland to affect the release of growth hormone. The GHRH receptor is a member of the G-protein-coupled receptor family (Mayo *et al.*, 1995). Binding of GHRH to its receptor triggers the G protein, in this case  $G_s$ , to trigger a cascade of intracellular events involving cyclic AMP (cAMP) as the second messenger. This causes calcium mobilization, the phosphorylation of proteins that are involved in the synthesis of growth hormone, and the release of growth hormone from secretory granules. The

synthesis of the growth hormone that is triggered by GHRH probably involves the cAMP-induced phosphorylation of the cAMP response element-binding protein (CREB), which binds to an enhancer element in the promoter of the somatotropin gene to stimulate its transcription.

The somatostatin gene contains two exons that are transcribed into a 0.85-kb mRNA. This mRNA is translated into a 116 amino acid precursor protein, preprosomatostatin. This precursor is cleaved by endopeptidases and is a tissue-specific process. In the hypothalamus, somatostatin is cleaved into two biologically active forms, somatostatin-14 and somatostatin-28, the latter having an N-terminal extension of the somatostatin-14 molecule (Fig. 40.5).

The binding of somatostatin to its receptor causes a cascade of events involved in the inhibition of growth hormone release. To date, there are five known somatostatin receptors (SS-Rs), with different properties and affinities. All these receptors involve an inhibitory G protein ( $G_i$ ), which reduces cAMP and causes cell hyperpolarization and a diminution of  $Ca^{2+}$  influx into cells.

**Growth Hormone.** Growth hormone, or somatotropin, is a 191 amino acid protein that contains two disulfide bonds that give it a three-dimensional conformation that is necessary for its biological activity. Release of the growth hormone is triggered by GHRH and is inhibited by somatostatin. The growth hormone plays a negative feedback role in the somatotrophic axis, feeding back at the level of the GHRH neuron in the hypothalamus to inhibit GHRH mRNA levels and synthesis and stimulating somatostatin gene expression and release. Not only does the regulation of growth hormone involve the balance between GHRH and somatostatin, but it also involves other neurotransmitters and neuroactive substances, such as dopamine, vasoactive intestinal peptide, pituitary adenylate cyclase-activating peptide, TRH, galanin, neuropeptide Y, motilin, and interleukins. In addition, other hormones, such as the thyroid hormone, glucocorticoids, sex steroid hormones, and metabolic fuels, can influence the release of growth hormone, highlighting the interwoven nature of the different neuroendocrine systems.

The growth hormone is released into the general circulation, where approximately 50% of this molecule is transported in association with a growth hormone-binding protein that is the same as the extracellular domain of the growth hormone receptor. This molecule and the growth hormone receptor (GH-R) are alternative splice products of the same precursor RNA

into two distinct mRNAs: one for the growth hormone-binding protein and one for the GH-R.

The GH-R is a member of the cytokine receptor family (Behncken and Waters, 1999). Binding of growth hormone to its plasma membrane receptor causes receptor dimerization and triggers a cascade of protein phosphorylations mediated by the JAK-STAT system, the activation of nuclear transcription factors, and the stimulation of somatotropin-regulated genes.

**IGF-I.** A major target for the growth hormone is the IGF-I system. IGF-I is a growth factor that exerts effects on neurite outgrowth and nervous system development. In addition, it is an important mediator of the somatotrophic axis and, in fact, was originally referred to as somatomedin. Both GH and IGF-I individually have similar effects on somatic growth and development; however, the two hormones act much more efficiently in combination. In addition, it appears that the growth-promoting effects of IGF-I are particularly important in the central nervous system. This is consistent with the observation that along with its production by the liver, IGF-I is also produced in the brain, and it is probably this central IGF-I that is responsible for many of its neurotrophic effects.

Like the growth hormone, IGF-I plays a feedback role in the inhibition of GHRH biosynthesis (Fig. 40.5). This may involve central and not peripheral IGF-I, as most animal studies have demonstrated that only centrally but not peripherally administered IGF-I has this effect. At the level of the pituitary, IGF-I appears to be the major regulator of negative feedback of growth hormone synthesis and release. Somatotropes contain IGF-I receptors, and IGF-I inhibits growth hormone gene expression and release under basal and GHRH-stimulated conditions. IGF-I can also act as a negative feedback regulator of GHRH neurons, as it can cross the blood-brain barrier to a limited extent. Moreover, IGF-I is synthesized in the central nervous system, including the hypothalamus, and therefore local IGF-I can exert an influence on GHRH neurons. It also has been shown that IGF-I can stimulate somatostatin release, albeit at higher doses than those necessary to inhibit GHRH release, suggesting that IGF-I may be more involved in the suppression of GHRH than the enhancement of somatostatin levels.

The IGF-I gene has been cloned in a number of species and encodes a precursor molecule of 105 amino acids that is cleaved into the mature IGF-I of 70 amino acids. IGF-I in the circulation binds to several binding proteins, the major one being IGF-I binding protein 3 (IGFBP-3). Free IGF-I is more biologically active than bound IGF-I, and therefore IGFBP-3 levels are an

important regulator of the actions of IGF-I. At its target tissues, IGF-I binds to its receptor, a member of the receptor tyrosine kinase family, which utilizes the MAP kinase system as its second messenger system.

### *Neuroanatomy of GHRH/Somatostatin Systems*

Most GHRH-containing neurons are located in the basomedial hypothalamus in the arcuate nucleus, lateral to the floor of the third ventricle (Fig. 40.5). These neurons project axons to the external zone of the median eminence, from which GHRH is released into the portal capillary system (Fig. 40.2). GHRH neurons can also send axons to other hypothalamic regions, and this may be involved in the regulation of feeding behavior by GHRH. GHRH neurons receive inputs from other neuronal systems in the central nervous system, including  $\alpha$ -adrenergic, dopaminergic, serotonergic, and enkephalinergic neurons.

Somatostatin cell bodies have a very different localization from the GHRH system. Unlike GHRH neurons, whose perikarya are concentrated in a discrete nucleus, somatostatin somata are more dispersed throughout the central nervous system. Perikarya of the somatostatin neurons involved in the regulation of growth hormone release are found primarily in the periventricular region of the anterior hypothalamus (Fig. 40.5). As is the case for other hypothalamic hormones, their axon terminals project to the external zone of the median eminence. Somatostatin neurons also make projections to GHRH neurons, and it is believed that this is one mechanism for the inhibition of GHRH neurons by somatostatin cells.

Inputs from metabolically active substances affect the somatostatin system. Amino acids are thought to stimulate, and fatty acids and glucose to inhibit, somatostatin secretion. There are also a number of neurotransmitters involved in the regulation of somatostatin levels. Catecholamines such as dopamine and norepinephrine are implicated in this process, as are acetylcholine and GABA. Neuropeptides, including substance P, neurotensin, and bombesin, can alter somatostatin levels, and factors involved in gluoregulation, such as glucose and gluoregulatory enzymes and hormones, modify activity of the somatostatin system.

### *Disruptions of the Somatotrophic Axis*

Somatic growth and development are affected by disruptions of the somatotrophic axis, and the consequences are dependent on when during development the system is affected. In early development, growth hormone deficiency can result in an extremely short stature, with adults sometimes reaching a maximal

height of less than 1 m. Growth hormone deficiency is generally treated with growth hormone replacement using recombinant growth hormone. In some cases, GHRH, rather than growth hormone, is replaced in a pulsatile manner. Dwarfism is sometimes caused by mutations in the IGF-I system, or in the GH receptor. Laron dwarfism, characterized by mutations in the GH receptor gene, results in very low IGF-I levels, but GH levels are high, probably due to reduced negative feedback from the low IGF-I concentrations.

If GH is oversecreted or dysregulated during development, the consequence can be gigantism, resulting in an extremely large stature. When abnormal GH stimulation occurs after adulthood, this results in acromegaly. In adulthood, only certain tissues remain responsive to growth hormone stimulation, including the jaws, nose, orbital ridges, fingers, elbows, and knees, and these tissues are stimulated to grow while other tissues are not, causing deformations in proportions and appearance.

## **Stress: The Brain–Pituitary–Adrenal Axis**

### *Overview and Characteristics*

In order to survive, an animal must be able to adapt to stress, which can be manifested in a variety of forms. These stressors can include the acute stress of escaping predation or the chronic stress of a disease, the social situation, or social status. Thus, a stress is an internal or external cue that disrupts the homeostatic status of the animal.

The neuroendocrine system involved in mediating the stress response is the brain–pituitary–adrenal axis. The hypothalamic releasing hormone controlling this axis is corticotropin-releasing hormone (CRH), produced in highest levels in the medial parvocellular part of the paraventricular nucleus (mpPVN; Fig. 40.6). CRH somata send neural projections to the external layer of the median eminence (Fig. 40.2), typical of all hypothalamic neuroendocrine cells. From here, CRH is released from the external zone of the median eminence and targets the corticotropes of the anterior pituitary gland. Additionally, arginine vasopressin (AVP), another hypothalamic hormone produced in the magnocellular elements of the PVN, acts at pituitary corticotropes to exert synergistic effects. The corticotropes have receptors for and respond to both CRH and AVP with the synthesis and release of adrenocorticotrophic hormone (ACTH). ACTH is released from the pituitary gland into the general circulation, where it acts at receptors on the adrenal cortex to stimulate the production and release of glucocorticoids. The

these glucocorticoids serve similar functions and both hormones target glucocorticoid receptors in their respective species.

### **Structures and Properties of CRH, ACTH, Glucocorticoids, and Their Receptors**

**CRH.** Corticotropin-releasing hormone is a 41 amino acid peptide expressed in the parvocellular region of the PVN in the hypothalamus (Fig. 40.6). It is also found in other CNS regions and outside of the brain in adrenal gland, placenta, ovary, immune tissues, and at inflammatory sites. The CRH receptor is linked to the activation of adenylate cyclase. The CRH receptor is also found in the central nervous system, with highest concentrations in the olfactory bulb, cerebellum, cerebral cortex, and striatum and lower concentrations in the spinal cord, hypothalamus, medulla, midbrain, thalamus, pons, and hippocampus (DeSouza, 1987).

**ACTH.** ACTH derives from the cleavage of a precursor protein, proopiomelanocortin (POMC), in the corticotropes (Fig. 40.6). POMC is cleaved to a number of smaller peptides, including  $\beta$ -endorphin,  $\beta$ -lipotropin (LPH),  $\gamma$ -LPH,  $\alpha$ -melanocyte-stimulating hormone (MSH),  $\beta$ -MSH, and  $\gamma$ -MSH. ACTH is the primary effector of the stress axis, and its release into the general circulation from the pituitary corticotrope has effects on the target organ, the adrenal cortex, to affect the production of glucocorticoids.

The ACTH receptor is a member of the melanocortin family of receptors (Naville *et al.*, 1999). It is a seven-transmembrane domain G-protein-coupled receptor expressed primarily in adrenal cortex. The binding of ACTH to its receptor activates adenylate cyclase and cAMP production.

**Glucocorticoids.** Glucocorticoids are members of the steroid hormone family. As is the case for sex steroid hormones (discussed later), they derive from a cholesterol precursor. Following a series of enzymatic reactions, the major corticosteroids, such as cortisol (in humans; Fig. 40.6) or corticosterone (in rats), are synthesized.

The glucocorticoid receptor (GR) is widely distributed in the central nervous system, including the hypothalamus and, more specifically, the CRH cells of the PVN. Thus, glucocorticoid negative feedback can occur directly on the hypothalamic cells driving the stress axis. GRs are also abundant in the hippocampus, in pyramidal cells, and in dentate granule cells. The hippocampus appears to play a role in mediating the stress response, and there are multiple redundant pathways between the hippocampus and the PVN.

GRs are found in many other brain regions such as the olfactory cortex, cerebral cortex, amygdala, septum, thalamus, midbrain raphe nuclei, cerebellum, and brain stem (Morimoto *et al.*, 1996). The widespread distribution of this receptor suggests important and diverse effects of glucocorticoids in the central nervous system.

Glucocorticoids can also bind to the mineralocorticoid receptor (MR), the primary ligand of which is aldosterone. Moreover, the brain MR has a higher (~10-fold higher) affinity for glucocorticoids than the GR. Both of these receptors are members of the steroid hormone superfamily. They are thought to reside in the cytoplasm of target cells in the unliganded state. When bound to their ligands, GRs or MRs translocate into the nucleus, where they bind to specific sites on the promoter of the responsive gene. Thus, GR and MR are transcription factors. Their efficacy in stimulating or inhibiting gene transcription is modulated by their binding to other molecules, such as heat shock proteins, which can alter the translocation of the receptor-ligand complex to the nucleus, or transcriptional coactivators, which modulate the complexes associated with the gene (Chapters 3 and 4).

Chronic exposure to glucocorticoids can cause damage to the brain, which is particularly apparent in the hippocampus, a brain region abundant in GRs. It has been observed that chronic corticosteroids changes the morphology of CA3 dendritic fields and may lead to neurodegeneration and eventually cell death. Nevertheless, whereas chronic high levels of glucocorticoids may be toxic, a lack of glucocorticoids can also be detrimental. In the dentate gyrus, maintenance of the dentate granule cell number appears to require glucocorticoids, and adrenalectomy results in the loss of granule cells. Moreover, neurogenesis in the adult dentate gyrus also appears to be glucocorticoid dependent. There are functional correlates to the effects of glucocorticoids on the hippocampus, with these hormones playing roles in learning and memory. Acute stress can interfere with the ability of an organism to learn, and chronic stress is correlated with deficits in spatial learning.

### **Neuroanatomy of the CRH System**

CRH neuronal perikarya are localized primarily in the medial parvocellular part of the paraventricular nucleus (mpPVN; Fig. 40.6) and project neuroterminals to the external zone of the median eminence (Fig. 40.2). The PVN is an important integrative region of the hypothalamus, as it summates inputs from other regions throughout the brain including the brain stem, the midbrain/pons groups, the limbic system, the circumventricular organs, and other hypothalamic nuclei.

Inputs from the brain stem are catecholaminergic pathways involved in the transmission of visceral information. The catecholamine system plays an important role as a stress mediator, possibly as an autonomic nervous system neurotransmitter. Noradrenergic projections to the PVN arise from the nucleus of the solitary tract (A2 cell group), the A1 cell group of the ventrolateral medulla, and the locus coeruleus. Inputs from the midbrain may involve the midbrain raphe cell groups, which are serotonergic in nature. The midbrain periaqueductal gray and pontine central gray regions relay sensory information to the PVN, as do caudal thalamus and cholinergic brain stem regions (laterodorsal tegmental nucleus and the pedunculopontine nucleus). These inputs appear to play a role in relaying somatic and special sensory information. Inputs to the PVN from the limbic system arise from the prefrontal cortex, septum, amygdala, and hippocampus, and a notable projection to the PVN is from the bed nucleus of the stria terminalis to the PVN. These inputs relay information on cognition and emotion. The circumventricular organs (subfornical organ, OVLT) convey information to the PVN from blood-borne chemosensory signals. The major neurotransmitters involved in this function are GABA and angiotensin II. Finally, the hypothalamus itself signals to the PVN, and these connections may provide signals about the motivational state of the animal or relay other stress-specific signals. However, the functions of these interhypothalamic projections are not well understood.

### *Disruptions in the Stress Axis*

The negative feedback loop of CRH–ACTH–glucocorticoids is kept in a delicate balance. In response to stress, there is a large increase in the activity of the stress axis, but the system is downregulated rapidly by negative feedback from the glucocorticoids to the brain and pituitary gland, causing it to return the output of the stress axis to basal low levels.

Overactivity of the stress axis can increase susceptibility to infection and tumors and reduce inflammatory and autoimmune disease (O'Connor *et al.*, 2000). For example, Cushing's disease is characterized by hypercortisolemia and abnormal secretion and/or bioactivity of ACTH. The high levels of cortisol suppress CRH release and cause alterations in immune function. People with Cushing's disease have an increase in appetite and can experience changes in fat distribution. However, the brain–pituitary–adrenal axis can adapt to overactivity, and thus the immune system suppression that occurs in Cushing's disease is milder than that which would be predicted by the high levels of circulating cortisol. Elevations in activity of the

stress axis can also impair memory, probably through actions of glucocorticoids on the hippocampus.

Underactivity of the stress axis can cause the opposite effects of hyperactivity, namely resistance to infection and tumors but increased susceptibility to inflammatory and autoimmune disease. In the case of adrenocortical insufficiency, there is generally a failure of the adrenal cortex to respond to ACTH. Addison's disease is characterized by an insufficient release of glucocorticoid secretion, and its symptoms include muscle weakness and fatigue, psychological symptoms, gastrointestinal symptoms, and changes in skin pigmentation. Fortunately, glucocorticoid and mineralocorticoid replacement can help mitigate these symptoms.

## **Reproduction: The Brain–Pituitary–Gonadal Axis**

### *Overview and Characteristics*

Reproduction is critical to the survival of the species. In vertebrate organisms, the reproductive axis comprises (1) the gonadotropin-releasing hormone (GnRH) neurons, also called luteinizing hormone-releasing hormone (LHRH) neurons, of the hypothalamus and preoptic area; (2) the gonadotropes of the anterior pituitary gland; and (3) the gonads (ovary in females and testis in males) (Fig. 40.7). GnRH neurons of the hypothalamus and preoptic area project their neuroterminals to the median eminence, where the GnRH peptide is released in a pulsatile manner (Gore, 2002). GnRH acts at the gonadotropes of the anterior pituitary to cause the production of two hormones collectively called the gonadotropins: luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Fig. 40.7). These hormones in turn are released in a pulsatile manner into the general circulation and bind to receptors on specialized cells in the ovaries or testes to stimulate steroidogenesis, spermatogenesis in males, and oogenesis in females. The gonads of both sexes respond to this activation by synthesizing and secreting the sex steroid hormones, estrogens, progestins, and androgens. Although the dominant steroid hormones produced by the ovaries are estrogens and progestins, ovaries also produce appreciable amounts of androgens. The testes produce androgens at higher levels than females, but they also secrete estrogens and progestins. Thus, there is no such thing as a "male" or "female" sex steroid hormone. Rather, what differs between the sexes are the concentrations of these hormones.

The sex steroid hormones, once released into the circulatory system, act at receptors that are located throughout the body to exert their classical effects on

**FIGURE 40.7** Left: Schematic representation of the brain-pituitary-gonadal axis showing GnRH neurons in the preoptic area/anterior hypothalamus projecting their neuroterminals to the external zone of the median eminence. This occurs bilaterally, although only a unilateral projection is shown. GnRH travels through the portal vasculature to cause the synthesis and release of the gonadotropins, LH and FSH, from gonadotropes. These molecules act at the gonads (ovary and testis) to cause the biosynthesis and release of sex steroid hormones. These are released into general circulation to affect secondary sex characteristics and act at other somatic tissues. Sex steroid hormones feed back negatively at the brain and pituitary to regulate biosynthesis of GnRH and the gonadotropins in males and females. In addition, prior to ovulation, these steroids exert positive feedback in females. Right: The decapeptide structure of GnRH, general structural features of the gonadotropins, and the structures of progesterone, 17 $\beta$ -estradiol, and testosterone are shown. Abbreviations: AH, anterior hypothalamus; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; iii, third ventricle.

secondary sex characteristic development and on adult reproductive function. In addition, sex steroid hormones act on receptors in the brain, including the hypothalamus, to exert diverse effects on the CNS. One of the major effects of sex steroid hormones is as a feedback modulator of the hypothalamic GnRH neurons. However, along with the traditional negative feedback exerted in neuroendocrine systems, in females, ovulation is controlled by *positive* feedback from sex steroid hormones. This concept of negative/positive feedback regulation is discussed later, and is unique to the reproductive neuroendocrine system of females.

### Physiological Functions

**Activity of the Reproductive Axis Varies during the Life Cycle.** Not surprisingly, functions of the reproductive axis change during the life cycle of the organism, as reproductive function varies with developmental stage (Plant, 1988). During the late embryonic/early postnatal period, as the GnRH system finishes its neuroanatomical development, there is increased activity of the brain-pituitary-testicular axis in males and, to a lesser extent, the brain-pituitary-

ovarian axis in females. Shortly after birth, the reproductive system becomes quiescent, possibly due to the development of inhibitory inputs to GnRH neurons or the lack of stimulatory inputs to this system. This quiescent period, sometimes called the "prepubertal hiatus," is characterized by low GnRH, gonadotropin, and steroid hormone release.

At the onset of puberty, the GnRH system becomes activated, probably due to the removal of inhibitory afferents to GnRH neurons, dominated by GABAergic neurons, and the ability of stimulatory afferents to GnRH neurons to exert a stimulatory tone on GnRH regulation. To date, numerous substances have been implicated in the activation of GnRH neurons at the onset of puberty, including glutamate (through the NMDA receptor), kisspeptin, norepinephrine, neuropeptide Y, and growth factors such as transforming growth factor- $\alpha$  and IGF-I. Once mature reproductive function has been attained (ovulation in females, viable sperm in ejaculates of males), the pulsatile release of GnRH and its regulation of the reproductive axis continues for much of the life cycle. In many species, females exhibit reproductive cycles (estrous cycles, menstrual cycles) of varying lengths, such as the four-

day estrous cycles of small rodents and the 28-day menstrual cycles of humans and many nonhuman primates.

In human females but not most other species, menopause, the cessation of menstrual cycles and lack of ovulation, signals the end of the reproductive life cycle. The most obvious characteristic of menopause is a loss of ovarian follicles, called follicular atresia. Although many other mammals undergo reproductive senescence, characterized by a lack of spontaneous reproductive cycles, this is not always due to follicular atresia. Instead, in these species, such as rodents, reproductive senescence is probably due to the loss of drive from hypothalamic GnRH neurons and/or changes in pituitary gonadotropin responses to GnRH rather than overt ovarian changes. In humans, it is quite possible that there are also hypothalamic and pituitary changes that may play a role in the menopausal process that are only just beginning to be understood.

***Pulsatile, Diurnal, and Seasonal Release of GnRH and LH/FSH.*** GnRH is released in a pulsatile manner from neuroterminals in the external zone of the median eminence (Fig. 40.2). Virtually every pulse of GnRH causes a pulse of LH (e.g., Fig. 40.3) and, to a slightly lesser extent, FSH, although some "silent" pulses of GnRH (that occur in the absence of the corresponding release of the gonadotropins) can be observed. Although the pulsatile release of LH appears to be driven entirely by pulses of GnRH, as is evidenced by the concordance of these pulses, the regulation of pulsatile FSH also involves the gonadal peptide inhibin. Inhibin is a glycoprotein produced in the gonad that selectively acts at the pituitary gland to suppress FSH release.

The mechanisms by which GnRH pulses are generated are not entirely understood, as these neurons are widely dispersed through the hypothalamus and preoptic area; although contacts between GnRH somata have been observed, these are not abundant. Recent evidence suggests that GnRH dendrites may make anatomical contacts. It is also possible that GnRH neurons coordinate their pulses via some signals at the level of the median eminence where the GnRH neuroterminals converge. Finally, other afferent systems contacting and regulating GnRH neurons may release their neurotransmitters in a pulsatile manner, and this may be a way of coordinating the widely scattered GnRH perikarya to release pulses of GnRH in a coordinated manner.

A pulsatile manner of GnRH release is necessary for the maintenance of pituitary gonadotropin function. When GnRH is infused continuously, the GnRH recep-

tor in the pituitary is downregulated and gonadotropin secretion is inhibited. If exogenous GnRH is infused in a pulsatile manner, the GnRH receptor is upregulated on the gonadotropes. The pulsatile release of GnRH is more or less constant in males, with pulses occurring approximately every 1–2h. However, in females, the nature of GnRH pulses varies across the reproductive cycle. In primates that have a 28-day menstrual cycle, LH pulses (measured as proxy for GnRH pulses) occur approximately once per hour during the early follicular phase, but slow to a frequency of once every 90min later in the follicular phase as estrogen negative feedback increases. Just prior to ovulation, a large increase in GnRH release can be measured, although it is still controversial whether discrete pulses continue to be superimposed on this "GnRH surge." Nevertheless, it is likely that there is a change in the mode of GnRH release during the preovulatory period.

The pulsatile release pattern of GnRH, LH, and FSH is superimposed upon a diurnal pattern of the release of these hormones (Gore, 1998). Thus, the timing of the preovulatory LH surge in rodents is coordinated with the 24-h light/dark cycle (i.e., it is a diurnal but not a circadian rhythm). Although in women these diurnal rhythms are not as obvious as those in rats, it appears that the release of gonadotropins has a weak diurnal rhythm in humans. Men have also been reported to have nocturnal increases in reproductive hormone release. Interestingly, the diurnal rhythm of reproductive hormone release is regulated developmentally. Prior to the onset of puberty, there is little day/night difference in GnRH, LH, or FSH release. At the onset of puberty, a diurnal rhythm develops, characterized by nocturnal increases in the release of these hormones. This nocturnal increase is most pronounced late in puberty, and once adult reproductive function is attained, the rhythm diminishes. The mechanism for, and the function of, the pubertal diurnal rhythm of GnRH and gonadotropins currently is not understood but is one of the most robust diurnal rhythms observed in all the neuroendocrine systems.

The reproductive axis can exhibit rhythms even longer than those entrained to the 24-h clock. Many species are seasonal breeders, in which reproductive processes are coordinated to a time of the year when the likelihood of the survival of the offspring is highest. Seasonal breeding animals such as sheep have an almost completely inactive reproductive axis during the nonbreeding season, with very low GnRH release, low basal and GnRH-stimulated gonadotropin release, and a lack of ovulation. In many of these species, day length is what drives the seasonal breeding cycles, although this varies among the species. For hamsters,

short nights stimulate the reproductive system, whereas short nights inhibit the reproductive axes of sheep.

### **Structures and Properties of GnRH, Gonadotropins, Sex Steroid Hormones, and Their Receptors**

**GnRH.** GnRH is a 10 amino acid peptide that is synthesized from a 92 amino acid precursor molecule (Fig. 40.7). During cleavage of the prohormone, GnRH is produced together with a 56 amino acid peptide referred to as GnRH-associated peptide (GAP). Both GnRH and GAP are released from neuroterminals of these cells into the portal vasculature; however, whereas GnRH is a strong stimulator of LH and FSH release from pituitary gonadotropes, GAP has only a weak ability in this regard. GAP also is able to inhibit prolactin secretion; nevertheless, a specific physiological role for GAP is still unknown.

The GnRH peptide is evolutionarily conserved. All mammals studied to date, with the exception of the guinea pig, have an identical GnRH decapeptide in the hypothalamus-preoptic area. Nonmammalian vertebrates have decapeptides similar to the mammalian GnRH molecule, and the conservation is maintained all the way across the evolutionary spectrum to the jawless fish, which have a GnRH molecule that is 60 to 70% structurally homologous with the mammalian GnRH decapeptide (Morgan and Millar, 2004).

Unlike other neuroendocrine cells, GnRH neurons of most vertebrates have an unusual embryonic origin, deriving from cells that are first detected in the olfactory placode (Wray, 2002). During embryonic development, GnRH neurons migrate into the brain, reaching their final destinations in the preoptic area and hypothalamic regions during mid- to late embryogenesis. Also, unlike most other neuroendocrine peptide systems, GnRH neurons are relatively scattered through these regions and are not tightly concentrated in a single discrete nucleus.

GnRH binds to its receptor in pituitary gonadotropes to activate the synthesis and release of the gonadotropins. The GnRH receptor is a member of the G-protein coupled receptor family, containing seven transmembrane domains. The G protein involved in this function is probably  $G_q$  and/or  $G_{11}$ . The binding of GnRH to its receptor appears to activate several second messenger systems, including the protein kinase A and protein kinase C pathways, as well as the phospholipase C pathway (Sealfon *et al.*, 1997).

**Gonadotropins.** The gonadotropins, LH and FSH, originally were named after their functions in the female ovary, namely their ability to cause luteinization of the follicle (hence LH) and to promote follicular

development (hence FSH). However, these same gonadotropins are synthesized and released from the anterior pituitary gland of males and play a critical role in the regulation of testicular function. Thus, in the testis, LH is primarily responsible for steroidogenesis, and FSH for spermatogenesis.

LH and FSH are glycoprotein hormones (Fig. 40.7) and are in the same family as TSH. These three molecules have a common  $\alpha$ -subunit, but vary in the  $\beta$ -subunit. They are glycosylated polypeptides, and the  $\alpha$  and  $\beta$ -subunits are linked covalently. Both LH and FSH are approximately 28 kDa. The common  $\alpha$ -subunit is a 92 amino acid molecule, the LH- $\beta$  molecule is 115 amino acids, and the FSH- $\beta$  molecule is 115 amino acids in humans. These hormones bind to their respective LH or FSH receptors, which are G-protein coupled receptors found in target tissues of the ovary or testis.

**Sex Steroid Hormones.** Sex steroid hormones are synthesized from the precursor cholesterol in a multi-step process. Cholesterol first is converted to pregnenolone, which is converted to progesterone (Fig. 40.7). This hormone is a major end point for biosynthesis in gonadal tissues and exerts potent effects on the body and brain. Progesterone serves as a precursor for the synthesis of testosterone (Fig. 40.7) following conversion first to  $17\alpha$ -hydroxyprogesterone and then androstenedione. Testosterone is the dominant steroid hormone in males, although it is also found in females. It serves as a precursor via the enzyme  $5\alpha$ -reductase for  $5\alpha$ -dihydrotestosterone, which is responsible for many of the masculinizing effects of steroids in males. Testosterone is also the direct precursor via the enzyme p450 aromatase for  $17\beta$ -estradiol (Fig. 40.7), which is the primary estrogen responsible for sexual behavior and physiology in females, and which also plays roles in masculine physiology and behavior. The sex steroid hormones bind to their receptors, members of the nuclear hormone superfamily. The binding of a steroid hormone to its receptor, and subsequent receptor dimerization, allows these transcription factors to bind to specific sites on the promoter of the target gene, called androgen-response elements (AREs), estrogen-response elements (EREs), and progesterone-response elements (PREs). This enables the receptor-ligand complexes to induce or repress gene transcription in their target tissues.

Sex steroid hormones are synthesized and secreted from the ovaries or testes to regulate the expression of secondary sex characteristics and to maintain adult reproductive function. In the Leydig cells of the testis, LH released from the pituitary gland is responsible for testosterone biosynthesis. Together with FSH,

testosterone acts to coordinate and stimulate spermatogenesis in testicular seminiferous tubules. The testosterone that is released from the testis acts at secondary sex targets such as the internal and external genitalia (prostate, seminal vesicles, penis) to cause their development and maintain their functions. In addition, testosterone acts at muscle to increase muscle mass, causes the growth of facial and body hair, and enlarges the epiglottis, which is responsible for the deepening of the voice. In the ovary, FSH stimulates follicular development during each ovarian cycle, and LH is the primary stimulator of ovulation. Steroidogenesis in the ovary is also stimulated by FSH and LH. The resulting ovarian hormones, primarily  $17\beta$ -estradiol and progesterone, are responsible for the development of female secondary sex characteristics such as the genitalia and mammary tissue.

Sex steroid hormone feedback in the male is accomplished by the usual neuroendocrine negative feedback mechanism (Fig. 40.7). Pulses of GnRH cause pulses of the gonadotropins, which in turn are responsible for pulses of testosterone. Feedback of testosterone onto the brain causes an inhibition of hypothalamic GnRH neurons, and testosterone also feeds back negatively onto the pituitary gonadotropes. At the pituitary gland, sex steroid hormones appear to act primarily to decrease the sensitivity of pituitary gonadotropes to GnRH, resulting in a decrease in LH pulse amplitude.

In the female, the ovarian steroid hormones estradiol and progesterone can act at the hypothalamus to provide negative feedback. During most of the reproductive cycle, these hormones feed back at the brain and the pituitary gland to suppress the release of GnRH and the gonadotropins, respectively. However, during the mid- to late follicular stage in primates, or on the day of proestrus in rats with a four- to five-day estrous cycle, feedback effects of estrogens on GnRH release become positive. The stimulatory effects of estradiol on the hypothalamus result in the occurrence of the "preovulatory GnRH surge," which in turn triggers a preovulatory LH surge, that triggers the final maturation of the ovum in the follicle and results in ovulation and the subsequent development of the corpus luteum. After ovulation, feedback of ovarian steroid hormones upon the hypothalamus and pituitary reverts to the negative mode until the next cycle.

Unlike the other neuroendocrine systems, the primary feedback site of gonadal steroid hormones does not appear to be the GnRH neurons. Although GnRH neurons express the  $ER\beta$ , they do not express appreciable levels of  $ER\alpha$ , androgen receptors (AR), or progesterone receptors (PR). Therefore, it is thought that other neural cells that make afferent inputs to

GnRH neurons, and which express nuclear sex steroid receptors, may mediate effects of sex steroid feedback onto GnRH cells. The mediation of gonadal steroid feedback by intermediary cells in the CNS, primarily those expressing the  $ER\alpha$ , may also help to explain the "switch" between negative and positive feedback onto the GnRH neurons in females (Wintermantel *et al.*, 2006). For example, some afferent inputs to GnRH neurons that inhibit GnRH release may exert a dominant tone during most of the reproductive cycle and be responsible for negative feedback. Other afferent inputs that stimulate GnRH release may be regulated by higher levels of estrogens and underlie the positive feedback response to ovarian steroids that results in the preovulatory GnRH surge.

### *Neuroanatomy of the GnRH System*

GnRH neurons are not localized in a discrete hypothalamic nucleus, but are relatively widely dispersed across a continuum of the hypothalamus and preoptic area (Fig. 40.7). Although the rostral-caudal extent of the localization of GnRH perikarya can vary among species, in general, most GnRH cells are found in the preoptic area, septal nuclei, diagonal band of Broca, and anterior hypothalamus (particularly basal regions). All the neuroendocrine GnRH neurons project a process to the median eminence, where the GnRH decapeptide is released in a pulsatile manner. It should be noted that other groups of GnRH neurons have been detected in other, nonneuroendocrine regions such as olfactory regions and midbrain, but their functions are not well understood. It is speculated that they may play roles in the links between pheromones and reproduction, or between reproductive physiology and behavior. The GnRH neurons involved in neuroendocrine control that are described in this chapter are also referred to as GnRH-1 cells, to differentiate them from the GnRH cells in nonneuroendocrine regions, deemed GnRH-2 and GnRH-3 neurons.

The morphology of the hypophysiotropic GnRH-1 neurons is somewhat different from other neuroendocrine neurons, possibly due to differences in the cells' embryonic origin in the olfactory placode. GnRH neurons are oval or fusiform in shape and extend a single axon to the median eminence. They also receive relatively little synaptic input on their perikarya, although recent evidence suggests they may receive afferent input on their dendrites. Nevertheless, GnRH neurons are functionally regulated by numerous neurotransmitters and neurotrophic factors, and this is probably related to the integrative nature of the GnRH neuron. In order for reproduction to be successful, the organism must be able to assess the conditions of internal and external environment to determine that

conditions are optimal. The numerous inputs to GnRH neurons from other sensory and neuroendocrine cells enables these key reproductive neurons to evaluate the organism's health and fitness and the external conditions (e.g., season, food availability, the presence of predators or a conspecific mate) and to coordinate the timing of reproduction, which is quite costly, with the optimal external and internal circumstances. Thus, GnRH cells are regulated by inputs from neurotransmitters such as glutamate, GABA, catecholamines and monoamines, neuropeptides such as kisspeptin, CRH,  $\beta$ -endorphin, vasopressin, neurotensin, neurotrophic factors, and many other substances. In this way, GnRH neurons receive cues regarding nutritional status, thermogenesis and exercise, stress, and social cues and can integrate these inputs to coordinate the timing of reproduction with the appropriate stimuli.

### *Disruptions in the Reproductive Axis*

There are two natural genetic mutations lacking normal GnRH systems. In humans, Kallmann's syndrome is characterized by the failure of GnRH neurons to migrate properly during embryonic development. Although these patients develop essentially normally in most other ways (except that they are anosmic due to abnormalities of the olfactory placode from which both GnRH neurons and olfactory cells derive), they never enter puberty and are infertile. Replacement of pulsatile GnRH to these individuals can stimulate the onset of puberty and maturation of the secondary sex characteristics and fertility. The hypogonadal (hpg) mouse has a defect in the GnRH gene. Similar to their human Kallmann's syndrome counterparts, these animals never undergo reproductive development and can be "rescued" by GnRH replacement.

Other defects of the reproductive system involve the timing of the onset of puberty. In idiopathic central precocious puberty, GnRH is released far earlier than is normal, for example, in patients as young as 1 year of age. Although the mechanism by which the GnRH release is stimulated precociously is unknown, this results in activation of the release of pituitary gonadotropins, stimulation of the gonads, and the early development of secondary sexual characteristics. Treatment with long-lasting GnRH agonists, which initially stimulate but rapidly down-regulate pituitary GnRH receptors, cause a downregulation of the reproductive axis and can halt pubertal development until the normal timing of puberty occurs. In the case of delayed puberty, the normal pubertal release of GnRH does not occur, and exogenous GnRH can be infused in a pulsatile manner to cause the stimulation of puberty in these individuals.

## Lactation and Maternal Behavior

### *Overview and Characteristics of the Lactotrophic Axis*

The pituitary hormone prolactin is a major regulator of lactation in mammals. However, unlike the other pituitary hormones, a unique releasing neuropeptide hormone for prolactin has not been identified in the hypothalamus, although there is a prolactin-inhibiting factor, dopamine (Fig. 40.8). Prolactin is synthesized in pituitary cells called lactotropes. Its release into the circulatory system from the anterior pituitary gland causes milk synthesis and secretion into the alveoli of the mammary glands in response to the suckling stimulus. Prolactin, together with oxytocin, which is involved in milk ejection (see later), is responsible for the maintenance of lactation.

It is generally accepted that hypothalamic dopamine plays a major role in the inhibition of prolactin release, and dopamine is probably the prolactin-inhibiting factor (Ben-Jonathan *et al.*, 1989; Fig. 40.8). Dopamine is abundant in the hypothalamus and is found in high concentrations in the median eminence, where it can be released to influence the function of the anterior pituitary gland via the portal capillary system. Evidence for a negative influence of the hypothalamus on prolactin secretion was provided by studies demonstrating that experimental isolation of the pituitary gland from the hypothalamus resulted in a large increase in basal prolactin secretion. Moreover, drugs that decrease dopamine levels in the pituitary portal circulation increase prolactin secretion, and application of exogenous dopamine can inhibit endogenous prolactin release. It was also reported that dopamine receptors are present on pituitary lactotropes, and finally, that changes in dopamine concentrations in the portal capillary system correlate with changes in prolactin release under physiological conditions.

Regarding the stimulation of prolactin release by a hypothalamic factor(s), though many molecules have been proposed, none appears to be a unique prolactin-releasing hormone. TRH, vasoactive intestinal polypeptide, and oxytocin can stimulate prolactin release but they do not appear to have the one-to-one relationship between a true hypothalamic releasing factor and its adenohipophysial hormone. Thus, the search for a unique hypothalamic-releasing hormone for prolactin is ongoing.

### *Physiological Functions of the Lactotrophic Axis*

**Role of Prolactin in Reproductive Physiology and Lactation.** The release of prolactin varies by age, sex, and reproductive status. Levels of prolactin are higher in females than males, probably due to the higher

**FIGURE 40.8** Left: Major regulatory pathway of prolactin secretion from anterior pituitary lactotropes. Prolactin release is inhibited by tuberinfundibular dopaminergic neurons in the arcuate nucleus. The release of prolactin from the pituitary stimulates the mammary gland to produce and release milk. Other hypothalamic factors shown, TRH and OT, are thought to regulate the prolactin system, although their roles are less well defined than that of dopamine. In all cases a unilateral projection is shown, although this regulation occurs bilaterally. Right: The structure of dopamine is shown, and general structural information about the PRL sequence provided. Abbreviations: ARC, arcuate nucleus; DA, dopamine; OT, oxytocin; PRL, prolactin; PVN, paraventricular nucleus; SON, supraoptic nucleus; TRH, thyrotropin-releasing hormone; iii, third ventricle.

estrogen levels in females, which stimulate prolactin release. During reproductive cycles in females, prolactin levels vary, with levels being higher during the luteal than the follicular phase in humans. In rats, prolactin levels peak shortly before the preovulatory LH surge that causes ovulation, a time when estrogen levels are high. Prolactin levels also increase during pregnancy, decrease just before birth, and increase again as a response to suckling.

The role of prolactin in lactation is its best-studied and probably most important function. In all mammals, prolactin acts on the mammary gland to prepare and maintain its secretory activity. It causes the growth of ductal and lobuloalveolar tissues and causes increases in mRNA levels and translation of the milk protein, casein. Prolactin release is stimulated directly by suckling and results in the synthesis of milk. In addition, there is a relationship between suckling and the inhibition of reproductive function, as suckling can delay implantation of fetuses conceived during a postpartum estrus or cause long periods of anovulation. Prolactin may also play a role in maternal behavior, although this is not well understood.

Prolactin can influence the reproductive axis through its actions on the ovary. There, prolactin causes increases in LH receptors in the corpus luteum, progesterone synthesis by the corpus luteum, and high- and low-density lipoprotein binding in membranes of the corpus luteum. These functions may

be related to uterine endometrial development and implantation of the blastocyst in rats, although it is not clear if this is the case in humans.

Other functions of prolactin include osmoregulation, primarily in fish and amphibians. The expression of prolactin receptors in kidney, gut, skin, and urinary bladder is consistent with this role. Prolactin receptors have a widespread distribution throughout the body of many species. Predictably, they are abundant in mammary gland, but they are also found in other tissues involved in reproduction, as well as the liver, kidney, gastrointestinal tract, and brain. Thus, it is likely that prolactin may play roles in these tissues that are independent of lactation or reproductive function.

***Pulsatile and Circadian Release of Prolactin.*** Like the other pituitary hormones, prolactin is released from the anterior pituitary in a pulsatile manner. Its release is entrained to the 24-h clock, similar to other hormones. This appears to be a diurnal rhythm, as it is driven by sleep cues rather than the circadian clock, similar to its related hormone, growth hormone (Gore, 1998).

#### ***Structures and Properties of Prolactin and Its Receptors***

Prolactin is a member of the somatotropin (growth hormone) family of molecules. Its gene shares consid-

erable homology with the growth hormone gene. The prolactin protein is a 23- to 24-kDa protein containing three disulfide bridges, giving it a unique structure. There are multiple forms of the prolactin receptor, and its expression is widespread throughout the body. Isoforms of the prolactin receptor range in size from 329 to 591 amino acids and they have structural overlap with cytokine receptor family members. Prolactin receptors are found in the mammary gland, liver, kidney, adrenals, gonads, uterus, placenta, prostate, seminal vesicles, lymphoid tissues, intestine, choroid plexus, hypothalamus, and other tissues.

### Neuroanatomy of the Hypothalamic Dopamine System

The major hypothalamic population of dopamine neurons believed to regulate prolactin release is called the tuberoinfundibular dopaminergic system, also referred to as the A12 cell group. Their perikarya lie in arcuate nuclei (Fig. 40.8), and their neuroterminals project to the median eminence in the external zone, the latter projection being similar to that of other hypothalamic releasing and inhibiting hormones.

At the anterior pituitary gland, dopamine binds to the D2 subtype of dopamine receptor on lactotropes to cause its inhibitory effects on the synthesis and release of prolactin. The binding of dopamine to the D2 receptor causes a decrease in cAMP concentrations in lactotropes and causes an inhibition of prolactin gene transcription. Another second messenger system, the Ca<sup>2+</sup>/phosphokinase C system, may also play a role in this process, although this latter mechanism is not well understood.

As discussed earlier, prolactin release is regulated by neurotransmitters other than dopamine. The hypothalamic hormone thyrotropin-releasing hormone (TRH), the primary function of which is the regulation of the thyroid hormone axis, also has been shown to stimulate prolactin release. Another neuropeptide, vasoactive intestinal peptide (VIP), can stimulate prolactin release, and blockade of the VIP system with

antisera inhibits basal prolactin secretion. In addition, oxytocin neurons regulate the prolactin system, possibly through direct actions on lactotrope cells (Fig. 40.8).

### Disruptions in the Prolactin System

Hyperprolactinemia is the elevated secretion of prolactin. This is a common human pituitary disorder and can be a result of disrupted dopamine transmission, which normally would suppress prolactin release. Hyperprolactinemia can result from pituitary adenomas that secrete prolactin. As a result of hyperprolactinemia, inappropriate lactation can occur, as can be the case with drugs that affect the dopamine system (neuroleptics, dopamine receptor blockers, antidepressants, antihypertensives, oral contraceptives).

## THE HYPOTHALAMIC-NEUROHYPOPHYSIAL SYSTEMS

Although the major focus of this chapter is the regulation of anterior pituitary function by hypothalamic releasing/inhibiting factors, following is a brief discussion of the hypothalamic neurons that innervate the posterior gland, specifically, arginine vasopressin (AVP) and oxytocin (OT) neurons. Further discussion of these hormones is found in Chapters 39 and 7, respectively.

### Oxytocin and AVP

#### The OT and AVP Genes and Peptide Structures

The oxytocin and AVP neuropeptides are synthesized from genes localized on the same chromosome, but they are in a "head to head" organization separated by a domain called the intergenic region. Therefore, these genes are transcribed in opposite directions (Fig. 40.9; Young and Gainer, 2003). The AVP and OT

**FIGURE 40.9** Structural organization of the AVP and OT genes. The RNA sequences are transcribed off of a single gene but in opposite directions, indicated by arrows. Each gene is made up of three exons that encode a signal peptide, the neurohormone (either AVP or OT) and a neurophysin that may be involved in chaperoning the neuropeptides. AVP also contains an additional sequence for a glycoprotein. The regions are separated by an intergenic sequence. The nonapeptide sequence of each neurohormone is shown below their respective genes, with differences indicated by underlines. Abbreviations: AVP, arginine vasopressin; GP, glycoprotein; NP, neurophysin; OT, oxytocin; SP, signal peptide. Modified from Young and Gainer (2003).

genes are structurally similar, comprising three exons that encode a signal peptide, the neuropeptide (either AVP or OT), and a neurophysin whose function is not entirely known but may be involved in chaperoning the neuropeptides as they are processed in secretory vesicles (Fig. 40.9; Burbach *et al.*, 2001). AVP and OT are highly homologous nonapeptides (Fig. 40.9).

### *Physiological Functions*

AVP and OT have numerous functions in the brain and body, and a brief discussion of their diverse neuroendocrine-neurohypophysial functions is provided here. For further details, refer to Burbach *et al.* (2001). One of the most important roles of AVP, also called antidiuretic hormone, is salt and water balance. In mammalian systems, changes in osmolality of extracellular fluids alter secretion of AVP, and to a lesser extent OT, which can regulate salt and water intake through actions on kidney tubules and by exerting behavioral effects on drinking and salt appetite. AVP plays a further role as a vasoconstrictor in response to hemorrhage. As discussed earlier, AVP also is involved in the regulation of the stress response. Some of these effects may be mediated through transport of AVP to pituitary corticotropes via the portal capillary vasculature leading to the anterior pituitary gland. In addition, neurohypophysial actions of AVP on osmolality may indirectly modulate the brain-pituitary-adrenal axis.

Oxytocin is best known for its roles related to parturition and milk ejection in mammals. OT plays roles in uterine contraction during delivery. With regard to lactation, OT responds to the suckling stimulus by stimulating contraction of the cells around the alveoli of the mammary gland to stimulate milk ejection. OT, together with AVP, plays key roles in social behaviors related to successful reproduction, such as maternal and paternal behaviors and pair bonding (Lim and Young, 2006).

### *Properties of the OT and AVP Receptors*

Effects of OT and AVP are mediated by their specific receptors, localized in various target organs. To date, one OT receptor and three AVP receptors (V1a, V1b, V2) have been identified (Young and Gainer, 2003). All are G-protein coupled receptors. The V2 receptor is not found in the CNS, but is highly expressed in kidney. The V1a and V1b receptors are found in brain, and the V1b receptor is highly expressed in pituitary corticotropes. Knockouts of the mouse V1b receptor cause deficits in social aggression (Young and Gainer, 2003).

### *Neuroanatomy of the Oxytocin and AVP System*

The hypothalamic-neurohypophysial AVP and OT neurons have large cell bodies that are 20–40  $\mu\text{m}$  in diameter, and are referred to as magnocellular neurons (as opposed to their parvocellular counterparts of 10–15  $\mu\text{m}$ ). These cells are localized in two major hypothalamic regions: the supraoptic nucleus (SON), comprised entirely of magnocellular neurons; and the paraventricular nucleus (PVN), which has both magnocellular and parvocellular divisions (Burbach *et al.*, 2001). The hypothalamic-neurohypophysial neurons in the SON and PVN project processes that enter the pituitary stalk and terminate in the posterior pituitary gland, where the hormones can gain access to the general circulatory system (Fig. 40.1). In addition, some of neurohypophysial axons may branch into other regions, including the median eminence, whereby OT and AVP may influence anterior pituitary gland functions. For example, OT contributes to prolactin release through actions on the lactotropes, and AVP interacts with CRH on the corticotrope to modulate stress responses.

## HORMONES AND THE BRAIN

### **Steroid Hormone Receptors in the Brain**

In order for steroid hormones to be able to exert effects on brain and behavior, they must have specific steroid hormone receptor-positive targets. The hypothalamus, the site of steroid hormone regulatory feedback, is a predictable target for steroid hormones. Indeed, the hypothalamus and related regions such as preoptic area are abundant in estrogen receptors (ERs), androgen receptors (ARs), and progesterone receptors (PRs), which can be detected even during fetal development (Roselli *et al.*, 2006). Neuroscientists have begun to look beyond the hypothalamus as a CNS target for steroid hormones, in order to understand how these molecules may mediate or mitigate nonreproductive CNS functions including neuroprotection, synaptic plasticity, neurogenesis, cognition, and neurodegeneration. The findings that sex steroid hormone receptors are widespread in the CNS help explain some of these observations. In addition, along with the nuclear sex steroid hormone family, nonnuclear membrane steroid hormone receptors have been identified that may explain actions of steroid hormones, particularly those that occur more rapidly than those mediated by nuclear receptors, in the CNS.

## Sexual Differentiation of the Brain

The brain is sexually differentiated, meaning that there are morphological, anatomical, and functional differences between males and females. In mammals and many other vertebrates, these differences appear to be established, or “organized,” in late gestation and early postnatal life, due to early hormonal exposures. The developing fetus is exposed not only to its own gonadal hormones, but also to maternal and environmental factors, exposures to all of which have permanent effects on brain development, and ultimately, on adult neural and behavioral functions.

The early effects of sex steroid hormones are mediated by specific receptors that are abundant in the hypothalamus and other brain regions. Two examples of brain regions that are particularly sensitive to perinatal sex steroid exposure and are sexually differentiated include (but are not limited to) specific hypothalamic and preoptic areas, as well as the spinal nucleus of the bulbocavernosus (SNB), the latter which innervates the base of the penis or clitoris. Perinatal differences in sex steroid hormones act to alter the size of these brain regions such that they differ between males and females; in general, because the fetal testis is much more active than the ovary, testicular hormones are responsible for these neuroanatomical changes.

Although it might be predicted that testosterone is responsible for these effects in males, depending upon the brain region, it is often testosterone’s metabolite,  $17\beta$ -estradiol, that is much more potent in many of these actions in mammalian species. Testosterone is a direct precursor to estradiol, metabolized by the P450 aromatase enzyme. This enzyme is found in the hypothalamus, as well as many other brain regions that are steroid sensitive. The perinatal *organizational* effects of testosterone and estradiol are crucial in order for normal sex-specific reproductive physiology and behavior to occur in adulthood. These behaviors also require further actions of gonadal steroid hormones, which are secreted in increasing amounts during the pubertal process. These so-called *activational* effects of steroids at puberty require that normal organization has occurred early in life. It is also becoming clear that the pubertal period is characterized by continued development of the brain, including neural plasticity that is modulated by steroid hormones. Thus, puberty may be considered as a second organizational period, as well as one during which activation of neonatally-organized circuits occurs (Sisk and Foster, 2004).

The issue of sexual dimorphism in the human brain has been quite controversial, but there is no question

that there is strong evidence for morphological and functional differences in specific brain nuclei in humans (Cahill, 2006). Homologues to the sexually dimorphic nuclei of rats also appear to be dimorphic in humans. For example, Onuf’s nucleus, which is homologous to the rat SNB, has more motor neurons in men than in women. In the human anterior hypothalamus, roughly equivalent to the rat sexually dimorphic nucleus of the POA (SDN-POA), there are sex differences in the size of some of the interstitial nuclei, called INAH (for interstitial nuclei of the anterior hypothalamus), with men having larger volumes than women of some of these nuclei. This issue is particularly controversial, as it has been reported that the INAH-3 of homosexual men is intermediate in size between that of heterosexual men (having the largest INAH-3) and that of women (having the smallest INAH-3). Further research is needed to confirm these results and to determine the implications of different-sized INAHs on sexual behavior and identity. Other brain regions have been shown to be sexually dimorphic in humans. For example, hippocampus, amygdala and neocortex have robust sex differences in size and neurochemistry (Cahill, 2006; Fig. 40.10).

**FIGURE 40.10** (This legend is quoted from the review by Cahill, 2006.) An illustration of sex differences in the size of various human brain regions. Goldstein *et al.* measured the volume of 45 brain structures taken from MRI scans in a sample of male ( $n = 27$ ) and female ( $n = 21$ ) subjects. For both sexes, the size of each region was determined relative to volume of the cerebrum. As shown here, significant differences between the sexes were detected in widespread brain regions. The authors also found that the size of the sex differences were related to the presence of sex steroid receptors in homologous brain regions during critical developmental periods, as determined in animal studies, suggesting that sex differences in the adult stem from sex hormone influences on brain development. Data from Goldstein, J. M. *et al.* (2001). Normal sexual dimorphism of the adult human brain assessed by *in vivo* magnetic resonance imaging. *Cereb. Cortex* 11, 490–497.

Although the mechanisms for these differences cannot be studied experimentally in humans, Cahill (2006) has speculated that some but not all differences are attributable to sex steroid hormones.

## Hormones and Sexual Behavior

There are clearly differences in the sexual behavior of males and females, which are dependent upon organizational and activational effects of gonadal steroid hormones. For example, copulatory behavior in male rodents comprises mounts of the female by the male, penile intromissions, and ejaculations. A receptive female rodent will respond to male copulatory behaviors with a lordosis response, characterized by a rigid stance and an arched back. These behaviors are driven in large part by the responses of hypothalamic nuclei to hormones, and the nature of the adult behavior is determined by the prenatal/neonatal exposure to hormones. Thus, the hypothalamus of adult males, which has been masculinized neonatally by testicular testosterone (aromatized to estradiol), will respond to the testosterone produced by the adult gonad (metabolized to DHT) by causing the typical male pattern of sexual behavior. In contrast, the female hypothalamus, which is not exposed neonatally to sufficient levels of ovarian hormones to cause masculinization of her brain, responds to estrogen produced by her adult ovary with the appropriate female lordotic response. Moreover, a normal adult male will not express lordosis behavior in response to exogenous estrogen, nor will a normal adult female exhibit male-typical sexual behaviors in response to exogenous testosterone, as their brains have not been organized in such a way as to produce a gender-inappropriate response in adulthood. However, a neonatally castrated male can respond to estradiol in adulthood with the expression of lordosis behavior, as his brain was not masculinized neonatally. Similarly, a female who was exposed to exogenous testosterone or estradiol neonatally can exhibit male-typical sexual behaviors as an adult if she is treated with testosterone.

It is necessary to distinguish between masculinizing and defeminizing effects of hormones in females, and the feminizing and demasculinizing effects of hormones in males. As mentioned earlier, female sexual behavior in rats is characterized most overtly by lordosis. The prevention of this behavior by exposure to sex steroid hormones neonatally would be an example of a defeminizing effect. In contrast, a female rat whose brain has been exposed to steroid hormones at birth, and in adulthood is injected with testosterone, may exhibit male-typical sexual behavior such as mounting another female. This is an example of the masculiniz-

ing effects of hormones. For males, the feminizing effects of hormones could be seen in a neonatally castrated male who, as an adult, is exposed to female sex steroids and responds with lordosis behavior in response to the mounting by another male. Demasculinization would occur in this male if, as an adult, he fails to perform normal male-typical sexual behavior (mounts, intromissions, ejaculations) in response to a female. Thus, hormones can cause both of these effects in males or females, depending on the time and duration of exposure.

The regions of the brain responsible for sex behavior differ between males and females. Sexual behavior in male rodents is largely driven by the preoptic area (POA) of the brain, just rostral to the hypothalamus, although other regions contribute to this process. Lesions of the POA in males cause the loss of sexual behavior, and testosterone implanted into the POA can induce sex behavior. In female rodents, the primary hypothalamic site regulating receptive sexual behavior is the ventromedial nucleus of the hypothalamus (VMH), although as in males, other regions also play contributing roles. Estradiol, followed by progesterone, facilitates the expression of the lordosis reflex and coordinates the timing of female receptivity with the preovulatory GnRH/LH surge that causes ovulation. Thus, the timing of mating behavior and ovulation is coordinated by the release of ovarian steroid hormones. During the reproductive cycle, circulating estrogen levels increase, and estrogen binds to its receptor in the VMH to cause the transcription of several genes, including that of the progesterone receptor. Then, progesterone levels rise and can bind to its newly induced receptor in the VMH. This causes proceptive behaviors in females and facilitates the lordosis response. Females that have been androgenized neonatally have a large reduction in the lordosis response to exogenous estrogen and progesterone replacement.

## Pheromones, the Vomeronasal Organ, and Sexual Behavior

Reproductive behavior in many species involves signals from pheromones, which are chemical signals used for communication between animals (Meredith, 1998). Pheromones are chemical messengers that typically are produced by specialized glands, such as the sebaceous glands in the flanks of animals, or released in urine or vaginal fluid. They are released not into the body but rather into the external environment to convey information about the physiological status of the animal to other individuals.

The ability to detect pheromones involves the vomeronasal organ, an auxiliary olfactory organ found near

the nasal cavity, and its projections to the accessory olfactory bulbs. Cells in these latter regions contact a number of brain regions, including the medial amygdala, cortical regions, and the bed nucleus of the stria terminalis, all of which are implicated in sex behavior. These regions in turn project to the hypothalamus and preoptic area. Thus, information from pheromones about mating status can be conveyed to parts of the brain coordinating reproductive physiology and behavior.

In most species, information about reproductive status, dominance status, or other social cues can be conveyed by pheromones, although it is still controversial whether humans have a vomeronasal organ and/or can sense pheromones. Those organisms using pheromones as chemosensory cues have developed mechanisms for depositing or releasing pheromones to "advertise" sexual competency or receptivity in order to attract a mate or to mark territory, to protect food supplies, mates, or offspring. Pheromones and the systems that mediate their effects play broader roles than those involved in reproductive physiology and behavior. Pheromones can dramatically influence the timing of sexual development and function. In female mice, exposure to male urinary pheromones accelerates the timing of pubertal development. Males respond to female urinary pheromones with sharp increases in luteinizing hormone release. It has also been reported that pheromones can coordinate the timing of reproductive cycles, even in humans, although the mechanisms and functions of these pheromones are still controversial and poorly understood. Nevertheless, it is clear that pheromones play important roles in coordinating physiology and behavior.

## Circadian Timekeeping

Life on Earth has adapted to the cyclic variation in conditions imposed by our planet's daily rotation on its axis and its annual revolution around the sun. Almost all organisms studied, from cyanobacteria to *Homo sapiens*, have intrinsic time-keeping systems that adjust physiology and behavior to anticipate the daily cycles of light and darkness. Physiological processes that vary over the 24-hour day include activity, alertness, hormone secretion, organ physiology, and gene expression. These variations are not merely passive responses to a rhythmic environment, but instead reflect an underlying biological mechanism that can measure time on a 24-hour time scale. This mechanism orchestrates physiology to achieve predictive, rather than reactive, homeostasis.

Biological time measurement on the 24-hour time scale is achieved by a circadian timing mechanism. The term *circadian* is derived from the Latin words *circa* and *diem*, meaning "about a day," referring to the cycle length of these rhythms. Circadian rhythms are defined as rhythms that persist with a cycle length of approximately 24 hours in constant environmental conditions (Figs. 41.1, 41.2). These rhythms are generated by a biological timing mechanism that normally is synchronized (entrained) to the 24-hour day by environmental cues. Light is the most widely used signal for entrainment of circadian clocks, but temperature, hormone levels, nutrient availability, and other cues can also affect oscillations.

In this chapter, we will present the current state of knowledge regarding the mammalian circadian timing system, including discussion of the molecular basis for oscillations within individual cells, and the anatomical and neurochemical substrates regulating circadian rhythmicity.

### OVERVIEW OF THE MAMMALIAN CIRCADIAN TIMING SYSTEM

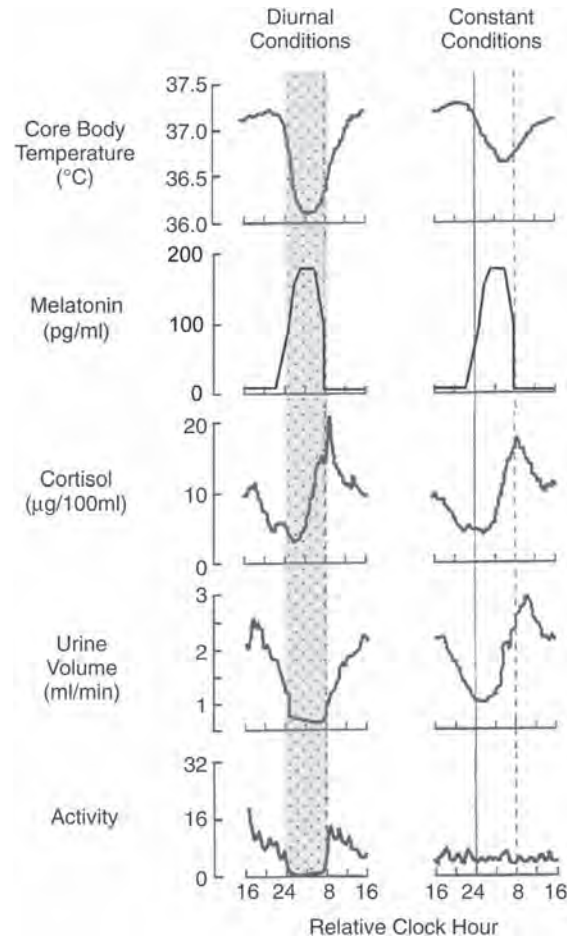

A biological timing system in its simplest form consists of an intrinsic clock mechanism that measures time, an input mechanism that allows the clock to become synchronized or reset by changes in the environment, and output pathways that lead to generation of overt rhythms such as daily changes in locomotor activity, sleep, and hormone levels. The mammalian circadian timing system is considerably more complicated than this simple linear scheme, because it is composed of a hierarchy of circadian oscillators (Fig. 41.3). At the pinnacle of this oscillatory system is a small brain area, the suprachiasmatic nuclei (SCN) of the anterior hypothalamus. The SCN often are called the master circadian clock, because these nuclei (one on each side of the brain) play a key role in coordinating oscillations in other tissues, and in regulating behavior. Many other cells and tissues also have the capacity to oscillate with a cycle length of approximately 24 hours. The molecular mechanism underlying these cell-autonomous circadian oscillations is a transcriptional feedback loop described in detail later.

The primary input pathway to the SCN circadian clock is through retinal detection of light. Remarkably, the retinal photoreceptors that lead to visual image formation are not needed for circadian photoreception. Instead, a specialized population of intrinsically photosensitive retinal ganglion cells detect light and also project directly to the SCN. In rodents, the retinohypothalamic tract (RHT) is composed primarily of the axons of these specialized ganglion cells, and the RHT is necessary for synchronization of the SCN clock to light.

**FIGURE 41.1** Locomotor activity rhythm of a mouse. This figure is a “double-plotted actogram” that shows the activity pattern of an adult mouse housed individually in a cage with a running wheel. When the mouse rotates the wheel by running within it, a computerized system detects and records the wheel revolutions and then can be used to plot the wheel revolutions (as bars coming up from the baseline, with their height proportional to the number of revolutions) versus time, for weeks of data. Each horizontal line represents 48 hours of data. On the first line of the record, the first 48 hours of data are shown. In the second line of the record, the data shown are from hours 24–72 of data collection. Thus, each 24-hour period of data after the first 24 hr is shown both to the right of and below the previous day’s data; this artificial reproduction of the data (double-plotting) helps to see the rhythmicity when the cycle length of rhythmicity differs from 24 hours (see for example Fig. 41.7 lower). When housed in a 12L:12D lighting cycle (LD), the mouse is active almost exclusively at night. When the lighting cycle is disabled so the animal is in constant darkness (DD), the animal continues to show rhythmicity but with a cycle length slightly less than 24 hours. This record reveals two defining principles of circadian rhythms: circadian rhythmicity is intrinsic, rather than being generated in response to environmental variation, and the circadian clock normally is synchronized to the 24-hour day length by light. Note also the precision of the rhythmicity when the mouse is in DD. Activity onset is defined as a spontaneous, sustained increase in wheel running that occurs after a sustained period of inactivity. It is relatively easy to draw a “best-fit” line through the activity onsets (yellow line). The actual time of activity onset each day does not deviate far from this “best-fit” line, indicating the cycle length between successive activity onsets is measured with great accuracy. Spend a few minutes to think about how you would design a biological timekeeping system that can measure a day while having a variation between successive cycles that is less than 1% (15 minutes per 24 hours; note that the actual variation is often considerably less than this amount). Actogram provided by Jason DeBruyne, UMass Medical School.

**FIGURE 41.2** Diurnal and circadian rhythms in human physiology. The panels on the left show rhythms in several functions in human subjects maintained in a lighting cycle, with a period of sleep in the dark indicated by the shading. These rhythms are true circadian rhythms, as they persist in constant conditions. The panels on the right show the same endpoints studied in subjects maintained for 40 hours on a constant routine, with very low levels of illumination and with wakefulness maintained, while the subjects remain constantly in a semi-recumbent posture and receive small meals at regular intervals throughout the study period. The apparent loss of the activity rhythm in constant conditions is due to the protocol-enforced inactivity of the subject. (Adapted from Czeisler and Khalsa, 2000.)

The main output of the SCN is encoded by the neuronal firing rate of SCN neurons. In addition to direct synaptic interactions, rhythmic neuropeptide secretion into the cerebrospinal fluid may be an important mechanism for regulation of downstream targets. Anatomically, the outputs of the SCN are focused within the hypothalamus, but their influence is widespread, consistent with the pervasive influence of the SCN on physiological functions ranging from the modulation of cognitive function to neuroendocrine

**FIGURE 41.3** The mammalian circadian timing system consists of a hierarchy of oscillators. Oscillatory neurons in the SCN interact with each other to produce a set of coherent outputs. These outputs, which include behavioral and physiological rhythms, synchronize cell-autonomous oscillations in other brain regions and in peripheral tissues. (From Reppert and Weaver, 2002.)

responses. Output from the SCN serves to synchronize autonomous cellular oscillators in other tissues. Local circadian oscillators regulate gene expression in a tissue-specific manner, likely contributing to local organ physiology. Microarray studies conducted on brain, liver, heart, and kidney tissue in mammals reveal that as much as 10% of the genome is rhythmically transcribed, and many of the genes that are rhythmically expressed represent key, tissue-specific metabolic control points (Miller *et al.*, 2007). Thus, the circadian timing system has a pervasive impact on physiological processes via its output pathways.

### THE SUPRACHIASMATIC NUCLEI ARE THE SITE OF THE PRIMARY CIRCADIAN PACEMAKER IN MAMMALS

The SCN have been recognized as the master circadian clock in rodents since the early 1970s (Weaver, 1998). Lighting conditions (especially constant light)

were known to affect neuroendocrine function in rats, and the eyes were known to be necessary for the effects of light, but the pathways by which light had these effects were not known. At that time, “new” techniques for anterograde tract-tracing were used to assess retinal projections, and revealed a direct retina-to-SCN projection, the retinohypothalamic tract (RHT). To determine if the SCN were an important node on the anatomical pathway for detection of light, Moore and Eichler (1972) destroyed the rat SCN and observed loss of rhythmic serum corticosterone in a population of rats. Using a similar approach, Stephan and Zucker (1972) discovered that the rhythm of drinking in individual rats was lost following destruction of the SCN. Together, these two studies demonstrated the necessity of the SCN for circadian rhythmicity. Hundreds of subsequent studies have confirmed the necessity of the SCN for rhythmicity in physiology and behavior.

### SCN: Oscillator and Pacemaker

Lesion studies leading to loss of rhythmicity do not necessarily show that the SCN function as the primary

circadian pacemaker. An alternative possibility is that the SCN could be a necessary element on a key output pathway leading to physiological rhythmicity, rather than a pacemaker. The presence of rhythms in SCN metabolic activity, electrical activity, and gene expression profiles *in vivo* do not distinguish between these possibilities. Studies demonstrating rhythms in neuropeptide secretion, metabolic activity, and electrical firing rate in SCN tissue maintained *in vitro* do show that the SCN contain a functional oscillator. The SCN do not simply oscillate, however; through their outputs, the SCN regulate rhythms in physiology and behavior, and thus serve as a circadian pacemaker. This pacemaker role of the SCN is revealed most clearly by studies showing that locomotor activity rhythms can be restored in hamsters by transplanting fetal SCN tissue into the hypothalamus of animals previously made arrhythmic by SCN lesion. Furthermore, transplants between hamsters with different circadian periods reveal that the cycle length (period) of restored rhythmicity is dictated by the genotype of the SCN tissue donor and not by the recipient (Ralph *et al.*, 1990). Thus, the SCN serve as a pacemaker that communicates rhythmicity to tissues regulating behavioral rhythms.

### Summary

The SCN are the master circadian pacemakers in mammalian brain. The SCN oscillate *in vivo*, and also when placed *in vitro*. More importantly, however, the SCN generate output signals that lead to physiological and behavioral rhythms. Critical to the function of the SCN as the master pacemaker is its position at the interface between the outside world (detected primarily by retinal photoreception) and the light-insensitive tissues that comprise the rest of the body.

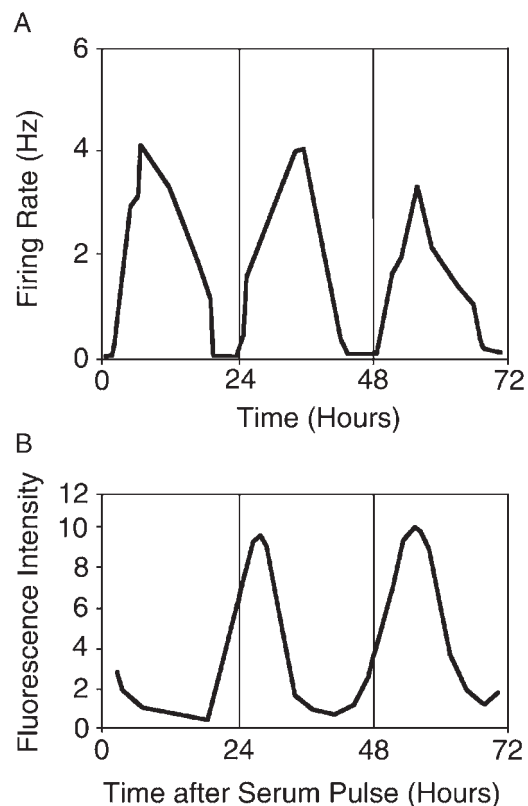

## A HIERARCHY OF CELL-AUTONOMOUS CIRCADIAN OSCILLATORS

### Single-Cell SCN Oscillators Are Coupled to Form a Coherent Clock

The rodent SCN are composed of approximately 10,000 neurons per side of the brain, with heterogeneity of neuropeptide phenotype, connectivity, and other properties (Silver and Schwartz, 2005; Morin, 2007). Despite this heterogeneity, most cells within the SCN are believed to have the capacity for cell-autonomous rhythmicity. Rhythmicity was first detected in individual SCN neurons using extracellular recording of SCN neuronal firing (Welsh *et al.*, 1995; Liu *et al.*, 1997;

Fig. 41.4A). More recent studies reveal rhythmicity in single SCN cells using imaging methods designed to detect temporal variations in reporter gene expression.

The cycle lengths of individual oscillating SCN cells are much more variable than the periods of animal behavior or the period observed for rhythms (e.g., in neuropeptide secretion) from slices of SCN tissue maintained *in vitro*. Thus, some mechanisms for interaction among the heterogeneous SCN neurons must occur for SCN neurons to synchronize their diverse periods to an intermediate value, to coordinate their phase (timing), and thus to provide a coherent output (Aton and Herzog, 2005). GABA and vasoactive intestinal peptide (VIP) have both been proposed as neurochemicals that may coordinate SCN neurons. VIP is expressed in a subset of neurons in the central “core” region of the SCN, whereas the vast majority of SCN neurons express the inhibitory neurotransmitter,

**FIGURE 41.4** Cell-autonomous circadian rhythmicity. (A) Circadian rhythmicity in an individual SCN neuron. SCN neurons in dispersed cell culture express rhythms of spontaneous firing rate, as detected by electrodes embedded in the floor of the culture dish on which the neurons were plated. (Adapted from Welsh *et al.*, 1995; Liu *et al.*, 1997). (B) Circadian rhythmicity in an individual fibroblast. Imaging of reporter gene expression was used to detect rhythmicity in culture. (Adapted from Nagoshi *et al.*, 2004.)

GABA (Moore *et al.*, 2002). Mice lacking VIP (or the VPAC2 receptor for VIP) have very weak and unstable rhythms in locomotor activity, yet individual SCN neurons from these mice appear to maintain rhythmicity (Maywood *et al.*, 2006). These findings strongly suggest that a “coupling deficit” leads to altered circadian rhythmicity in these lines of mice.

The entire population of SCN neurons usually functions in concert as an orchestrating oscillator. Under specific conditions, however, SCN cells can be induced to become coupled into two functionally relevant subpopulations that can independently influence circadian behavior. For example, by long-term exposure to constant light, the left and right hamster SCN can be induced to oscillate in opposite phases, with each side regulating locomotor activity, leading to activity profiles with two peaks per 24 hours (de la Iglesia and Schwartz, 2000). In rats, abnormal lighting cycles can be used to dissociate ventrolateral and dorsomedial subdivisions of the SCN from each other, resulting in simultaneous expression of rhythms with two different periods; each activity component apparently is driven by a different region of the SCN. These experiments emphasize that the multioscillatory nature of the circadian system can be appreciated even within the SCN, and that coupling among SCN neurons normally prevents conflicting output signals.

### Peripheral Oscillators

For many years, the widely accepted dogma in the circadian field was that only the SCN possessed the capacity for self-sustaining, autonomous rhythmicity. The identification of a family of mammalian *Period* genes (homologues of *period*, a gene essential for circadian rhythmicity in *Drosophila*) helped to change this perception. The mammalian *Period* genes are widely expressed (Zylka *et al.*, 1998), suggesting that rhythmicity could occur in additional tissues. This was clearly shown to be the case in a landmark study by Balsalobre *et al.* (1998). Their demonstration that brief exposure to a high concentration of serum could lead to rhythmic gene expression in fibroblasts immediately transformed thinking about circadian oscillators. More recent single-cell analysis reveals that fibroblasts have ongoing (but uncoordinated) rhythms, and a serum pulse merely synchronizes these rhythms so that it can be detected in the population (Nagoshi *et al.*, 2004; Fig. 41.4B). The serum pulse is not a unique stimulus; acute activation of each of several distinct signaling pathways can induce a rapid molecular response and subsequent rhythmicity in fibroblasts, suggesting that multiple pathways converge upon the oscillator.

It is now generally believed that most mammalian cell types are capable of circadian rhythmicity. In normal circumstances, the rhythmicity in tissues outside the SCN is synchronized by SCN-dependent output signals. These signals include daily fluctuations in hormone levels (e.g., melatonin and glucocorticoids) and other physiological and behavioral rhythms (e.g., body temperature and food intake). Thus, there is a hierarchy of oscillators within the body. Rhythmic outputs controlled by the SCN serve as inputs to peripheral oscillators, synchronizing molecular rhythmicity among cells within a peripheral tissue (Fig. 41.3). In the absence of rhythmic input from the SCN, oscillators in some tissues become desynchronized and thus the organ as a whole loses detectable rhythmicity. In some other tissues, it appears that interactions among oscillating cells are sufficiently robust to maintain rhythmicity of the organ as a whole (Granados-Fuentes *et al.*, 2004). Although this suggests that there are circadian pacemakers in additional tissues besides the SCN, it is worth noting that only the SCN pacemaker appears capable of performing all roles expected of a circadian clock. Even peripheral organs that maintain rhythmicity appear insensitive to environmental lighting conditions and thus different tissues would oscillate with different periods and phases, so that their normal phase relationships to each other would be lost. It is thought that coordination of rhythms within a tissue may optimize organ-level physiological processes, whereas a circadian timing system in general may achieve “internal temporal order” among organs so that organs are prepared to function most efficiently.

The SCN generally function as master circadian pacemakers, but there is now compelling evidence that, under specific circumstances, oscillators in other brain areas including the dorsomedial hypothalamus can regulate circadian behavior in the absence of the SCN (Stephan, 2002; Gooley *et al.*, 2006; Taratoglu *et al.*, 2006). SCN-independent oscillators in the olfactory bulbs can also influence olfactory response rhythms (Granados-Fuentes *et al.*, 2006). Although these oscillatory mechanisms are likely normally overshadowed or coordinated in the presence of a functioning SCN, these examples reveal the importance of recognizing the potential physiological impact of tissue-autonomous oscillators outside the SCN. Our understanding of the implications of the hierarchical nature of the mammalian circadian timing system is advancing rapidly.

### Summary

Many cell types possess the capacity for circadian oscillation. Neurons within the SCN oscillate, and also

communicate with each other, such that the SCN are able to provide a coherent output resulting in rhythmicity of other functions. Oscillating cells in other tissues generally require occasional SCN-dependent input to remain synchronized. In some cases, however, cell-cell communication is adequate to maintain coordinated cellular rhythmicity in a tissue even in the absence of SCN input.

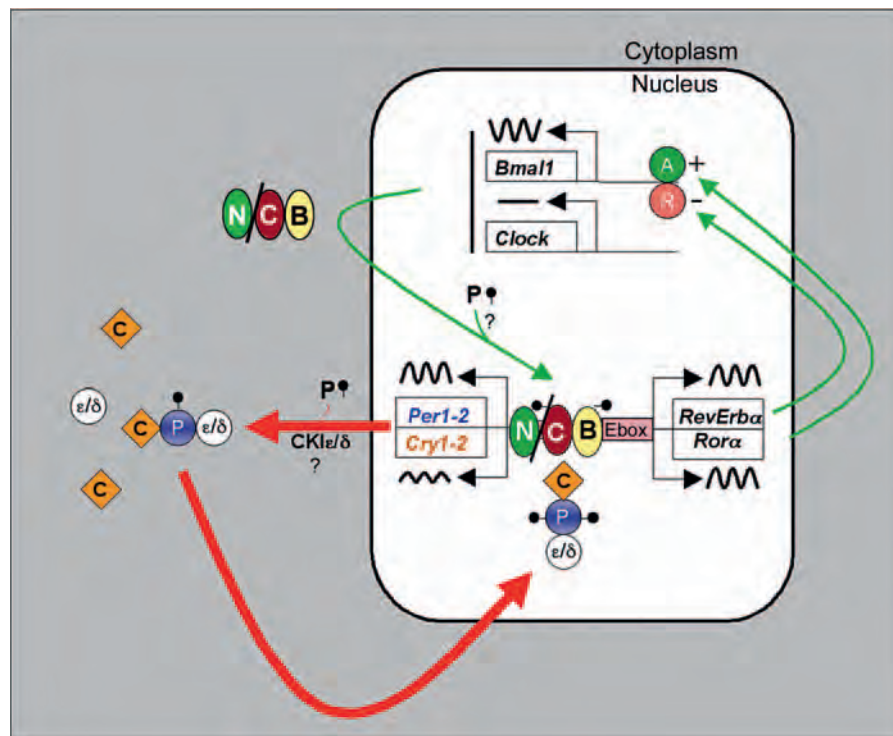

### THE MOLECULAR BASIS FOR CIRCADIAN OSCILLATION IS A TRANSCRIPTIONAL FEEDBACK LOOP

The preceding discussion emphasizes that circadian rhythmicity occurs within single, isolated cells. How do individual cells measure 24-hour time intervals? Studies conducted in many labs over the past 10 years have revealed a great deal about the molecular mecha-

nisms for mammalian circadian rhythmicity (Reppert and Weaver, 2002; Fig. 41.5).

Progress made in understanding the circadian clock mechanisms in the fruit fly, *Drosophila melanogaster*, was instrumental in developing our current understanding of mammalian clock mechanisms. Most of the genes involved in the fly circadian mechanism have mammalian homologs, and their roles in circadian function have now been examined in mammals. Although there have been some alterations in gene products performing specific functions, and gene duplication in mammals has led to greater complexity, the general features of the core clock mechanism are similar between flies and mammals (Box 41.1).

The molecular mechanism for measuring time on a 24-hour time-scale is based on a self-sustaining transcriptional/translational feedback loop present within individual cells (Fig. 41.5). According to the current molecular model for this feedback loop (Reppert and Weaver, 2002; DeBruyne *et al.*, 2007), heterodimers of

**FIGURE 41.5** The molecular mechanism for circadian rhythms in mammals is a transcriptional feedback loop. Transcriptional activation leads to expression of *Per* and *Cry* genes. Posttranslational modifications, including phosphorylation (black P lollipop) mediated in part by casein kinases (CKI $\epsilon$  and  $\delta$ ), affect the interactions of PER (P in blue circle) and CRY (C in gold diamond) proteins with each other and regulate nuclear entry of the inhibitory complex. CRY proteins are the major effector of negative feedback, whereas the high-amplitude rhythm of PER production controls the timing of negative feedback. Collectively, these events lead to a delayed, negative feedback to shut off the transcriptional activation, resulting in a negative feedback loop (red arrows). The positive drive to the system comes from the transcription factors CLOCK (C in red oval) and BMAL1 (B in yellow oval), or NPAS2 (N in green oval) and BMAL1. An interlocking loop involving the orphan nuclear receptors RORA (A) and REVERB- $\alpha$  (R) controls the expression of *Bmal1*. The antiphase rhythmicity in this positive loop (green arrows) is not essential for rhythm generation, but BMAL1 itself is necessary. (Adapted from Reppert and Weaver, 2002.)

## BOX 41.1

CIRCADIAN TIMING MECHANISMS IN *DROSOPHILA*

Virtually nothing was known about the genetic and molecular mechanisms controlling circadian rhythms until the late 1960s, when Seymour Benzer and his graduate student, Ron Konopka, identified the first mutations affecting circadian behavior. Most scientists at the time were skeptical that individual genes could affect complex behaviors. Benzer was nevertheless determined to identify the genetic underpinnings of behavior, and embarked on an ambitious program using the animal model of choice for genetic studies, the fruit fly *Drosophila melanogaster*. Benzer and colleagues exposed large numbers of flies to a chemical mutagen to isolate mutant lines with abnormal behavior in various assays. To identify circadian genes, Konopka screened for mutant fly lines that had lost the ability to predict dawn, as assessed by observing the time of day at which the young flies emerged from their pupal cases. Using this approach, Konopka and Benzer isolated three mutant lines with abnormal circadian rhythms. In one line, the flies emerged from their pupal cases too early, in a second line they were too late, and in a third line the flies emerged at random times. All three mutations mapped to the same

genetic locus, named “*period*” (*per*). Importantly, the three *period* mutants had similar circadian defects in their locomotor activity rhythms, which provided strong evidence that Konopka and Benzer had identified a gene central to the circadian pacemaker.

Benzer’s pioneering idea of using unbiased genetic screens to identify genes involved in circadian behavior has led to identification of additional “clock genes” by several other labs. The subsequent genetic, molecular, and biochemical studies have led to a remarkably detailed understanding of the *Drosophila* circadian pacemaker (Figure 1). CLOCK (CLK) and CYCLE (CYC) are two basic helix-loop-helix transcription factors that heterodimerize and bind to E-boxes within the *per* and *timeless* (*tim*) promoters. PER and TIM dimerize in the cytoplasm, with TIM stabilizing PER. Several kinases (DOUBLETIME, CASEIN KINASE 2, and SHAGGY [the *Drosophila* homolog of glycogen synthase kinase 3]) and PROTEIN PHOSPHATASE 2A regulate the stability and thus the rate of PER and TIM accumulation, and the timing of their nuclear entry. Once in the nucleus, the PER/TIM heterodimer (or possibly PER alone) binds to

**FIGURE 1** Model of the molecular circadian clock in *Drosophila*. In the core transcriptional feedback loop (left side of the figure), CLOCK (CLK) and CYCLE (CYC) positively regulate *period* (*per*) and *timeless* (*tim*) transcription. PER is phosphorylated by DOUBLETIME (DBT) and CASEIN KINASE II (CKII), while TIM is phosphorylated by SHAGGY (SGG). PER phosphorylation is also negatively regulated by PROTEIN PHOSPHATASE 2A. PER and TIM enter into the nucleus with DBT to inhibit the activity of CLK/CYC. In a secondary feedback loop shown in grey, VRILLE (VRI) and PAR DOMAIN PROTEIN 1ε (PDP1) regulate *clk* transcription.

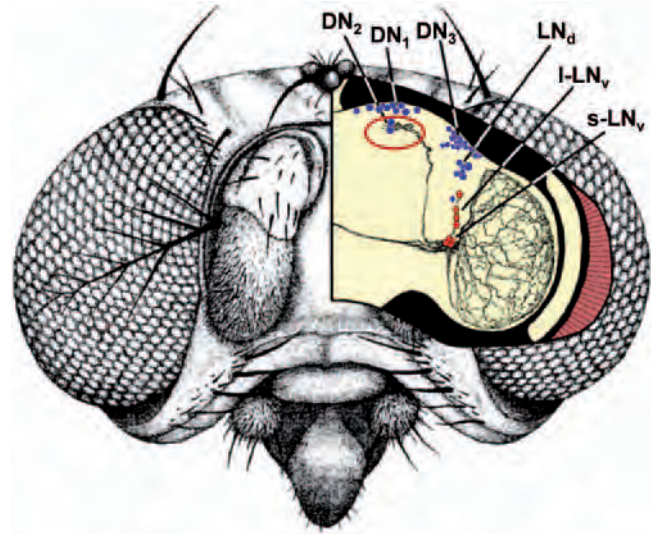

(continues)

## BOX 41.1 (cont'd)

the CLK/CYC dimer and disrupts its interaction with E-box sequences. The inhibition of *per* and *tim* gene expression is maintained for several hours, until the hyperphosphorylated and unstable PER and TIM proteins decay. CLK/CYC can once again bind to E-Box sequences and restart the circadian cycle. The kinase DOUBLETIME, which translocates into the nucleus with PER and TIM, may also play an important role for repression by regulating CLK phosphorylation and degradation. The CLK/CYC, PER/TIM feedback loop is essential for maintaining rhythms in *Drosophila*. There is a secondary feedback loop that appears to contribute to the precision and robustness of circadian oscillations through the regulation of *clk* mRNA levels.

The *Drosophila* molecular clock is synchronized primarily to environmental light/dark cycles by an intracellular photoreceptor, CRYPTOCHROME (CRY). Light activates CRY, and CRY then binds to and triggers the rapid degradation of TIM. Since TIM stabilizes PER, the degradation of TIM also results in a reduction in PER levels that resets the circadian pacemaker.

Despite the ability of cells throughout the fly to respond directly to light, there is increasing evidence for important interactions between oscillatory neurons in the regulation of behavior. About 150 neurons in the *Drosophila* brain have been identified as putative clock neurons due to their expression of circadian proteins, including PER (Figure 2). To dissect the roles of different groups of neurons, sophisticated genetic approaches have been used to target PER expression to specific neurons of mutant flies otherwise lacking PER, and to genetically eliminate specific cells by targeted expression of proapoptotic genes. These studies show that the ventral subpopulation of lateral neurons (the LN<sub>v</sub>s) is necessary and sufficient for locomotor activity rhythms to persist under constant darkness. The LN<sub>v</sub>s secrete a neuropeptide, pigment dispersing factor (PDF), that synchronizes other circadian neurons and regulates behavior. In addition, the LN<sub>v</sub>s play an important role in the control of morning behavioral activity, whereas a dorsal group of lateral neurons, the LN<sub>d</sub>s, is more important for the control of evening activity. A subpopulation of dorsal neurons also influences circadian behavior, particularly its responses to light. Future studies using more anatomically restricted manipulations will further elucidate the function of smaller subsets of neurons. Additionally, advances in live imaging techniques and *in vivo* electrophysiological recordings will provide information about how the activ-

**FIGURE 2** Circadian neurons in the brain of *Drosophila melanogaster*. Neurons expressing circadian proteins are shown in blue (dorsal neurons 1–3 [DN<sub>1</sub>, DN<sub>2</sub>, DN<sub>3</sub>] and dorsal lateral neurons [LN<sub>d</sub>]). Neurons expressing circadian proteins and the circadian neuropeptide pigment dispersing factor (PDF) are shown in red (small and large ventral lateral neurons [s-LN<sub>v</sub> and l-LN<sub>v</sub>]). The PDF-positive neural projections are drawn in black. The most important projections for the synchronization of the circadian network are the s-LN<sub>v</sub> projections directed toward the DN<sub>1</sub> and DN<sub>2</sub> groups. Indeed, PDF level oscillates in the termini of these projections (circled in red), presumably because PDF is rhythmically released. (Adapted from Helfrich-Förster, 2005.)

ity of neurons within the circadian network is integrated to control circadian behavior.

As the first components of the mammalian molecular clock were identified in the late 1990s, it quickly became clear that important concepts learned from the *Drosophila* circadian clock also apply to mammals. At the molecular level, the circadian pacemaker of both *Drosophila* and mammals involve homologous proteins in analogous transcriptional feedback loops. Interestingly, the first identified genetic cause of a human circadian rhythm disorder, familial advanced sleep phase syndrome, is due to a mutation in human *Per2*, a human homolog of the *Drosophila per* gene (Box 41.2). Furthermore, recent studies suggest that the neural mechanisms controlling *Drosophila* circadian behavior may also provide useful insights on mammalian circadian rhythms. In mammals, vasoactive intestinal polypeptide (VIP) plays a similar role as PDF in the fly. In both systems, a small subset of peptide-expressing pacemaker cells remain

## BOX 41.1 (cont'd)

rhythmic under constant conditions, and are believed to synchronize each other and maintain rhythmicity in other clock cells. Moreover, mutations affecting the *Drosophila* and mammalian ligands (PDF or VIP) or their receptors lead to a loss of coordinated rhythms among the clock neurons, resulting in arrhythmic behavior after several days in constant conditions. Thus, even the mechanisms that coordinate neurons of the circadian network appear to have been preserved, despite gross differences in the anatomy of insect and mammalian brains.

several basic helix-loop-helix, PAS-domain containing (bHLH-PAS) transcription factors (CLOCK and BMAL1, or NPAS2 and BMAL1) activate transcription of several genes, including *Period* and *Cryptochrome* genes, through E-box elements. High-amplitude rhythmicity in the rate of transcription of two *Period* genes (*Per1* and *Per2*; Fig. 41.6) is believed to be rate-limiting for formation of complexes between the PERIOD proteins and products of *Cry1* and *Cry2*. The CRY proteins are the primary transcriptional inhibitor proteins that disrupt the activity of the CLOCK:BMAL1 complex (Kume *et al.*, 1999; Sato *et al.*, 2006). The temporally regulated nuclear accumulation of PER/CRY complexes is believed to be critical for closing the feedback loop, disrupting the transcriptional activation of the *Per* and *Cry* genes (Lee *et al.*, 2001). This molecular oscillation, with alternation between a phase of transcriptional activation and a phase of PER/CRY-mediated repression, occurs with a cycle length of approximately 24 hours and results in rhythmic expression of a large number of clock-controlled and output genes.

Posttranslational modifications build a time delay into the oscillatory mechanism. Without this delay step, transcription of *Per* genes rapidly would lead to nuclear accumulation of PER:CRY complexes and a premature inhibition of their transcriptional activation, and the clock would either cycle with a period substantially less than 24 hours, or (if the feedback was very quick) the system would equilibrate to a nonrhythmic steady state. Phosphorylation of the PER proteins alters their intracellular localization, protein:protein interactions, and stability, and thereby contributes to regulating circadian cycle length. Rhythmic phosphorylation of PER proteins is due at least in

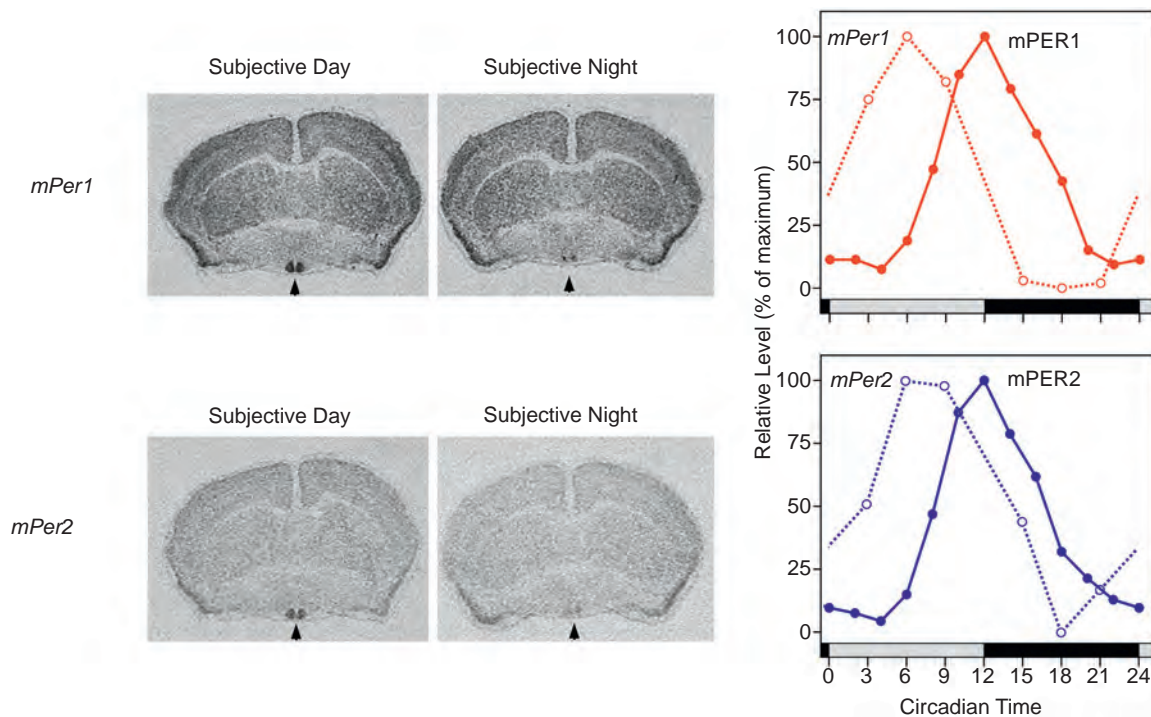

part to the activity of casein kinase 1 epsilon and casein kinase 1 delta, and mutations of these kinase genes alter circadian cycle length in flies, hamsters, mice, and humans. A circadian-based sleep disorder in humans is due to alterations in casein kinase-mediated phosphorylation of PER2 proteins, leading to rhythms having an aberrantly early phase (Box 41.2). Other important posttranslational processes likely further regulate protein stability; enzymes involved in proteasomal degradation of clock proteins likely influence circadian cycle length (Gatfield and Schibler, 2007).

An interlocked, second feedback loop is important for the rhythmic regulation of BMAL1. Among the E-box driven genes regulated by CLOCK and BMAL1 are two members of the orphan nuclear receptor gene family, *Rev-erb-alpha* and *Rora*. The protein products of these genes compete for binding to an orphan nuclear receptor binding site in the promoter of the *Bmal1* gene, and have antagonistic effects on *Bmal1* gene expression. Overexpression of the repressor, REV-ERB- $\alpha$ , in the liver greatly reduces *Bmal1* expression in this tissue, leading to loss of tissue-autonomous rhythmicity (Kornmann *et al.*, 2007). Thus, this loop is essential for regulating the production of BMAL1. Although rhythmicity of BMAL1 production is of relatively minor importance for maintaining rhythmicity, there is an absolute requirement for BMAL1 in the circadian oscillator (see later).

## Molecular Redundancies Revealed by Studies of Knockout Mice

The importance of the genes just discussed in the circadian mechanism has been revealed in part through studies of mice with targeted gene disruption. These

**FIGURE 41.6** High-amplitude circadian rhythms of *mPer* gene expression in the mouse SCN. **Left:** Adjacent sections through the SCN from brains collected at the time of peak *Per* transcript levels during the subjective day (left column) or during the middle of the subjective night (right column) were processed for *in situ* hybridization to detect *mPer1* and *mPer2* mRNAs. “Subjective” refers to the fact that the animals were in constant darkness on the day of tissue collection, rather than in a lighting cycle. The SCN are indicated by an arrowhead in each panel. **Right:** *Per* RNA (open circles and dashed lines) and PER protein (filled circles and solid lines) rhythms in mouse SCN. *mPer1* (upper panel) and *mPer2* (lower panel) RNA levels were assessed by *in situ* hybridization from samples collected on the first day in constant darkness. Protein levels were determined by counting nuclei within the SCN from sections processed for immunohistochemical detection of mPER1 and mPER2. The bar below the panel represents the lighting cycle the animals were exposed to on days prior to the day of tissue collection. Circadian time 0–12 corresponds to subjective day, when the lights would have been on had the animals remained in a lighting cycle.

studies reveal that, in most cases, there is at least partial redundancy of function among members of these gene families (Table 41.1). Mice homozygous for mutation of either *mPer1* or *mPer2* alone have period defects and/or a gradual loss of rhythmicity, whereas mice homozygous for disruption of both *mPer1* and *mPer2* become arrhythmic immediately in constant darkness. Similarly, mice with targeted disruption of either *mCry1* or *mCry2* have altered circadian period length, whereas the double-mutant mice lose circadian rhythmicity (e.g., become arrhythmic) immediately upon placement in constant darkness. Whereas mice homozygous for a semidominant mutation in the *Clock* gene (*Clock*<sup>Δ19</sup>) have severe behavioral and molecular phenotypes, mice with targeted disruption of *Clock* (and thus lacking CLOCK protein) unexpectedly retain behavioral rhythmicity. The closely related bHLH-PAS transcription factor NPAS2 (also called MOP4) apparently maintains the circadian clock in the absence

of CLOCK (Fig. 41.7). CLOCK appears to be much more abundant than NPAS2 in the SCN, and under normal circumstances it appears that transcriptional regulation occurs primarily through CLOCK:BMAL1 heterodimers. It remains possible that specific genes, or specific tissues, may be controlled to a greater extent by NPAS2:BMAL1 heterodimers.

An exception to the general rule of redundancy within gene families is BMAL1, which is necessary for maintenance of behavioral rhythmicity. A closely related protein, BMAL2, is not able to substitute for BMAL1 in maintaining behavioral rhythmicity.

### Clock-Controlled Genes: From the Core Clockwork to Cellular Rhythms

Genes that participate in the core negative feedback loop and are necessary for its function are called “clock genes.” The impact of the molecular feedback loop

## BOX 41.2

## CIRCADIAN-BASED SLEEP DISORDERS

The normal timing of sleep in young adult humans is from approximately 11 P.M. to 7 A.M. Most people will voluntarily move sleep to a later time when free of work constraints, and readily readjust their schedule back to an earlier time when the work week begins again. Several disorders affecting the timing of sleep and wake have been described, however, that affect the timing of sleep.

Based on information discussed elsewhere in this chapter, the most obvious disorder would be “Non-24-hour sleep wake syndrome,” in which individuals fail to entrain to the 24-hour day. This is relatively frequent in blind individuals, and is likely due to inadequate input to the SCN via the retinohypothalamic tract. These individuals have intervals where their biological day and night coincide with the solar day and night, but then the difference between their free-running period (usually ~24.5 hours) and the 24-hour day causes them to drift out of phase with the environment. This results in periods of insomnia and daytime drowsiness (when the individuals are out-of-phase) alternating with periods of coordination with the environment. Melatonin, administered at 24-hour intervals, is useful in synchronizing some blind individuals to a 24-hour cycle length.

Two additional disorders are delayed sleep phase syndrome (DSPS) and advanced sleep phase insomnia (ASPS). The former is characterized by late awakening and late bedtimes (typical wake interval from noon to 0400), and an apparent inability to reset the clock to earlier times of day. This disorder frequently begins in adolescence or in college, but is frequently noticed when individuals enter the working world as young adults; it is not considered unusual for young adults to have late-shifted schedules. ASPS, in contrast, is characterized by early morning awakening and an inability to maintain wakefulness into the evening (typical wake interval is from 0400 to 2000).

Studies of familial cases of ASPS have identified two genes which, when mutated, contribute to ASPS. Remarkably, these genes were already discussed in the context of the core circadian feedback loop defined in mice. The mutations defined in humans are a Serine → Glycine mutation at position 662 of human PER2 (within the casein kinase interacting domain of PER2), and a Threonine → Alanine mutation at position 44 of casein kinase I delta (a mutation that destroys the ability of

the kinase to phosphorylate substrates, including PER2). Many cases of ASPS are sporadic, and there is a natural tendency for normal, healthy elderly to live in an advanced phase (for reasons that are unclear). Nevertheless, finding that ASPS can be linked to mutations in human genes that are part of the core circadian oscillator strongly suggests that clock mechanisms studied in mice provide important information on the regulation of human rhythmicity.

Environmentally induced sleep disruption is perhaps more familiar. Jet lag is induced by flying across several time zones, and represents the lack of coordination of the flyer’s body to the new local time. Individuals usually entrain to a phase-shifted environment at the rate of about 1 hour per day, although careful control over when light exposure occurs may improve this rate.

Another environmentally imposed disruption of circadian rhythms and sleep occurs with shift work. Most people working the night shift remain entrained to the solar day, so that their biological rhythms (e.g., alertness, temperature, and hormonal rhythms) are in opposition to the demands of the work schedule. Some of the negative health effects of shift work may be due to the stress caused by trying to sleep when the biological clock dictates it is time to be awake, and trying to be alert and productive when our body expects rest. Clear performance deficits occur when individuals attempt to work for extended periods, ignoring the need for sleep and the detrimental effects of performing complex job tasks at an adverse circadian phase.

TABLE 41.1 Gene Families Regulating Mammalian Circadian Rhythms

Gene family	Gene	Mutation	Allele type	Effect on behavioral rhythmicity
bHLH/PAS	<i>Clock</i>	Clock <sup>Δ19</sup> (exon skipped)	Dominant negative	Long period then arrhythmic
	<i>Clock</i>	Targeted disruption	Null	Slightly short period
	<i>Npas2 (Mop4)</i>	Targeted disruption	Deletion	Slightly short period
	<i>Clock + Npas2</i>			Immediately arrhythmic
	<i>Bmal1 (Mop3)</i>	Targeted disruption	Null	Immediately arrhythmic
Period	<i>Per1</i>	Targeted disruption	Null	Short period, gradual arrhythmicity
	<i>Per2</i>	Targeted disruption	Deletion	Short period, gradual arrhythmicity
	<i>Per2*</i>	Missense (S662G)	Dominant negative	Short period, advanced phase
	<i>Per3</i>	Targeted disruption	Null	Slightly short period
	<i>Per1 + Per2</i>			Immediately arrhythmic
	<i>Per1 + Per2 + Per3</i>			Immediately arrhythmic
Cryptochrome	<i>Cry1</i>	Targeted disruption	Null	Short period
	<i>Cry2</i>	Targeted disruption	Null	Long period
	<i>Cry1 + Cry2</i>			Immediately arrhythmic
Casein kinase	<i>CKIδ*</i>	Missense (T44A)	Dominant negative	Short period, advanced phase
	<i>CKIδ</i>	Targeted disruption	Null	Not known; lethal when homozygous
	<i>CKIε**</i>	Missense (R178C)	Dominant negative	Short period, advanced phase
Orphan nuclear receptor	<i>Rev-erb-α</i>	Targeted disruption	Null	Short period
	<i>RorA</i>	Deletion (Staggerer)	Null	Rhythm instability

Mutations and mutant phenotypes listed were studied in mice, except as noted by asterisks: \* indicates human, \*\* indicates Syrian hamster. Missense mutations are those that lead to a change in a single amino acid residue; the residue and the change are indicated in single letter format: S662G indicates that a Serine residue at position 662 of human PER2 is mutated to glycine.

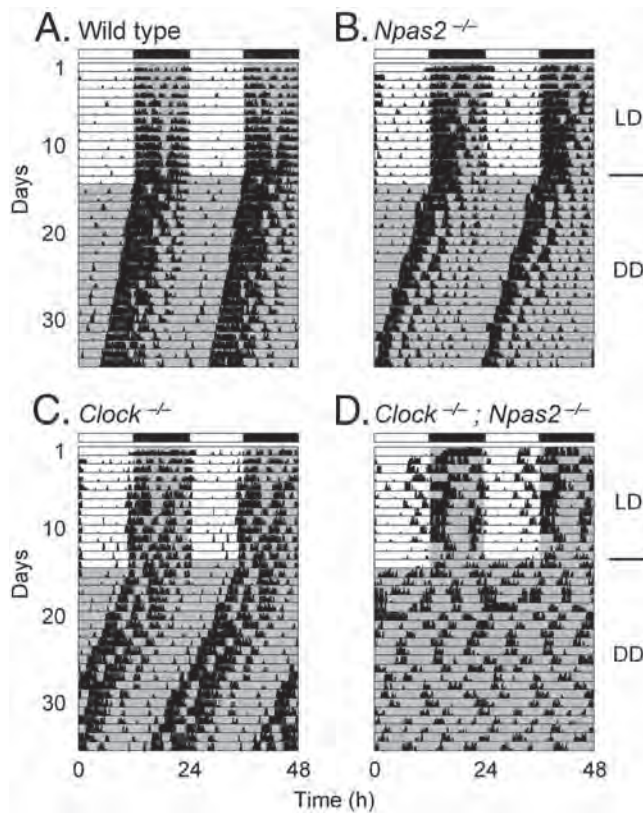

Null alleles are those without detectable protein products. Alleles designated as "Deletion" produce some protein products, but the deletion of genomic material results in deletion-mutant protein products that appear to lack functional activity. From a functional point of view, these are viewed as null alleles. "Null" alleles are those where there is either no product or the product is so truncated that it is irrelevant. "Dominant negative" alleles result in protein products that are altered in activity, such that the mutant product interferes with the activity of the product from the normal allele, thus producing a mutant phenotype in heterozygotes and a more severe phenotype in homozygotes (semidominant inheritance).

Additional genes not listed may modify the circadian feedback loop in more subtle ways. Only mutations that disrupt gene function are listed; some of these proteins also produce a circadian phenotype when their protein product is overexpressed (e.g., in transgenic animals).

occurs through the rhythmic regulation of additional genes, so-called "clock-controlled genes," which are distinguished from clock genes by the fact that they do not feed back on the core oscillatory mechanism in a manner that makes them necessary for rhythmicity. Some clock-controlled genes with E-box elements in their regulatory regions are controlled in the same manner as *Pers* and *Crys*: their transcription is activated directly by CLOCK:BMAL1 and inhibited by the activity of the PER/CRY complexes disrupting this transcriptional activation. The regulation of arginine vasopressin (AVP) in the SCN is a prototype for this mechanism (Jin *et al.*, 1999). The rhythmic expression of the AVP gene leads to a high-amplitude circadian rhythm of AVP in brain and in the cerebrospinal fluid

that is insulated from the osmotic regulation of AVP in blood. The rhythmic synthesis and secretion of AVP from SCN neurons may modulate electrical activity of nearby SCN neurons, increasing the amplitude of the SCN neuronal firing rhythm and thus affecting many rhythms. AVP of SCN origin also appears to play a role in regulation of the hypothalamo-pituitary-adrenal axis.

Notably, products of some genes regulated by the CLOCK:BMAL1 complex are themselves able to regulate transcription through additional regulatory elements. For example, a family of D-element binding proteins (DBP/TEF/TBP and E4BP4) are controlled via E-box elements, and these proteins compete for occupation of elements in responsive genes. Thus, the

**FIGURE 41.7** Molecular redundancy in the maintenance of mouse circadian rhythms. Panels A–D show double-plotted actograms from a wild-type mouse (A), an NPAS2-deficient mouse (B), a CLOCK-deficient mouse (C), and double-mutant CLOCK-deficient, NPAS2-deficient (D) mouse. Note that the double-mutant mouse becomes arrhythmic when placed in constant darkness (DD), whereas the mice of the other genotypes “free run” with a cycle length of less than 24 hours. The apparent rhythmicity when the double-mutant mouse is housed in a light-dark cycle (LD) is likely due to partial suppression of locomotor activity by light, a phenomenon called negative masking. Plotting conventions as in Fig. 41.1. Actograms provided by Jason DeBruyne, UMass Medical School (DeBruyne *et al.*, 2007).

rhythmic regulation of these transcription factors, and the multiple regulatory element combinations that can occur in responsive genes, results in a cascade leading to rhythmic gene expression with many possible peak times of expression and with tissue-specific regulation (Ueda *et al.*, 2005).

## Summary

The molecular basis for circadian oscillation is a transcriptional feedback loop. For rhythmic gene expression, a phase of transcriptional activation alternates with a phase of transcriptional repression, and the cycle length of this rhythm is approximately 24 hours. The bHLH-PAS proteins CLOCK and NPAS2

heterodimerize with BMAL1 to produce E-box dependent transcriptional activation. Among the genes controlled primarily by E-box regulation are *Per1* and *Per2*; their high-amplitude temporal regulation is critical to determining the timing of the phase of transcriptional repression, through regulating the formation of inhibitory complexes containing PER, CRY, and casein kinase proteins. Casein kinases phosphorylate the PER proteins, influencing their abundance and activity. This is likely important for building a posttranslational time delay into the feedback loop. The CRY proteins are the primary inhibitory components of the complex. In parallel with the regulation of “clock genes,” the feedback loop regulates the expression of effector genes and also of transcription factors that widen the influence of the circadian clock to affect key (often rate-limiting) metabolic steps in a tissue-specific manner.

## CIRCADIAN PHOTORECEPTION

In the following sections, we will discuss the mechanisms by which the circadian clock in the mammalian SCN is synchronized to the daily light:dark cycle.

### Entrainment of the SCN Pacemaker Occurs through Daily Phase Shifts

The intrinsic period of the circadian pacemaker is revealed by measuring it in constant environmental conditions, or in animals made insensitive to light (e.g., by removal of the eyes). Rhythms that are not entrained (e.g., not synchronized by a rhythmic environmental cue) are referred to as “free-running” rhythms. The period length of rhythms that are free-running is usually not exactly 24 hours (Fig. 41.1). Instead, the circadian oscillator has a species-typical intrinsic period. Rats housed in constant darkness have a free-running period of approximately 24.3 hr, whereas mice under the same conditions free-run with a period of approximately 23.6 hr. There are strain variations within these species as well. For an animal to entrain to a light:dark cycle that has a 24.0-hour cycle length, light must shift the animal’s clock each day by an amount equal to the difference between their intrinsic, free-running period and the 24-hour period of the lighting cycle. Although it might seem simpler for the clock to have a cycle length of exactly 24 hours (and forget about daily readjustments), there is seasonal variation in lighting conditions in natural environments, most notably a seasonal change

in the length of the light period each day, and a time-keeping system that tracks dusk and dawn each day is needed for accurate entrainment under these circumstances.

In assessing the response of the circadian system to light, it is often more informative to assess the response of animals to brief light pulses rather than to full light-dark cycles (Fig. 41.8). A brief pulse of light is provided when an animal is free-running in constant conditions, allowing control over the timing, intensity, and even wavelength of the stimulus. Experiments of this type reveal that the response of the circadian system to light is very dependent upon the time of the day at which the light exposure occurs (Fig. 41.8). In a night-active (nocturnal) animal like a mouse or hamster studied in constant conditions, the time when the animal “thinks” it is night (as reported by its locomotor activity rhythm) is referred to as “subjective night,” and the time that corresponds to internal daytime (the inactive period) is “subjective day.” Light falling soon after the animal becomes active (early in the subjective night) leads to a phase delay, for example, activity on subsequent

days begins at a later time, consistent with a light-induced shift in the timing of the oscillator. Conversely, light exposure late in the night will cause a phase advance. During large portions of the animal’s subjective day, light exposure does not lead to a phase shift. Plotting the response to brief pulses of light occurring at different times in the animal’s rest/activity cycle leads to generation of a phase response curve (Fig. 41.8). In general, the shape of the phase response curve to light is very similar across species, whether nocturnal or diurnal and regardless of whether their intrinsic period is less than or greater than 24 hours. Many pharmacological stimuli also cause phase-dependent phase shifts of the SCN oscillator, and the shape of the phase response curve to nonphotic stimuli differs from the phase-response curve to light.

### A Specific Retinal Photoreceptive System Mediates Circadian Entrainment

In mammals, detection of light by the circadian system requires the presence of the retina. Remark-

**FIGURE 41.8** Schematic representation of the phase-dependent phase shifts that occur following exposure of free-running animals to brief pulses of light. (A–E) Each panel represents an actogram of one animal housed in constant darkness and exposed to one, 1-hr light pulse (yellow box). The phase shift is the difference, on the day of the light pulse, between a line drawn through activity onsets before the light pulse (blue lines) with a line through activity onsets after the light pulse (yellow line). In some cases, the behavioral shift is not complete on the first cycle after the light exposure, and the shift seems to occur over several days. The intermediate activity onsets are called “transients” and are ignored when determining the phase after the shift. (F) Phase response curve. The phase shift induced by a brief light pulse is highly dependent upon the time at which the light exposure occurred. Circadian time (CT) 12 is defined as the time of activity onset in a nocturnal animal. Light exposure occurring during the biological daytime (CT 0–12) does not cause a shift. Responses occur only during the animals’ biological nighttime. Early in the subjective night, light exposure delays the clock, so activity begins at a later time on subsequent cycles. (C) Late in the subjective night, light exposure causes a phase advance as detected by earlier activity onsets after the light pulse. (D,E) Phase-dependent phase shifts allow the circadian oscillator to be entrained to environmental cycles.

ably, however, the retinal photoreceptors that are required for visual image formation are not needed for circadian photoreception. Studies of mutant mice show that circadian sensitivity to light persists even in mice with virtually complete loss of the rods and cones. Other nonvisual responses to light (inhibition of locomotor activity, suppression of nocturnal melatonin secretion, and pupillary constriction) also occur in the absence of rods and cones. These findings suggest that a photoreceptive protein expressed in the inner retina mediates nonvisual responses to light.

In mammals, a small percentage of retinal ganglion cells express an opsin-like pigment, melanopsin, that initially was identified as a putative photopigment in the light-responsive dermal melanophores of frog skin (Provencio *et al.*, 1998, 2000). More recently, melanopsin has been shown to contribute to circadian photoreception in the mammalian retina (for review see Peirson and Foster, 2006). Melanopsin-containing retinal ganglion cells respond directly to light, even when isolated from the rods and cones that normally provide their input, and their responsiveness requires the presence of melanopsin. These intrinsically photosensitive retinal ganglion cells (ipRGCs) have extremely large dendritic trees (spanning several hundred micrometers) in the retina, making them ill-suited for spatial localization (Fig. 41.9A). Remarkably, the phototransduction mechanism in melanopsin-containing cells appears to be more similar to the invertebrate visual signaling cascade (in which phosphoinositide signaling activates cation channels of the transient receptor potential channel type), rather than through the typical vertebrate photoreceptor cascade involving transducin, cGMP, and cyclic nucleotide gated ion channels (Peirson and Foster, 2006).

A direct anatomical connection from the retina to the SCN, the RHT, was first identified in the early 1970s. The axons of melanopsin-containing ipRGCs comprise the majority (ca. 80%) of the RHT fibers (Fig. 41.9B). The RHT is necessary for entrainment of circadian rhythms. The RHT also appears sufficient for entrainment, as destruction of virtually all other retinal pathways does not disturb photic entrainment of circadian rhythms. Thus, the melanopsin-expressing ganglion cells are ideally suited for a role as luminance detectors mediating circadian photoreception. Axons from the melanopsin-containing ganglion cells also project to the intergeniculate leaflet, modulating entrainment, and to the olivary pretectal nucleus, a site critical for pupillary constriction in response to light (Fig. 41.9C, D). Additional projections of the melanopsin-expressing retinal ganglion cells have been described that contribute to other, nonvisual responses to illumination (Fig. 41.9E). These include

projections to the ventrolateral preoptic area, important in the regulation of sleep, and to the ventral subparaventricular zone (SPZ) implicated in the acute inhibition of locomotor activity by light (called “negative masking”).

Despite being well-positioned to serve as *the* circadian photoreceptive molecule, melanopsin is in fact not the only photopigment involved in circadian photoreception. Melanopsin-deficient mice have a reduction in the effects of light on phase shifting, negative masking of locomotor activity, and pupillary responses at high light intensities, but these responses do persist so long as rods and cones are intact. Importantly, mice that lack rod and cone function and also lack melanopsin appear completely blind with respect to both image formation and nonimage forming responses to light (Hattar *et al.*, 2003; Fig. 41.10; see also Panda *et al.*, 2003). Rods and cones thus appear able to signal through other retinal ganglion cells or through the melanopsin-expressing RGCs, even if the latter cells are melanopsin-deficient. It remains to be determined whether destruction of the melanopsin-expressing cells prevents circadian photoreception. If this is the case, it will indicate that the melanopsin-expressing ipRGCs represent a specific conduit or “labeled line” through which information for nonvisual photoreception reaches the brain. The distinct pattern of anatomical connections formed by the melanopsin-expressing RGCs suggests that this is likely (Fig. 41.9E).

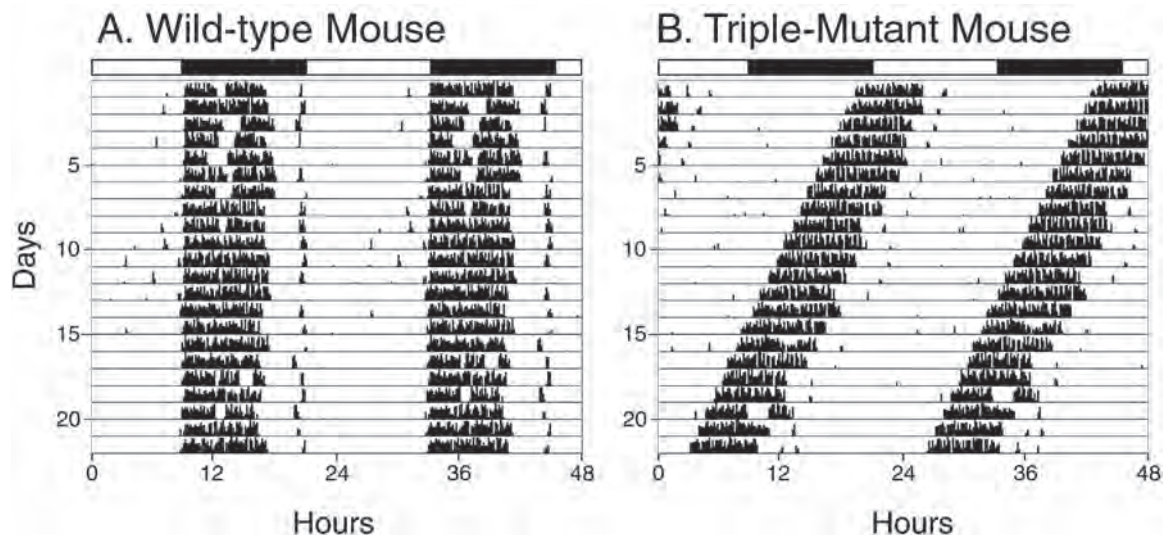

### Retinal Input to the SCN: Anatomy and Neurochemistry

The melanopsin-expressing retinal ganglion cells that project to the SCN in the retinohypothalamic tract use glutamate as their primary neurotransmitter. A large percentage of these retinal neurons also contain the neuropeptides Substance P and/or Pituitary Adenylate Cyclase Activating Peptide (PACAP). Application of these agents to SCN slices *in vitro* causes phase-dependent phase shifts of intrinsic SCN rhythms. Furthermore, glutamate receptor antagonists block light-induced phase shifts *in vivo*, revealing the functional importance of glutamatergic input to the SCN.

Axon collaterals of the melanopsin-positive retinal ganglion cells innervate neurons in the intergeniculate leaflet that express neuropeptide Y (NPY). These NPY-containing neurons project to the SCN as the geniculohypothalamic tract. The geniculohypothalamic tract is thought to play a major role in nonphotic phase shifting, a phenomenon in which behavioral arousal (usually accompanied by intense locomotor activity) during the circadian day leads to increased NPY release

**FIGURE 41.9** Circadian photoreception occurs primarily through retinal ganglion cells containing melanopsin. (A) Melanopsin-expressing retinal ganglion cells in the mammalian retina have large dendritic trees. These cells are ill-suited for spatial localization, but are ideally suited for luminance detection. This image shows an ipRGC's immunolabeled with an anti-melanopsin antiserum, in a flat-mounted human retina. Melanopsin immunoreactivity appears green. Note the localization of melanopsin in the cell body and throughout the dendritic arbor rendering the entire cell photosensitive. Also note the characteristic varicosities decorating the dendrites. Image provided by Ignacio Provencio, University of Virginia. Scale bar = 100 microns. (B) The SCN receives a strong, bilateral input from melanopsin-containing RGCs. Central projections of melanopsin-expressing retinal ganglion cells were detected using a beta-galactosidase reporter gene inserted into the melanopsin locus. Tissue was processed for histochemical detection of beta-galactosidase activity, resulting in deposition of blue reaction product in cells and processes containing melanopsin. Melanopsin-containing cell bodies are present only in the retina, so the blue staining seen in the brain represents axons of these retinal neurons. The right eye of the animal had been removed over 2 weeks prior to staining. Labeled, retinal fibers in the optic tract (ot) have degenerated on the apparent left side of the image, leaving weak, granular labeling. The staining in the SCN remains strong on both sides, indicating the extensive, bilateral projections to the SCN. (In contrast, other projections of these cells are ~95% crossed.) Melanopsin-containing processes also extend into the subparaventricular zone (SPZ). Scale bar = 100 microns. (C) Central projections of melanopsin-containing retinal ganglion cells, detected using beta-galactosidase activity as discussed in panel B. The olivary pretectal nucleus (OPN) and intergeniculate leaflet (IGL) receive a crossed input from melanopsin-expressing retinal ganglion cells. Image provided by Samer Hattar, Johns Hopkins University School of Medicine (Hattar *et al.*, 2006). (D) Melanopsin is localized within a subset of retinal projections. The anatomical level is comparable to Panel C. The projections of the entire population of retinal ganglion cells were revealed by intraocular injection of cholera toxin B (CTB) subunit three days prior to tissue collection, allowing anterograde labeling of the fibers of all retinal ganglion, followed by detection of the toxin (green). Note the intense labeling of the dorsal subdivision of the lateral geniculate nucleus (LGd). Melanopsin expression in retinal terminals was detected by red immunofluorescence; in this merged image, the overlap of red and green channels in the melanopsin-containing retinal ganglion cells yields yellow labeling in the IGL and OPN. Scale bar in D (applies to C and D) = 500 microns. Image provided by David Berson, Brown University (Hattar *et al.*, 2006). (E) Schematic illustration of the axonal projections of melanopsin-expressing retinal ganglion cell. Principle targets (SCN, OPN, IGL, and lateral habenula [LHb]) are indicated by dark red shading. Secondary targets indicated by light red shading are the SPZ, superior colliculus, peri-supraoptic nucleus (pSON), and ventral subdivision of the lateral geniculate nucleus (LGv). Minor targets (not shown) include the preoptic area, bed nucleus of the stria terminalis, medial amygdaloid nucleus, anterior hypothalamic area, lateral hypothalamus, LGd, and periaqueductal gray. Adapted from Hattar *et al.*, 2006.

**FIGURE 41.10** Rods, cones, and intrinsically photosensitive retinal ganglion cells expressing melanopsin mediate circadian entrainment. Panel A is a double-plotted actogram of a control mouse showing normal entrainment to the light:dark cycle. Panel B shows a double-plotted actogram from a triple-mutant mouse, lacking rod and cone phototransduction mechanisms and also lacking melanopsin. Triple-mutant animals free-run as though there is no lighting cycle. Triple-mutant animals also lack pupillary constriction responses and acute inhibition of locomotor activity by light (Hattar *et al.*, 2003). The disruption of rod and cone signaling is accomplished by breeding to generate animals homozygous for disruption of the alpha subunit of rod transducin and the cone cyclic nucleotide gated channel A3 subunit. Actograms provided by Samer Hattar, Johns Hopkins University School of Medicine.

within the SCN and leads to a phase shift of activity rhythms. The indirect retinal pathway through the intergeniculate leaflet also appears to modulate photic entrainment.

The direct RHT and the indirect retino-geniculohypothalamic pathway converge in the SCN, in the “core”

region defined by the dense retinal input and by a subpopulation of neurons expressing vasoactive intestinal peptide (VIP). As noted earlier, VIP appears to play a key role in synchronizing the activity of SCN neurons. Another major input to the SCN core is a serotonergic input from the raphe nuclei, which mod-

ulates the impact of light input to the SCN through presynaptic serotonin receptors on RHT terminals.

Neurons of the core region project heavily within the SCN, to both the core and the surrounding “shell” region, and also beyond the SCN borders, primarily to the subparaventricular zone (SPZ) of the hypothalamus, a region along the third ventricle lying just caudal and dorsal of the SCN (Fig. 41.11; see later). The SCN shell receives inputs from the SCN core, and also from other hypothalamic and thalamic regions, limbic cortex, and brain stem. The core/shell organization of the SCN is most readily apparent in the Syrian hamster. There is increasing evidence for functional, as well as phenotypic, differences among neuronal subpopulations within the SCN (Silver and

Schwartz, 2005). Indeed, molecular, phenotypic, and functional heterogeneity of the SCN strongly suggests that a simple subdivision of the SCN into core and shell is inadequate for describing its complexity (Morin, 2007).

### Molecular Mechanisms of Entrainment: Light-Induced *Per* Expression

*Per1* and *Per2* gene expression are rhythmic in the SCN, with high levels during the daytime (Fig. 41.6). Peak nuclear PER protein levels are achieved at the time of the light-to-dark transition. These molecular rhythms persist in constant darkness. Exposure to light at night causes a transient increase in both *Per1* and *Per2* transcript levels. Light-induced increases in PER1 and PER2 protein also occur, but are difficult to detect early in the night due to the high levels of PER already present. As with many other signaling responses, *Per* gene expression in the SCN is unresponsive to light exposure during the subjective daytime. (A third *Period* gene, *Per3*, is unresponsive to light even at night. *Per3* appears to be an output gene, rather than being part of the core circadian oscillatory mechanism or the resetting mechanism.)

An increase in PER1 and PER2 levels early in the night would extend the period of transcriptional inhibition by the PER/CRY complex. This may be the mechanism by which light exposure early in the night causes a phase delay. In contrast, light-induced PER expression late in the night would lead to an earlier-than-normal initiation of PER/CRY-mediated inhibition, resulting in an advance of SCN molecular rhythmicity in subsequent cycles. Thus, light-induced alterations of PER expression and interaction of the light-induced PER with the molecular feedback loop may explain the phase-dependent phase shifting effect of light shown in Figure 41.8 (earlier).

Although light does not influence *Per* levels during the animal’s subjective daytime and does not cause phase shifts at this time, nonphotic manipulations can cause phase shifts when administered during the daytime (e.g., novelty-induced voluntary locomotor activity, arousal, serotonin receptor activation). These manipulations lead to reduced *Per* gene expression in the SCN. Thus, acute regulation of *Per* gene expression may be the mechanism by which a variety of manipulations affect circadian phase.

### Summary

The circadian clock in the SCN is entrained to the daily light-dark cycle by light causing phase-dependent phase shifts each day. The retinae are

**FIGURE 41.11** Distribution of vasoactive intestinal peptide (VIP) immunoreactivity in the rat brain reveals the major output pathways from the SCN. Staining reveals VIP-immunoreactive cell bodies in the SCN and their projections. The major projection of the SCN is to a cell column dorsal and caudal of the SCN, including the ventral (v) and dorsal (d) parts of the subparaventricular zone (SPZ) and the dorsomedial nucleus of the hypothalamus (DMH). (From Lu *et al.*, 2001.)

needed for entrainment, but the retinal photoreceptors necessary for visual image formation, the rods and cones, are not needed. Instead, a population of intrinsically photoreceptive retinal ganglion cells conveys information about the level of light to the SCN, via the RHT, and to other brain regions that regulate nonvisual photoreception. The photopigment in these retinal ganglion cells is melanopsin, and they utilize glutamate and neuropeptides as their transmitters. In the absence of melanopsin, rods and cones appear capable of signaling, perhaps through the ipRGCs, to result in nonvisual responses to light, including entrainment. The impact of nocturnal light exposure on SCN physiology includes numerous signaling responses and induction of *Per* gene expression. Light-induced alterations in *Per* gene expression likely provide a key role in resetting of the molecular feedback loop within SCN neurons.

## CIRCADIAN OUTPUT MECHANISMS

### From Molecular Feedback Loops to Firing Rate Rhythms

The molecular feedback loop within individual SCN neurons ultimately has its impact on physiological processes through regulation of SCN neuronal firing rate. Rhythmic regulation of potassium channels in the membrane of SCN neurons appears to be critical for producing circadian rhythms in membrane potential and firing rate. Large-conductance, calcium-activated potassium channels (BK channels) are rhythmically expressed in the SCN, with high levels of transcript and of BK channel activity during the night, contributing to the reduction in firing rate at night (Meredith *et al.*, 2006). Disruption of the BK channel (*Kcnma1*<sup>-/-</sup>) results in higher SCN firing rate selectively at night, and the mutant mice have greatly reduced amplitude of several circadian output rhythms. In addition, fast delayed rectifier potassium currents (Kv3.1b and Kv3.2) are larger in the SCN during the circadian daytime, and blocking activity of these currents leads to loss of rhythmicity in SCN neurons (Itri *et al.*, 2005). It thus appears that multiple ionic mechanisms contribute to rhythmicity in SCN neuronal firing rate, and regulation of channel activity is probably accomplished through both transcriptional and posttranscriptional mechanisms.

Rhythmic firing of SCN neurons not only serves as its mechanism of communication with downstream target regions, but also plays an important role in synchronizing the cellular oscillators within the SCN to each other. When sodium-dependent action potentials

are blocked for several days, SCN neurons become desynchronized from one another. The mechanism for this may be as simple as the loss of rhythmic, synaptic release of neurotransmitters including VIP. There is some evidence for gap junction-mediated synchronization of SCN neuronal firing, but little evidence for gap junction-mediated coordination of circadian phase (Aton and Herzog, 2005).

### Humoral Outputs from the SCN also Influence Locomotor Activity Rhythms

The rhythmic electrical activity of SCN neurons likely leads to rhythmic neurotransmitter release and modulation of downstream, synaptic targets along defined anatomical pathways as discussed in greater detail later. Several lines of evidence indicate that the SCN also influences locomotor activity through secretion of humoral output molecules. Among these lines of evidence are the findings that (1) transplants of fetal SCN tissue that restore locomotor activity rhythms do not restore other rhythms, including endocrine rhythms, and (2) transplanted SCN tissue encapsulated so as to allow diffusion of small molecules while preventing axonal outgrowth nevertheless can restore locomotor activity rhythms in SCN-lesioned hamsters (Silver *et al.*, 1996). The latter finding suggests that substances secreted by the SCN act in regions near the SCN (but not in the SCN itself) to regulate locomotor activity. Three substances have been identified that are rhythmically expressed in the SCN and inhibit locomotor activity when infused near the SCN, and thus are proposed to play a role in regulating locomotor activity rhythms. These substances are transforming growth factor alpha, cardiostatin-like cytokine 1, and prokineticin 2.

### Summary

For oscillations in the abundance of circadian clock gene products in SCN neurons to affect physiology and behavior, the molecular feedback loop must impact on more overt aspects of cellular rhythmicity. One mechanism for this to occur is through circadian regulation of transcripts encoding ion channels, and indeed, two types of potassium channels have been identified that contribute to circadian rhythmicity. Through regulation of potassium channel levels, rhythmic transcription factor activity is translated into rhythmicity in neuronal firing rate and neurotransmitter release. Though much of the output of the SCN comes via synaptic interactions to downstream targets, substances released from the SCN by a humoral mechanism can influence locomotor activity.

## BOX 41.3

## CHRONOPHARMACOLOGY

Many drugs, toxins, and stressors have effects that vary over the 24-hour day. Many of these variations represent true circadian rhythms in responses (e.g., they persist in constant environmental conditions). Chronopharmacology is the subdiscipline of chronobiology that seeks to identify and understand these rhythms, and is an important field as altering the time of drug administration can have a profound impact on its efficacy, toxicity, and the ratio between these two measures (the therapeutic index). For this reason, there is often a specific time for optimal response to a chemotherapeutic agent, and this optimal timing varies between agents depending on their mechanism of action. Rhythmicity in drug effects could be due to alterations in bioavailability (absorption, metabolism, or excretion) or in end organ sensitivity. Rhythmic variation in therapeutic index has been well documented for several chemotherapeutic agents and anesthetics. There are also robust rhythms in responses to toxic agents, including infectious agents such as *E. coli* and endotoxin derived from bacterial cell walls. Recent

studies have begun to unravel the molecular mechanisms underlying rhythms in detoxification and drug sensitivity, and focus attention on rhythmicity within target cell populations.

### DIVERSITY OF OUTPUT PATHWAYS LEADING TO PHYSIOLOGICAL RHYTHMS

Animals that lack circadian rhythms (those with destruction of the SCN or genetic disruption of key circadian clock genes) survive and these animals generally can reproduce. Nevertheless, the circadian timing system is thought to optimize “internal temporal order” by coordinating rhythms in different tissues, and to allow anticipation of physiological demands imposed by the predictably changing environment. The impact of the circadian oscillator is exerted through the rhythmicity it imposes on physiological functions (Box 41.3).

The following sections will address the regulation of several physiological rhythms. In most cases, we emphasize how these rhythms are “wired” to the SCN through neuroanatomical pathways and emphasize rhythms for which the SCN can be viewed as a driving pacemaker. It is important to note that, to date, there has been relatively little effort to address the role of tissue-autonomous rhythmicity in the neural and peripheral tissues regulated by the SCN. (For impor-

tant exceptions to this statement, see Kornmann *et al.*, 2006; Granados-Fuentes *et al.*, 2006.)

### Amplification of SCN Output and Divergence of Output Pathways

Considering the pervasive influence of the SCN on rhythmic physiology, the direct anatomical output of the SCN is surprisingly limited. SCN efferents project heavily to a column of cells dorsal and caudal of the SCN that includes the subparaventricular zone (SPZ) and the dorsomedial nucleus of the hypothalamus (DMH) (Figs. 41.11, 41.12). Neurons in the SPZ and DMH in turn project to brain regions that ultimately regulate rhythmic activities (Fig. 41.12). Many effector regions receive a small, direct innervation from the SCN that converges with the larger, indirect output via the SPZ. The SPZ thus appears to relay and reinforce the direct output of the SCN, and allows convergence of influences from other brain areas. Lesions that kill cell bodies in the ventral SPZ (while leaving axons passing through this region intact) disrupt the circadian rhythms of sleep/wakefulness and locomotor activity (Lu *et al.*, 2001). Amplification of SCN output in the SPZ is thus necessary for these rhythms; direct

FIGURE 41.12 Schematic representation of neuroanatomical outputs from the rodent SCN. Location of target structures is not accurate to scale. Abbreviations: DMH, dorsomedial hypothalamic nucleus; dSPZ, dorsal subparaventricular zone; LHA, lateral hypothalamic area; MPO, medial preoptic area; PVN, paraventricular nucleus of the hypothalamus; VLPO, ventrolateral preoptic area; vSPZ, ventral subparaventricular zone. (Adapted from Saper *et al.*, 2005.)

SCN output to target sites is insufficient for rhythmicity. In a similar manner, the dorsal part of the SPZ is a key relay for amplifying output from the SCN to the medial preoptic area that generates the rhythm in core body temperature. Fiber-sparing lesions of the dorsal SPZ selectively disrupt the body temperature rhythm while leaving sleep and activity rhythms intact (Fig. 41.12).

Another level of amplification and integration occurs in the DMH, which is heavily innervated by the ventral SPZ as well as receiving direct innervation from the SCN (Figs. 41.11, 41.12). Lesions of the DMH specifically disrupt circadian rhythms of sleep, locomotor activity, corticosterone secretion and feeding, but not body temperature (Chou *et al.*, 2003).

### Circadian Regulation of Sleep and Wake

Among the most widely recognized roles of the circadian timing system is in the regulation of behavioral state. Our level of alertness is strongly influenced by two biological factors, the time spent awake and the circadian time, and also by environmental factors

including lighting level and the degree of monotony in the task. Studies conducted with human subjects reveal a strong and opposing influence of circadian time and the time spent awake, a phenomenon described as the “opponent-process” model for behavioral state control. With increasing time awake, subjects experience (see Fig. 42.6) a greater homeostatic drive to sleep. The circadian timing system opposes this drive, by providing an arousing signal that reaches peak levels late in the afternoon/early evening in humans (Chapter 42).

The influence of the circadian timing system on sleep is mediated by SCN efferents that only indirectly impact upon the brain regions that regulate sleep (see Chapter 42). As noted earlier, a pathway from the SCN via the vSPZ and DMH is necessary for circadian regulation of sleep. In contrast to the sparse connections of the SPZ to sleep-regulatory areas, the DMH is a primary source of input to the ventrolateral preoptic area (VLPO) and to the neurons of the lateral hypothalamus that secrete the neuropeptide, orexin, that are critical for regulation of sleep. The output from the DMH to the VLPO is GABAergic, therefore promoting wakefulness by inhibiting the “sleep switch” neurons. The output from the DMH to the orexin neurons in the lateral hypothalamus contains glutamate and thyrotropin-releasing hormone, and is presumably excitatory, thus promoting wakefulness. The DMH has few direct projections to the brain stem areas that comprise the ascending arousal system, but the orexin neurons have extensive, excitatory projections to these regions (Saper *et al.*, 2005). Thus, a multistage pathway from the SCN to sleep regulatory centers allows integration of other inputs (emotional and cognitive inputs as well as the homeostatic drive for sleep) and sharp transitions between states, rather than simple and direct command control of behavioral state. The importance of orexin neurons in coordinating the activity of this system is revealed by narcolepsy, a sleep disorder caused by an apparently autoimmune destruction of the orexin-containing neurons in the lateral hypothalamus, and mimicked in animal models by disruption of orexin or orexin receptors.

One relatively small subclass of sleep disorders are the circadian-based sleep disorders. As discussed in Box 41.2, in circadian-based sleep disorders, the problem is with the relative timing of sleep, rather than its initiation or maintenance (as in more classical types of insomnia).

### Circadian Regulation of Neuroendocrine Functions

The SCN output pathway leading to rhythms in adrenal corticosteroid secretion starts with a projection

from the SCN to the paraventricular nucleus of the hypothalamus (PVN). A subset of neurons in the PVN contain corticotrophin releasing hormone (CRH), and project to the external zone of the median eminence. CRH, released into the pituitary portal system, regulates the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary. ACTH, in turn, is carried in the bloodstream to the adrenal gland, where it stimulates secretion of adrenal steroids. Adrenal steroids feed back to inhibit CRH and ACTH release in a typical neuroendocrine feedback loop. One would expect that a feedback loop of this type has a set point, where a steady state is reached that balances the releasing factor drive to increase secretion with the end-products inhibiting the releasing factors. This feedback loop is modulated by the circadian timing system, however: the set point for feedback apparently varies over the course of the day, such that higher corticosteroid levels are required to reduce ACTH release at some times of day than at others. As a result, corticosteroid levels vary over the course of the day with a sinusoidal rhythm. Light exposure at night can directly activate the sympathetic innervation of the adrenal gland, leading to increased corticosteroid production (Ishida *et al.*, 2005).

The SCN also regulates circadian rhythms in other neuroendocrine activities. In rodents, the timing of ovulation is strictly regulated and occurs early in the active period on the day of behavioral estrus (see de la Iglesia and Schwartz, 2006). In nocturnal species, ovulation is blocked by injection of the anesthetic, pentobarbital, early in the afternoon on the day in which ovulation is expected. Remarkably, after pentobarbital blockage of ovulation, ovulation occurs the following day—exactly 24 hours after it should have occurred. Ovariectomized, estradiol-treated female rats also have daily surges of luteinizing hormone in the late afternoon, indicating the neuroendocrine equivalent of ovulation even in the absence of the ovaries. These luteinizing hormone surges persist when animals are housed in constant darkness, and are not present in animals with SCN lesions. There is an SCN-dependent output that leads to daily activation of gonadotropin releasing hormone-containing neurons. This SCN output is an ipsilateral neuronal connection (rather than a humoral one) in hamsters (de la Iglesia *et al.*, 2003).

Twice-daily prolactin surges can be induced in female rats by mating or by vagino-cervical stimulation that mimics mating and induces pseudopregnancy. The prolactin surges are timed by the SCN. These prolactin surges are ultimately regulated by dopamine released from the median eminence. Feedback of prolactin on the hypothalamic dopamine

neurons is also important. The anatomical pathway from the SCN to the hypothalamic dopamine neurons has not been described in detail, but VIP neurons in the SCN and oxytocin neurons in the PVN appear to be involved (Egli *et al.*, 2004).

### Circadian Regulation of Autonomic and Pineal Function

A major class of physiological rhythms is in autonomic function. These pathways originate in the SCN, utilize GABA as a neurotransmitter, and generally project to the paraventricular nucleus of the hypothalamus (PVN). Neurons in the PVN (many containing oxytocin) have direct projections to the spinal cord, where they regulate the activity of autonomic preganglionic neurons. Additional pathways include modulation of vagal activity. These pathways regulate autonomic responses leading to circadian variation in blood pressure and heart rate. These pathways also influence metabolism through direct innervation of fat pads and the liver, the latter of which regulates the circadian rhythm in plasma glucose levels (Kalsbeek *et al.*, 2006; Cailotto *et al.*, 2005).

One very well-characterized pathway affecting an output rhythm through autonomic pathways is the pathway from the SCN to the pineal gland, critical for the rhythmic production of melatonin (Fig. 41.13A). GABA released from SCN neurons inhibits neurons in the PVN during the day, and the reduction in SCN GABA release at night apparently allows the PVN neurons to be more active, driving melatonin synthesis (Kalsbeek *et al.*, 2000). The PVN neurons project to autonomic preganglionic neurons in the intermediolateral cell column of the spinal cord. The preganglionic neurons project to the superior cervical ganglion, whose fibers innervate the pineal gland. Norepinephrine from these fibers increases the activity of the penultimate enzyme in melatonin biosynthesis, arylalkylamine N-acetyltransferase (AANAT), leading to melatonin synthesis (Fig. 41.13B). AANAT activity is controlled by a combination of transcriptional mechanisms and switch-like regulation of proteasomal degradation of AANAT protein.

### Circadian Regulation of Melatonin Is Critical for Seasonal Reproduction

Several strategies exist to deal with the varying environmental conditions and varying levels of resources that occur over the course of the year. These strategies include seasonal migration to allow highly mobile species to escape challenging conditions (Box 41.4), and seasonal regulation of physiology for those species that remain.

**FIGURE 41.13** (A) Schematic illustration of the neuroanatomical circuit regulating pineal melatonin secretion. Photic input detected in the retina is relayed to the suprachiasmatic nucleus (SCN), and from there to the paraventricular nucleus of the hypothalamus (PVN). A subset of PVN neurons projects to the intermediolateral cell column (IML) of the spinal cord. Preganglionic sympathetic cell bodies at thoracic levels 1 and 2 (T1 and T2) project to the superior cervical ganglion (SCG), which innervates the pineal gland. Norepinephrine released from the terminals of SCG neurons is the primary input to the pineal responsible for stimulating melatonin production at night. Light entrains the SCN clock controlling melatonin, but light at night also has an acute inhibitory effect on melatonin synthesis, by disrupting the sympathetic input to the gland. Blood melatonin levels drop within minutes after exposure to light at night. (B) Biosynthesis of melatonin from serotonin (5-hydroxytryptamine, 5-HT). The rate-limiting and highly rhythmic step is the regulation of arylalkylamine N-acetyltransferase (AANAT) activity, which modestly depletes the pineal gland of 5-HT at night as it converts 5HT to N-acetyl-serotonin (NAS). Hydroxy-indole-O-methyltransferase (HIOMT) converts NAS to melatonin (N-acetyl, 5-methoxytryptamine). There is no storage mechanism for melatonin; melatonin diffuses from the pineal into the cerebrospinal fluid and bloodstream as it is produced, making blood melatonin levels a good reflection of the sympathetic input to the gland.

## BOX 41.4

## LOST WITHOUT A CLOCK

An intriguing function of circadian clocks is their use in time-compensated sun compass orientation, a phenomenon that was first described by Karl von Frisch in foraging honeybees and by Gustav Kramer in migratory birds. Time-compensated sun compass orientation also is used by eastern North American monarch butterflies (*Danaus plexippus*) during their spectacular fall migration. During the fall journey, the butterflies use their navigation skills to fly south from the United States and southern Canada to overwinter in a few restricted sites atop the Transvolcanic Mountains in central Mexico, some having traveled distances approaching 3000 kilometers.

The amazing navigational abilities of monarch butterflies are part of a genetic program initiated in the migrants, as those that make the trip south are at least two generations removed from the previous generation of migrants. Time-compensated sun compass orientation is believed to be an essential component of navigation required for successful migration. Time compensation is provided by the butterfly's circadian clock. The clock allows the butterflies to continually correct their flight

direction, relative to changing skylight parameters, to maintain a fixed flight bearing as the sun moves across the sky during the day (Figure 1A). The importance of the circadian clock in regulating the time-compensated component of flight orientation in monarch butterflies has been shown in two ways. First, clock-shift experiments, in which the light-dark cycle in either advanced or delayed, cause predictable alterations in the direction the butterflies fly. Second, constant light, which disrupts the molecular clock mechanism, abolishes the time-compensated component of flight orientation. It is thus clear that time compensation is an absolute requirement for successful migration—without it the butterflies would simply follow the sun (Figure 1B).

**FIGURE 1** A. Monarch butterflies use a time-compensated sun compass to orient south during their fall migration. The butterfly circadian clock allows the butterflies to compensate for the movement of the sun. They are thereby able to maintain a constant bearing in the southerly direction over the course of the day. B. Monarch butterflies follow the sun without a functioning circadian clock. A broken circadian clock would disrupt the migration south, and the butterflies would not be able to travel successfully to their overwintering grounds.

Many mammalian species restrict breeding activity to specific times of year, resulting in birth of young in the spring and summer months when food is abundant and other conditions are most favorable for their survival. In many mammalian species, seasonal reproduction is accomplished through regulation of pineal melatonin secretion by the circadian timing system. Responses to seasonal changes in day length (so-called "photoperiodic responses") include seasonal reproduction, but also extend to a much wider array of physiological responses including seasonal molting of the coat (usually mediated by alterations in prolactin secretion), thermoregulatory adjustments (daily torpor and hibernation), alterations in metabolism and body weight, and alterations in behavior. These adjustments likely improve the probability of survival through challenging times. Like circadian rhythms, these seasonal responses are driven by a system that anticipates predictable environmental changes and prepares for them in a predictive, rather than reactive, manner.

The SCN-controlled circadian rhythm of pineal melatonin production controls photoperiodic responses in mammals. Melatonin is secreted into the bloodstream at night by the pineal gland. The nocturnal duration of melatonin secretion changes in parallel with the length of the night, making the melatonin signal a reliable internal cue encoding season. Removal of the pineal gland prevents seasonal responses to changes in day length, while administration of melatonin in patterns that mimic the profiles occurring at different times of year can predictably drive reproduction and other photoperiodic responses.

The actions of melatonin are mediated by specific, G-protein coupled receptors. Two receptor subtypes with high affinity for melatonin have been identified in mammals. The Mel<sub>1a</sub> (MT1) receptor subtype is responsible for the majority of melatonin receptor binding found in SCN and elsewhere in brain, while the Mel<sub>1b</sub> (MT2) receptor is expressed at considerably lower levels. Several photoperiodic species lack a functional Mel<sub>1b</sub> receptor gene, suggesting that the Mel<sub>1a</sub> receptor may be key for regulating seasonal responses.

The duration of melatonin receptor occupation is "measured" by responsive tissues, such that varying melatonin duration (as occurs over the course of the year) has profound effects on neuroendocrine function. The anatomical sites of melatonin receptor expression and melatonin action vary by species. In many species, Mel<sub>1a</sub> melatonin receptors in the pars tuberalis of the pituitary contribute to the regulation of prolactin secretion from the anterior pituitary. Melatonin receptors in the mediobasal hypothalamus contribute to gonadotropic responses important for the seasonal regulation of reproduction.

## Summary

The proximate output of the SCN is a rhythm of neuronal firing, which results in rhythmic synaptic and perhaps humoral activation of additional brain regions. The major target site for SCN axons is a region dorsal and caudal of the SCN, including the subparaventricular zone (SPZ) and extending into the dorso-medial hypothalamic nucleus (DMH). This extensive projection appears to amplify SCN neuronal output and provides a mechanism for the SCN to influence a wide variety of downstream targets in a manner that can be site-specific. The anatomical pathways leading to specific behavioral and physiological rhythms have been defined to varying extents. Already within the subparaventricular zone, there is divergence of the output pathway controlling rhythms in sleep/wake and locomotor activity (which requires the ventral SPZ) from the pathway regulating body temperature (which requires the dorsal SPZ).

One of the most extensively studied outputs is the pathway from the SCN, via the PVN and the sympathetic nervous system, to the pineal, regulating melatonin production. The circadian regulation of melatonin secretory duration regulates reproduction and other photoperiodic responses in seasonally breeding species. The regulation of photoperiodic responses is the most obviously adaptive role for circadian rhythmicity in mammals.

---

## GENERAL SUMMARY

---

Behavioral and physiological rhythmicity is widespread throughout the animal kingdom. A capacity for cell-autonomous rhythmicity exists in many cell types. Circadian rhythmicity in vertebrates and flies is based on an intracellular molecular feedback loop. Many mechanistic details of this molecular feedback loop have been elucidated in the past 10 years. There is frequently redundancy of function between closely related genes in mammals. The SCN serve as the coordinating pacemaker in the mammalian circadian timing system. In the absence of the SCN, rhythms in other tissues generally degrade because the synchronization between oscillators is lost. The SCN clock is entrained primarily by light. Lighting information is detected by a specific luminance-coding retinal system that involves intrinsically photosensitive retinal ganglion cells, that also serve as a conduit for information originating in rod and cone photoreceptors. SCN axonal output is focused dorsocaudally to the subparaventricular zone, and then diverges along specific ana-

tomical pathways to control a diverse array of rhythmic functions. Among the most physiologically important output rhythms in mammals is the regulation of pineal melatonin, as this hormone is key to regulating photo-periodic adjustments in response to changing day length. Other circadian outputs are of less obvious survival value, but an increasing understanding of the importance of the circadian influence on sleep/wake, metabolism, cardiovascular and neuroendocrine function, and resistance to toxicological challenges indicates that the circadian system dictates an “internal temporal order” that improves physiological and mental performance.

## Sleep, Dreaming, and Wakefulness

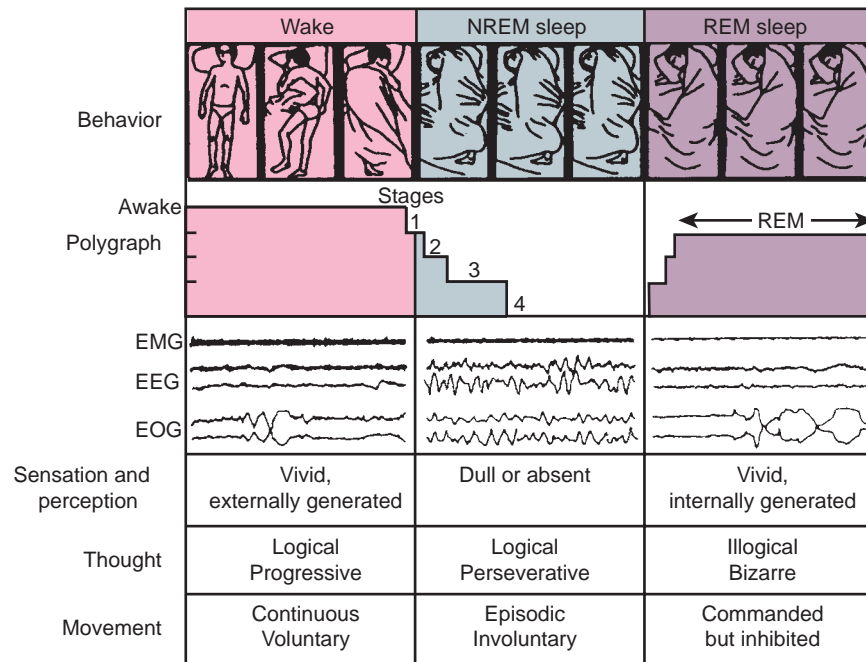

Sleep is a behavioral state that alternates with waking. It is characterized by a recumbent posture, a raised threshold to sensory stimulation, a low level of motor output, and a unique behavior—dreaming. The complex neurobiology of these behavioral features of sleep has been explored at the systemic, cellular, and molecular levels since the mid-1960s. Although these studies have provided substantial insight into the physiology and pathology of sleep, only recently have we begun to obtain definitive answers to the adaptive significance of sleep, the behavioral state that takes up one-third of our lives.

In contrast to sleep, the conscious behavior of waking is characterized by an active and deliberate sensorimotor discourse with the environment. For maintenance of waking behavior, neural gates must remain open for sensory input and motor output, the brain must be tuned and activated, and the chemical microclimate must be appropriate for processing and recording of information. Wakefulness is accompanied by conscious experience that reaches its highest level of complexity in adult humans. Waking behavior includes a number of cognitive aspects, such as sensation, perception, attention, memory, instinct, emotion, volition, cognition, and language, that make up our awareness of the world and self and form the basis of an adaptive interaction with our environment. This chapter focuses on the mechanisms of behavioral state control that make such interactions possible, with an emphasis on sleep as a component of adaptive behavior.

### THE TWO STATES OF SLEEP: RAPID EYE MOVEMENT AND NONRAPID EYE MOVEMENT

The behavioral signs of sleep vary regularly during every period of sleep; posture, arousal, threshold, and motor output change in a stereotyped, cyclic manner. Although these changes can be observed directly, their study is facilitated by placing electrodes on the scalp to measure the electrical activity of the brain. From these electroencephalograms (EEGs) (Fig. 42.1), two distinct substates of sleep—rapid eye movement (REM) and non-REM (NREM)—can be discerned. Both show interesting contrasts with waking, and these contrasts improve our understanding of states of consciousness.

At the onset of sleep, the brain begins to deactivate, and awareness of the outside world is lost. A well-described sequence of thalamocortical events causes the progressive slowing of brain waves, seen on EEG during this phase of NREM sleep. The threshold for arousal rises in proportion to the degree of EEG slowing, and at the greatest depth of sleep, awakenings are often difficult, incomplete, and brief. This sleep state is designated the slow wave or delta phase of NREM sleep. People have little or no recall of conscious experience in deep NREM sleep. Many autonomic and regulatory functions, such as heart rate, blood pressure, and respiration rate, diminish in NREM sleep, but some neuroendocrine activity

**FIGURE 42.1** Behavioral states in humans. Body position changes during waking and at the time of phase changes in the sleep cycle. Removal of facilitation (during stages 1–4 of NREM sleep) and addition of inhibition (during REM sleep) account for immobility during sleep. In dreams, we imagine that we move, but no movement occurs. Tracings of electrical activity are shown in ~20-s sample records. The amplitude of the electromyogram (EMG) is highest in waking, intermediate in NREM sleep, and lowest in REM sleep. The electroencephalogram (EEG) and electrooculogram (EOG) are activated in waking and REM sleep and inactivated in NREM sleep. Reprinted with permission from Hobson and Steriade (1986).

increases. The pulsatile release of growth hormone and sexual maturation hormones from the pituitary is maximal during sleep, with over 95% of the daily output occurring in NREM sleep.

At regular intervals during sleep, the brain reactivates into a state characterized by fast, low-voltage activity in the EEG, along with muscle atonia and rapid eye movements. This sleep state, termed rapid eye movement sleep because of prominent eye movements, differs from waking in several ways, but most notably by an inhibition of sensory input and motor output. Postural shifts precede and follow REM sleep; eye movements, intermittent small muscle twitching, and penile erection occur during REM sleep. The presence (or absence) of REM sleep erection is used clinically to distinguish between psychological and physiological male impotence. In REM sleep, many autonomic functions change; the fine control of temperature and cardiopulmonary function is lost.

People aroused from NREM sleep, especially early in the night, are confused, have difficulty reporting conscious experience, and return to sleep rapidly. Subjects aroused from REM sleep, especially during periods with frequent eye movements, often give detailed reports of dreams characterized by vivid hallucinations, bizarre thinking, and intense emotion.

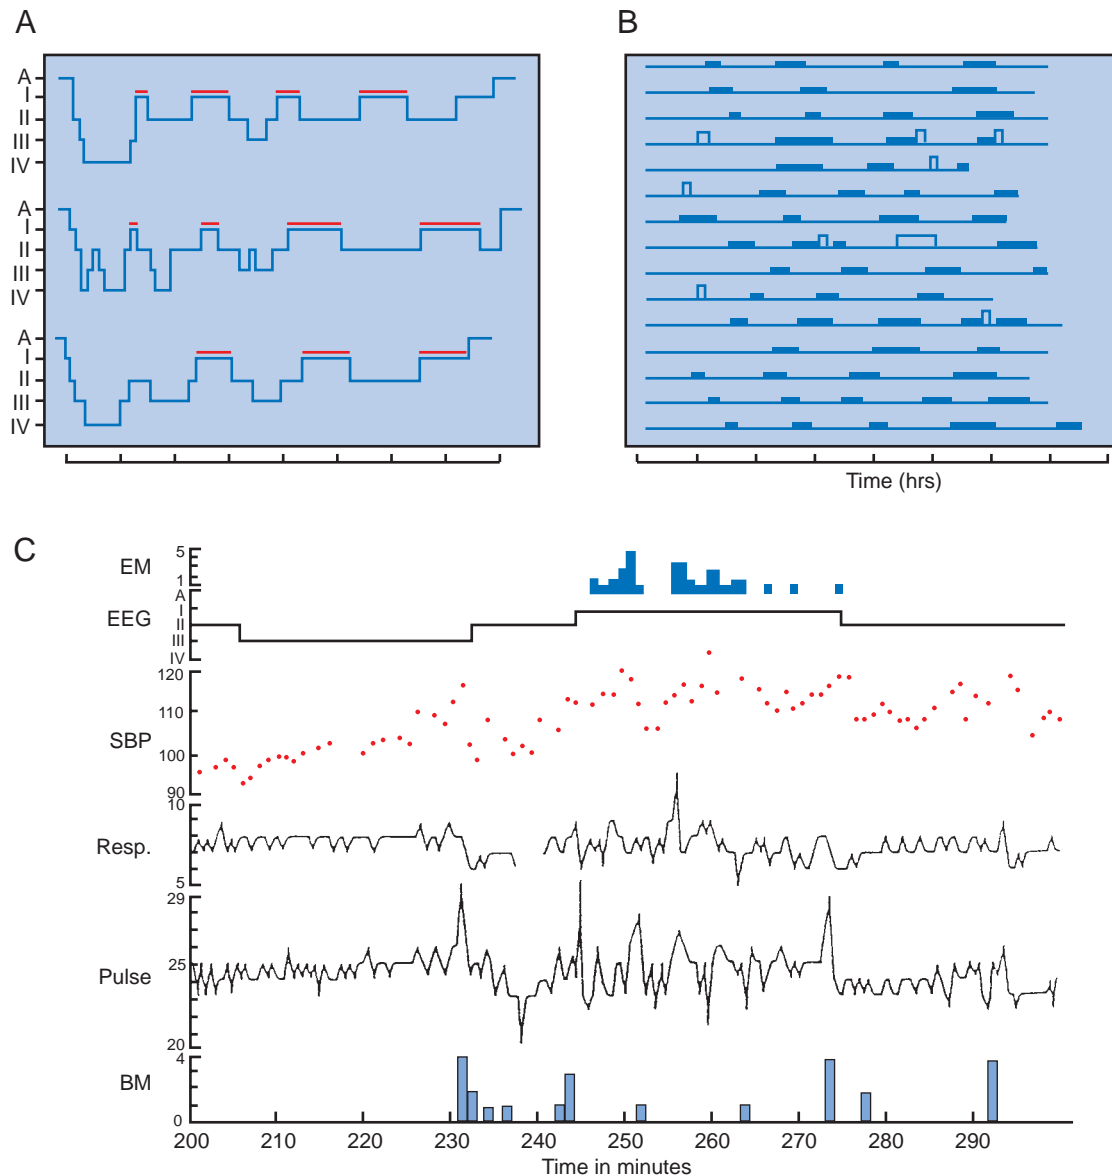

Although dreaming also occurs during NREM sleep, it is much more strongly associated with the activated brain of REM sleep.

### NREM and REM Phases Alternate throughout Sleep

REM and NREM sleep states alternate, with a cycle of about 90 min in adult humans. NREM phases are deeper and longer early in the night (Fig. 42.2A). Together with the regularity of the periods (Fig. 42.2B), this property has suggested that a damped oscillator is the underlying neural mechanism for NREM–REM cycles. The portion of the 24-h day devoted to NREM and REM sleep varies across the lifespan and across species (Fig. 42.3; Table 42.1).

### Sleep Appears to Have Multiple Functions

As a quiescent and ecologically protected behavior, sleep fosters conservation of energy, defense from predation, and an opportunity for repair of injury. The anabolic character of NREM sleep (e.g., brain and body inactivity and hormone release) suggests a rest and restoration function. In contrast, the high proportion of REM sleep in the developing brain, the high level

**FIGURE 42.2** Periodic activation in sleep cycles. (A) The sleep stages of three people are graphed. The first two or three cycles of the night are dominated by deep stages (3 and 4) of NREM sleep, and REM sleep (indicated by red bars) is brief or nonexistent. During the last two cycles of the night, NREM sleep is lighter (stage 2), and REM episodes are longer, sometimes more than an hour. (B) Fifteen nights of sleep. Each line represents one night of sleep, with REM periods shown as solid bars and periods of wake as taller, open bars. Each record began at the onset of sleep. The amount of time before the first episode of REM varies, but once REM has begun, the interval between episodes is fairly constant. (C) Eye movements (EM), EEG, systolic blood pressure (SBP), respiration (Resp.), pulse, and body movement (BM) over 100 min of uninterrupted sleep. The interval from 242 to 273 min is considered the REM period, although eye movements are not continuous during that interval.

of forebrain activity, and the stereotyped movements in REM sleep suggest a role of REM sleep in brain development and plasticity. Sleep is now known to be important for immune and hormone regulations and memory consolidation. Restriction of sleep to even four hours per night is sufficient to produce impairment of these functions. The crucial role of sleep is illustrated by studies showing that prolonged sleep

deprivation results in the disruption of metabolic and caloric homeostasis and eventually death.

### Summary

Sleep and waking are distinct, alternate behavioral states that are mutually exclusive, but interrelated. Within sleep, two substates of behavior are readily

**FIGURE 42.3** Portions of a 24-h day that are devoted to waking, REM sleep, and non-REM (NREM) sleep change over a lifetime. Although the timing of these changes *in utero* is not known with certainty (dotted lines), data from premature infants are consistent with REM sleep occupying most of life at a gestational age of 26 weeks. After 26 weeks, the time spent in waking increases until death.

distinguishable by electroencephalographic recordings, termed rapid eye movement (REM) and non-REM (NREM) sleep. NREM sleep in humans is subdivided further into four levels of increasingly deep sleep (stages I–IV). The characteristic behaviors of sleep include relaxed posture, elevated thresholds for sensory arousal, and diminished motor activity. The NREM and REM sleep phases alternate throughout the sleep period in cycles. Although all the functions of sleep are not yet known, much scientific evidence favors roles for sleep in the restoration, maintenance, and development of a range of physiological and cognitive functions.

## SLEEP IN THE MODERN ERA OF NEUROSCIENCE

Philosophical speculation about the nature of sleep and conscious behavior is as old as recorded history, and many philosophers, including the Ionian Greeks,

anticipated the physicalistic models that only recently have been articulated in modern neuroscience (for details of the following historical material, refer to Hobson, 1988). A signal event of the modern era of neuroscience was the discovery of the electrical nature of brain activity and, more specifically, the 1928 discovery of the human electroencephalogram (EEG) by the German psychiatrist Adolf Berger.

The state-dependent nature of the EEG helped Berger convince his skeptical critics that the rhythmic oscillations he recorded across the human scalp with his galvanometer originated in the brain and were not artifacts of movement or of scalp muscle activity. When his subjects relaxed, closed their eyes, or dozed off, the low-voltage brain waves associated with alertness gave way to higher voltage, lower frequency patterns (Fig. 42.4). These patterns stopped immediately when the subjects were aroused.

### Waking and Sleep Initially Were Viewed as Activated and Nonactivated States

Following Berger's discovery, a flurry of descriptive and experimental studies aimed at understanding the EEG itself, the full range of its state-dependent variability, and the control of that variability by the brain, were performed. Loomis and Harvey were the first to describe the tendency of the EEG to show systematic changes in activity as subjects fell asleep at night (tracings 3–5 of Fig. 42.4).

Because other mammals shared these correlations between arousal level and EEG, the Belgian physiologist Frederick Bremer made experimental transections of the mammalian brain to determine the nature and source of EEG activation (the low-voltage, fast pattern of waking) and deactivation (the high-voltage, slow pattern of sleep). Thinking the activity level probably depended on sensory input, Bremer transected the brain of the cat at the level of the first cervical spinal cord segment, producing a condition called *encephale isole*. He was surprised to find that the isolated forebrain was activated and alert despite this transection of a major portion of its sensory input. When he then transected the midbrain at the intercollicular level, creating the *cerveau isole* condition, he observed a sleep-like state with persistent EEG slowing and unresponsiveness. Bremer incorrectly inferred that removal of the trigeminal nerve afferents (which entered the brain stem between the level of the two cuts) accounted for the sleep-like state of the *cerveau isole*.

### Sleep Can Be Induced Electrically

That sleep might be an active brain process—and not simply the absence of waking as Bremer sup-

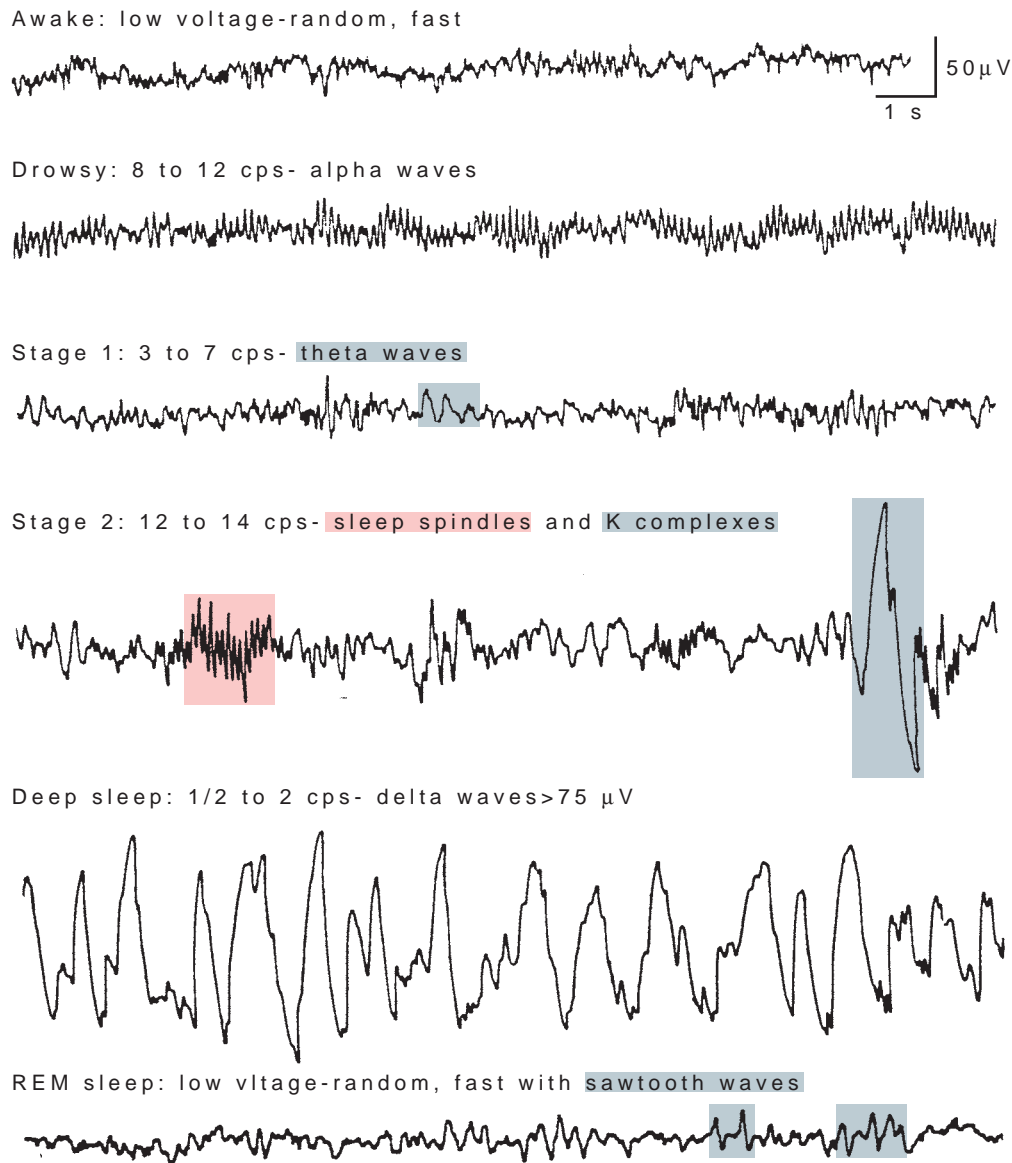

FIGURE 42.4 Electroencephalograms showing electrical activity of the human brain during different stages of sleep.

posed—was first experimentally suggested by the work of the Swiss Nobel laureate W. R. Hess. Hess was involved in a broad program investigating the effects of electrical stimulation of the subcortical regions mediating autonomic control (especially the hypothalamus). He discovered that by stimulating the thalamocortical system at the frequencies of intrinsic EEG spindles (short series of waves) and slow waves, he could induce the behavioral and electrographic signs of sleeping in unanesthetized cats. This discovery opened the door to the idea that sleep and waking might be active processes, each with its own specific cellular and metabolic mechanisms and functional consequences. This paradigm has since born abundant scientific fruit. For

example, the precise details of spindle and slow wave elaboration have been worked out (Steriade, 2000). In addition, the paradigm correctly anticipated the finding that central homologues of sympathetic neurons mediate waking, whereas central cholinergic neurons mediate REM sleep (Hobson and Steriade, 1986; Steriade and McCarley, 1990).

The intrinsic nature of brain activation was clearly demonstrated in 1949 when Giuseppe Moruzzi and Horace Magoun discovered that EEG desynchronization and behavioral arousal could be produced by high-frequency electrical stimulation of the midbrain. To explain their observation, Moruzzi and Magoun proposed that the nonspecific (i.e., nonsensory) reticu-

lar activating system operates both in series and in parallel with the ascending sensory pathways. This concept allowed for the translation of afferent stimuli into central activation (Bremer's idea) and opened the door to the more radical idea that not only waking but also adaptive behavior during sleep could be activated by brain stem mechanisms without a need for sensory stimulation.

Now that we accept the idea that the spontaneous activity of neurons determines the substages of sleep, it is difficult for us to appreciate the strength and persistence of its predecessor, the reflex concept of sleep. Scientific giants such as Ivan Pavlov and Charles Sherrington were so inspired by the reflex doctrine that they were convinced that brain activity simply ceased in the absence of sensory input (Box 42.1).

### The Brain–Mind Is Activated during REM Sleep

In 1953, Eugene Aserinsky and Nathaniel Kleitman, working in Chicago, discovered that the brain–mind did indeed self-activate during sleep. They observed regularly timed, spontaneous desynchronization of the EEG, accompanied by clusters of rapid, saccadic eye movements and acute accelerations of heart and respiration rates (see Figs. 42.1 and 42.2C). Working with Kleitman, William Dement then showed that these periods of spontaneous autoactivation of the brain–mind, namely REM sleep, were associated with dreaming and that this autoactivation process was also found in another mammal, the cat.

In adult humans, the intrinsic cycle of inactivation (NREM sleep) and activation (REM sleep) recurs with a period length of 90–100 min (Fig. 42.2). REM sleep occupies 20 to 25% of the recording time and NREM the remainder (75–80%) (Hobson, 1989). The NREM phases of the first two cycles are deep and long, whereas REM phases, during which sleep lightens, occupy more of the last two or three cycles.

### Input–Output Gating Occurs during Sleep

The paradoxical preservation of sleep in the face of dreaming in REM sleep began to be explained when Francois Michel and Michel Jouvet, working in Lyon in 1959, demonstrated that inhibition of muscle activity was a component of REM sleep in cats. Using transection, lesion, and stimulation techniques, the Jouvet team also discovered that the control system for REM sleep was located in the pontine brain stem. The pons is the source of EEG activation and REMs. Muscle inhibition is also mediated by pontine signals, but these are relayed via the inhibitory bulbar reticular formation to the spinal cord. Synchronous with each flurry of REMs, periodic activation signals, or pontogeniculo-occipital (PGO) waves, are sent from the pons up to the forebrain (and down to the spinal cord). The PGO waves trigger bursts of firing by geniculate and cortical neurons which, during waking, process sensory inputs and motor outputs, whereas other signals originating in the brain stem damp sensory input (via presynaptic inhibition) and motor output (via postsynaptic inhibition) (Calloway *et al.*, 1987).

#### BOX 42.1

### DEAFFERENTATION VERSUS INTERNAL MODULATION: A PARADIGM SHIFT FOR SLEEP NEUROBIOLOGY

Before the discovery of the neuromodulatory systems of the brain by the Swedish team led by Kjell Fuxe in the early 1960s, scientists who studied sleep could not understand that the brain could control its own state and that the stages of sleep were actively generated. Thus such neurobiological giants as Charles Sherrington were convinced that because sleep occurred *when* environmental stimulus levels were low (which is normally true), it also occurred *because* stimulus levels were low (which is false). In light of the discovery of the reticular activating system by Giuseppe Moruzzi and Horace Magoun in 1949 and REM sleep in 1953 by Eugene Aserinsky and Nathaniel Kleitman, this theory of deafferentation gradually

was replaced by a model of active internal control of the brain by the regular variations in balance between different brain regions and neuromodulators, especially NE, 5-HT, and ACh. This paradigm shift has not only led to the specification of increasingly detailed mechanisms for regulation of the brain state, but has opened the door to an appreciation of sleep as functionally significant in ways that are actively complementary to waking. This understanding of brain activity in sleep inevitably makes the emerging panoply of sleep disorders explicable and potentially treatable via a deeper understanding of sleep neurobiology.

*Edward F. Pace-Schott, J. Allan Hobson and Robert Stickgold*

Thus, in REM sleep the brain–mind is effectively offline with respect to external inputs and outputs and receives internally generated signals. Sensory input is also blocked during NREM sleep, but neither PGO waves nor the active inhibition of motor output is seen outside of REM sleep.

The cellular and molecular bases of these dramatic changes in input–output gating have been detailed using Sherrington's reflex paradigm together with extracellular and intracellular recording techniques (Hobson and Steriade, 1986). For example, such techniques revealed that during REM sleep, each motor neuron was subject to a 10-mV hyperpolarization, which blocked all but a few of the activation signals generated by the REM–PGO system. Furthermore, studies showed that this inhibition was mediated by glycine (Chase *et al.*, 1989). When this motor inhibition was disrupted experimentally by lesions in the pons, the cats, still in a REM-like sleep state but without the atonia, showed stereotyped behaviors (such as defense and attack postures). These behaviors reflected the activation, in REM, of the generators that produce the motor patterns for these instinctual, fixed acts (see Jouvet, 1999). In humans with REM sleep behavior disorder (see later), a similar acting out of dreams is observed.

These studies indicated that in normal REM sleep, motor inhibition prevents the motor commands of the generators of instinctual behavior patterns from being acted out. As a result, during REM these patterns are unexpressed in the outside world but occur in a fictive manner within the internal world of the brain–mind. One strong significance of these findings for a theory of dream consciousness lies in their ability to explain the ubiquity of imagined movement in dreams (Hobson *et al.*, 2000).

## Summary

The scientific history of sleep began with the application of electroencephalography in 1928, demonstrating that the electrical activity of the brain changed but did not cease during sleep. Subsequent refinements revealed the necessary role of the reticular formation for cortical arousal during sleep and the association of this arousal with desynchronized cortical activity. In addition, emulating the oscillatory EEG spindles of thalamic projections to cortex allowed sleep to be induced by direct thalamic electrical stimulation in experimental animals. Sleep studies in the 1950s showed REM sleep to be a “paradoxical” state in which sleep was at its deepest, yet accompanied by rapid eye movements and sympathetic signs of arousal, interpreted as dreaming, and accompanied by still further reductions of postural muscle tone. During REM sleep,

pontine waves of activity arise with each flurry of eye movements, during which motor activity is deeply depressed.

## ANATOMY AND PHYSIOLOGY OF BRAIN STEM REGULATORY SYSTEMS

### Brain Stem Reticular Formation Contains Specific Neuronal Groups Involved in Behavioral State Regulation

Moruzzi and Magoun's original concept of a nonspecific reticular activating system has been elaborated and greatly modified by subsequent anatomical and physiological studies. Two general principles have emerged. One is that most of the classic reticular core neurons have very specific afferent inputs and highly organized outputs. The other is that the reticular formation contains small groups of neurons that send widely branching axons to distant parts of the brain, where their neurotransmitters modulate brain function.

The input–output characteristics of each of the reticular formation's multiple subsystems reflect specific sensorimotor function, modulatory function, or both. For example, many neurons of the reticular formation are involved in the integration of eye, head, and trunk positions as these change to accommodate specific behavioral challenges and tasks. These reticular neurons receive inputs from skin, muscle, bone, and joint receptors in the periphery, which they integrate and link to the vestibular and cerebellar circuits that determine posture and movement. This information must also be integrated by higher brain structures in the visual, somatosensory, and motor systems to develop the complex motor patterns of adaptive behavior.

Several chemically specified neuronal groups also lie in the reticular formation. They have patterns of connections that differ from those of the previously discussed neurons of the reticular formation. Dahlstrom and Fuxe (1964) were the first to identify neuronal populations in the brain that produced norepinephrine (NE) and serotonin (5-hydroxytryptamine, 5-HT). (For additional discussion of these and other neurotransmitter systems discussed in this chapter, see Chapter 7 and Fig. 43.2.)

The groups of NE neurons (designated A1–A7 by Dahlstrom and Fuxe) are located in the pons and medulla in two major groups. One group consists of scattered neurons largely located in the ventral and lateral reticular formation. The most caudal neurons (A1–A3) project rostrally to the brain stem, hypothalamus, and basal forebrain, whereas the rostral groups (A5 and A7) project caudally to the brain stem and

spinal cord. These neuronal groups, together called the lateral tegmental neuron group (Moore and Card, 1984) appear to be involved in hypothalamic regulation and motor control.

The major NE cell group is the locus coeruleus (A4 and A6). This compact cell group is located in the rostral pontine reticular formation and central gray matter. The neurons of the locus coeruleus project widely but in a highly specific pattern. One group of locus coeruleus neurons appears to project largely caudally to sensory regions of the brain stem and spinal cord. Other neurons of the locus coeruleus project widely to the cerebellar cortex, dorsal thalamus, and cerebral cortex (Moore and Card, 1984). Thus, the projection patterns of the locus coeruleus appear to be primarily to sensory structures and to cortical structures involved in integration. From this we could expect the locus coeruleus to be involved in regulating sensory input and cortical activation. As we shall see, this expectation is in accord with the available information on function.

Two additional subsets of chemically identified neurons appear critically involved in behavioral state regulation. The first subset to be discovered contained the 5-HT neurons of the brain stem raphé (Dahlstrom and Fuxe, 1964) (B1–B9 in their nomenclature). These neurons extend from caudal medulla to midbrain and are located predominantly in the raphé nuclei, a set of neuronal groups located in the midline of the brain stem reticular formation. The largest numbers of 5-HT neurons are found in the midbrain nuclei, the dorsal raphé nuclei, and the median raphé nuclei (B8 and B9). These groups project rostrally, innervating nearly the entire forebrain in a pattern that also suggests a role in regulation of behavioral state.

The other important set of reticular formation nuclei involved in behavioral state control produces acetylcholine (ACh) as its neurotransmitter. ACh was well known as the transmitter of motor neurons, but early work indicated that ACh is found in nonmotor brain areas. Two sets of cholinergic neurons are involved in control of the behavioral state. The first set is two pontine nuclei: the laterodorsal tegmental nucleus and the pedunculopontine nucleus. Cholinergic neurons in these nuclei project to the brain stem reticular formation, hypothalamus, thalamus, and basal forebrain. The projection to the forebrain involves the second set of cholinergic neurons, those in the medial septum, the nucleus of the diagonal band, and the substantia innominata–nucleus basalis complex. This set projects to limbic forebrain, including the hippocampus, and to the neocortex.

In contrast to the modulatory neurons, which are characterized by their production of norepinephrine, 5-HT, and ACh, neurons in reticular formation nuclei

that are involved in sensorimotor integration typically produce either the excitatory transmitter glutamate or the inhibitory transmitter GABA.

### Sensorimotor and Modulatory Reticular Neurons Differ Functionally

Sensorimotor and modulatory neurons of the reticular formation differ markedly in their firing properties. Sensorimotor neurons, approximately 50 to 75  $\mu\text{m}$  in diameter, can fire continuously at high rates of up to 50 Hz and can generate bursts of up to 500 Hz. Their larger axons, especially those projecting to the spinal cord, have conduction velocities in excess of 100 m/s (Hobson and Steriade, 1986), making these neurons well suited to rapid posture adjustment and motor control.

Modulatory neurons are smaller (10–25  $\mu\text{m}$  in diameter) than sensorimotor neurons, and even those with long axons conduct their signals very slowly (1 m/s). They fire wider spikes (2 ms in duration) at much slower tonic frequencies (1–10 Hz) than sensorimotor neurons. In addition, they often show a very regular, metronome-like firing pattern, a reflection of the pacemaker properties they share with the Purkinje cells of the heart. As their leaky membranes spontaneously and slowly depolarize, they reach threshold, fire, and then self-inhibit, becoming refractory even to exogenous excitatory inputs. Modulatory neurons are much less likely than sensorimotor neurons to fire in clusters or bursts unless powerfully excited; even then, they adapt rapidly. Thus, modulatory neurons are well suited to detect novel input. Because of their vast postsynaptic domain, they can also help set behavioral and mental states.

The contrasting features of sensorimotor and modulatory neurons confer functionally important distinctions on their neuronal populations. The high rate of discharge of the sensorimotor neurons, acting through extensive interconnections that tie together sensorimotor neurons, causes exponential recruitment. This amplification occurs in response to novel stimuli requiring analysis and directed action (in the wake state) and in the generation of REM sleep, a state of sustained activation (when the system is offline with respect to its inputs and outputs).

In contrast, the feedback inhibition and pacemaker potentials of modulatory neurons allow the production of highly synchronized output during waking and sleeping. These features also somehow cause an exponential decline in the firing rate of these neurons during REM sleep, until firing stops. Studies suggest that this REM sleep inhibition may involve a GABAergic action that arises in the hypothalamus at sleep onset and

spreads through the brain stem as NREM sleep progresses to REM (Fig. 42.5). These contrasting properties of sensorimotor and modulatory neurons of the reticular formation are the physical basis for the reciprocal interaction that causes NREM–REM sleep cycles.

### Waking Requires Active Maintenance

Moruzzi and Magoun (1949) demonstrated that reticular formation is necessary to maintain the waking conscious state. Lesions in the midbrain reticular formation, sparing the lemniscal sensory pathways, result in a state that resembles NREM sleep. Although maintenance of the waking state often seems effortless, it requires brain mechanisms that compete with other active mechanisms that promote and mediate sleep.

Later, Dann *et al.* (1984) proposed that two mechanisms interact to regulate sleep–wake cycles. One of

these, outlined in detail in Chapter 41, is a circadian rhythm in the propensity to fall asleep (curve C, Fig. 42.5). The tendency to fall asleep is normally lowest early in the day, peaks at about late afternoon, and then declines in the evening. Thus sleepiness cycles independent of sleeping and waking. That is, if a subject is deprived of sleep, sleepiness will continue to follow a circadian rhythm. The second mechanism is a homeostatic property, designated S in Fig. 42.5. It increases as a function of the amount of time since the last sleep episode. S can be conceptualized as a sleep-promoting substance that accumulates during waking and dissipates during sleep. Although a large amount of work has been devoted to identifying a “sleep substance,” whether one or more such substances normally is involved in sleep regulation remains unclear (Strecker *et al.*, 2000; Krueger and Fang, in Lydic and Baghdoyan, 1999). Many factors likely contribute to the homeostatic regulation of sleep.

Waking is a complex state. Its fundamental features are the maintenance of sensory input from multiple receptors, the capacity for directing attention and accessing memory, the constant readjustments of posture, the maintenance of forebrain activation, and an array of motor output. It is worth noting here, however, that reticular formation plays a crucial role in the initiation and maintenance of both wakefulness and sleep. We now focus on the active control of sleep.

The onset of sleep occurs when the combined S and C factors near their peak and the environmental milieu is conducive to sleep. At this point, the brain stem and cortical mechanisms of waking are relaxed: vigilance lapses, muscle tone declines, eyelids close, and the EEG slows. Because the cortex is still active, removal of ascending influences often results in sudden unresponsiveness, which may be associated with dream-like imagery. This sleep onset mentation usually is abolished quickly by the thalamocortical oscillation of deeper NREM sleep. As NREM sleep begins, the incomplete relaxation of the mechanisms maintaining muscle tone may result in paroxysmal twitching, a form of myoclonus often affecting the legs.

### Hypothalamic Control of Sleep–Wake Transitions

Clinical and experimental findings have shown that lesions to anterior portions of the hypothalamus cause insomnia, and stimulation of this area promotes sleep, whereas lesions of the posterior hypothalamus cause hypersomnolence and neurons in this region decrease firing during sleep (Saper *et al.* 2001, 2005a). During NREM sleep, neurons in the ventrolateral preoptic area (VLPO) of the anterior hypothalamus show an increase in metabolic activity (Saper *et al.*, 2001, 2005). These VLPO neurons produce both the inhibi-

**FIGURE 42.5** The Borbely and Daan model of sleep regulation. Sleep is assumed to result from the actions of process C and process S. Process C follows a circadian rhythm and is independent of sleeping and waking. Process S, on the other hand, depends on sleep–wake behavior; S declines during sleep and rises continuously during sleep deprivation. The period of recovery sleep that follows sleep deprivation is more intensive but only slightly longer than normal. If curve C represents the threshold for waking up, then at any time, “sleep pressure” is the (vertical) distance between the S and C curves. The greater the distance, the greater the pressure to fall asleep. Reprinted with permission from Daan *et al.* (1984).

tory amino acid gamma-aminobutyric acid (GABA) and the inhibitory neuropeptide galanin and project to histaminergic neurons in the tuberomammillary nucleus (TMN) of the posterior hypothalamus as well as to brain stem noradrenaline (NE) and serotonin (5-HT) producing neurons of the locus coeruleus (LC) and dorsal raphe (DR) nuclei, respectively, all of which project widely to the thalamus and cortex where they promote waking (Saper *et al.* 2001, 2005, Fig. 42.6). The LC, DRN and TMN, in turn, innervate and inhibit the GABA and galaninergic neurons of the VLPO (Saper *et al.* 2001).

Saper and colleagues (2001, 2005) have suggested that this mutually inhibitory arrangement constitutes a biological analog of a bistable electrical “flip-flop” switch in which either the sleep (VLPO dominant) or wake (LC, DRN, TMN dominant) conditions are self-reinforcing stable states whereas intermediate states are highly transient (Fig. 42.7). The neuropeptide orexin (also called hypocretin) produced by cells in the lateral

hypothalamus plays a key modulatory role in this flip-flop mechanism by providing excitatory drive on aminergic neurons, thereby further stabilizing the waking end of the bipolar sleep–wake switch (Borbely, 1982; Borbely and Achermann, 2005; Daan *et al.* 1984, Fig. 42.5). In the sleep disorder narcolepsy, these orexin-producing neurons are lost, most likely due to an autoimmune mechanism (Black, 2005), and wake to sleep transitions can occur at inappropriate times.

### Homeostatic and Circadian Control of Sleep Onset

The two-process model of sleep propensity suggests that homeostatic mechanisms (Process S) interact with circadian factors (Process C) to regulate behaviorally expressed sleep and waking (Borbely, 1982; Borbely and Achermann, 2005; Daan *et al.* 1984, Fig. 42.5). The purine nucleoside adenosine is currently the most widely suggested endogenous somnogen—a substance whose accumulation in the brain over prolonged wakefulness constitutes the physiological basis of Process S (Basheer, *et al.* 2004). Although adenosine may directly inhibit basal forebrain cholinergic neurons that project to the cortex and promote waking (Basheer *et al.*, 2004) recent findings suggest that adenosine’s effects may occur elsewhere (Blanco-Centurion *et al.*, 2006) such as at A2A adenosine receptors in ventral striatal areas (Satoh *et al.*, 1999) or on GABAergic anterior hypothalamic and basal forebrain neurons projecting to the VLPO (Shiromani *et al.*, 1999). Evidence also exists for endogenous somnogenic actions of interleukin-1, prostaglandin D1, growth hormone releasing hormone (McGinty and Szymusiak, 2005) and the fatty acid oleamide (Mendelson and Basile, 2001).

Details of the molecular biological and cellular basis of Process C are in Chapter 41 (Lowrey and Takahashi, 2004). Briefly, molecular clocks in cells of the suprachiasmatic nucleus (SCN) of the anterior hypothalamus maintain a near-perfect 24-hour periodicity (Czeisler *et al.*, 1999) via interlocking positive and negative feedback control of transcription and translation of circadian genes (Lowrey and Takahashi, 2004). This endogenous clock is entrained to the ambient photoperiod via photoreceptive pigments like melanopsin in retinal ganglion cells (Peirson and Foster, 2006) that send glutamatergic signals to the SCN via the retinohypothalamic tract (Antle and Silver, 2005). The SCN conveys circadian information via the subparaventricular and dorsomedial nuclei of the hypothalamus to the VLPO to influence sleep–wake transitions (Saper *et al.*, 2005). Secretion of the pineal sleep hormone melatonin is also controlled by the SCN and provides an internal indicator of circadian time as well as feedback influence on the SCN via its melatonin receptors (Arendt, 2006).

**FIGURE 42.6** Integrated model of sleep onset and REM–NREM oscillation proposed by Shiromani *et al.* I. During prolonged wakefulness, accumulating adenosine inhibits specific GABAergic anterior hypothalamic and basal forebrain neurons, which have been inhibiting the sleep–active VLPO neurons during waking. II. Disinhibited sleep–active GABAergic neurons of the VLPO and adjacent structures then inhibit the wake–active histaminergic neurons of the TMN, as well as those of the pontine aminergic (DR and LC) and cholinergic (LDT/PPT) ascending arousal systems, thereby initiating NREM sleep. III. Forebrain activation by ascending aminergic and orexinergic arousal systems is disfacilitated. IV. Once NREM sleep is thus established, the executive networks of the pons initiate and maintain the ultradian REM/NREM cycle. ACh, acetylcholine; DRN, dorsal raphe nucleus; GABA,  $\gamma$ -amino butyric acid; LC, locus coeruleus; 5-HT, serotonin; LDT, laterodorsal tegmental nucleus; NE, norepinephrine; PRE, pontine reticular formation; TMN, tuberomammillary nucleus. From Pace-Schott and Hobson (2001).

**FIGURE 42.7** Thalamocortical oscillations in vivo. Sleep spindle oscillations are generated by synapses in the thalamus. (A, left) Potentials recorded through a microelectrode inserted in the deafferented reticular thalamic nucleus of a cat. The arrow points to one spindle sequence. (A, right) Spindle oscillations recorded from the thalamus of a cat with an upper brainstem transection that created an isolated forebrain preparation. The figure shows two spindle sequences (the second marked by an arrow) and, between them, lower frequency (delta) waves. (B) Neuronal connections involved in the generation of spindle oscillations. (C) Intracellular recordings of one spindle sequence (see A) in three types of neurons (cortical, reticular thalamic, and thalamocortical). Ca<sup>2+</sup>, calcium ions; IPSP, inhibitory postsynaptic potential.

### NREM Sleep Rhythms Require Thalamo-cortical Interaction

Reciprocally interconnected thalamic and cortical neurons form the circuits that are the physiological basis of the NREM oscillations including delta and slow (<1 Hz) oscillatory rhythms and the spindle and K-complex wave forms ((Steriade, 2000, 2006, see Fig. 42.4). In NREM, thalamic and cortical neurons shift into this oscillatory mode when the influence of ascending arousal systems of the brain stem, hypothalamus, and basal forebrain decrease. During waking, these ascending systems modulate thalamo-cortical circuits with the arousal-promoting neuromodulators acetylcholine (ACh), NE, 5-HT, and histamine. Similarly, during REM sleep, thalamo-

cortical rhythms are prevented by cholinergic thalamic activation originating from brain stem cholinergic nuclei (Steriade, 2000, 2006).

Intrinsic oscillations of NREM represent the combined influence of two neuronal mechanisms: (1) inhibitory influence by neurons of the thalamic reticular nucleus—a thin sheet of GABAergic neurons surrounding the thalamic periphery—on thalamic neurons projecting to the cortex; and (2) an oscillation within cortical neurons involving alternation between a prolonged hyperpolarization phase and a shorter, rapidly spiking, depolarized phase (Steriade, 2000, 2006, Fig. 42.8). This latter rhythm is generated entirely within cortical networks, is the neuronal basis of the <1 Hz slow EEG oscillation, and exerts an organizing or grouping influence on other intrinsic NREM sleep rhythms (Steriade, 2000, 2006).

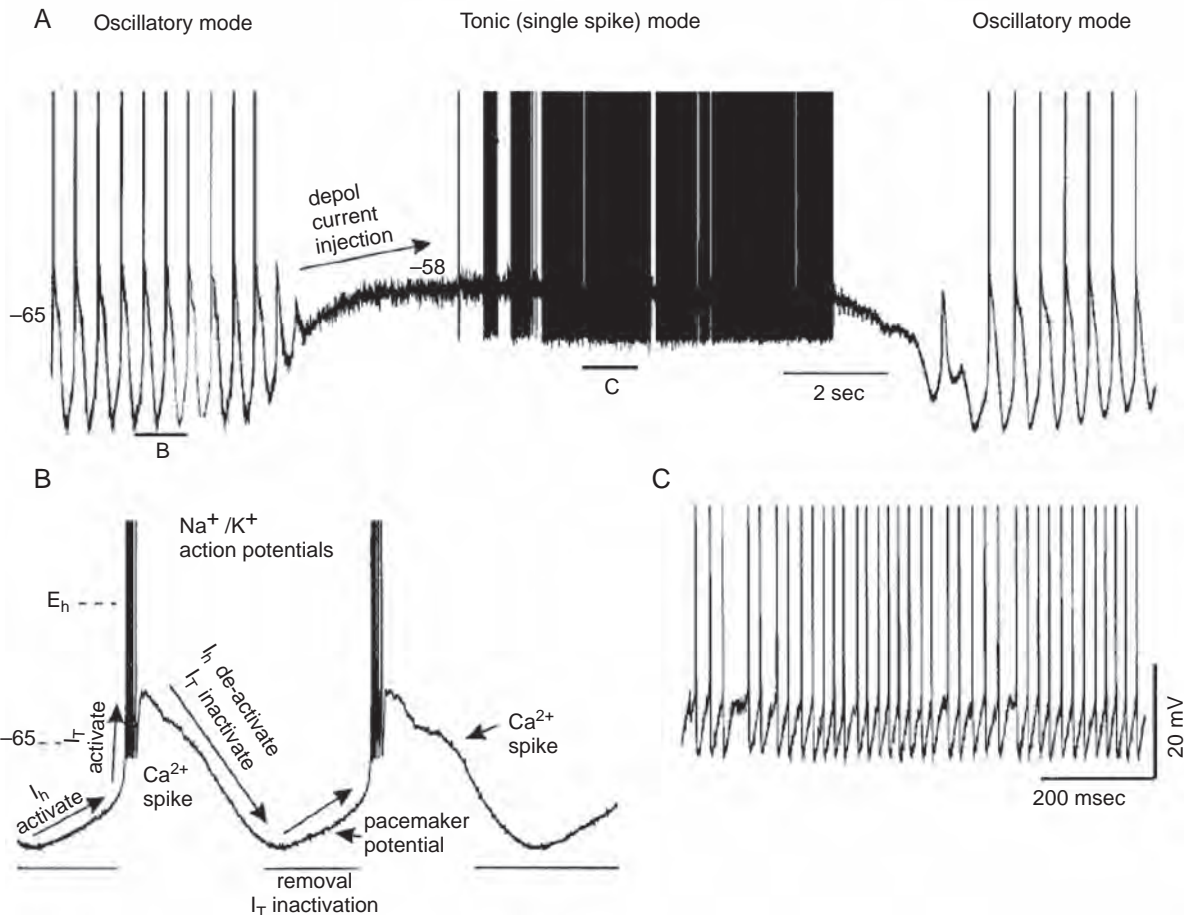

**FIGURE 42.8** Schematic representation of the REM sleep generation process. A distributed network involves cells at many brain levels (left). The network is represented as comprising 3 neuronal systems (center) that mediate REM sleep electrographic phenomena (right). Postulated inhibitory connections are shown as red circles; postulated excitatory connections as green circles; and cholinergic pontine nuclei are shown as blue circles. It should be noted that the actual synaptic signs of many of the aminergic and reticular pathways remain to be demonstrated and, in many cases, the neuronal architecture is known to be far more complex than indicated here (e.g., the thalamus and cortex). During REM, additive facilitatory effects on pontine REM-on cells are postulated to occur via disinhibition (resulting from the marked reduction in firing rate by aminergic neurons at REM sleep onset) and through excitation (resulting from mutually excitatory cholinergic–noncholinergic cell interactions within the pontine tegmentum). The net result is strong tonic and phasic activation of reticular and sensorimotor neurons in REM sleep. REM sleep phenomena are postulated to be mediated as follows: EEG desynchronization results from a net tonic increase in reticular, thalamocortical, and cortical neuronal firing rates. PGO waves are the result of tonic disinhibition and phasic excitation of burst cells in the lateral pontomesencephalic tegmentum. Rapid eye movements are the consequence of phasic firing by reticular and vestibular cells; the latter (not shown) excite oculomotor neurons directly. Muscular atonia is the consequence of tonic postsynaptic inhibition of spinal anterior horn cells by the pontomedullary reticular formation. Muscle twitches occur when excitation by reticular and pyramidal tract motoneurons phasically overcomes the tonic inhibition of the anterior horn cells. RN, raphé nuclei; LC, locus coeruleus; P, peribrachial region; PPT, pedunculopontine tegmental nucleus; LDT, laterodorsal tegmental nucleus; mPRF, meso- and mediopontine tegmentum (e.g., gigantocellular tegmental field, parvocellular tegmental field); RAS, midbrain reticular activating system; BIRF, bulbospinal inhibitory reticular formation (e.g., gigantocellular tegmental field, parvocellular tegmental field, magnocellular tegmental field); TC, thalamocortical; CT, cortical; PT cell, pyramidal cell; III, oculomotor; IV, trochlear; V, trigeminal motor nuclei; AHC, anterior horn cell. From Hobson et al. (2000).

The cortical slow oscillation initiates sleep spindles during its depolarized phase when cortico-thalamic neurons excite thalamic reticular neurons (Steriade, 2000, 2006). The resulting periodic inhibition by thalamic reticular neurons on thalamo-cortical neurons changes their firing from a transmission mode in which firing frequency is proportional to the strength of a sensory input to a bursting mode in which transmission of sensory information to the cortex is blocked (McCormick and Bal, 1997). This bursting mode is initiated when thalamo-cortical neurons are sufficiently hyperpolarized by thalamic reticular inhibition to activate a unique ion channel that opens only when their membrane potential falls well below its normal resting potential (McCormick and Bal, 1997). Opening of this channel begins a series of membrane events (“H” currents followed by “T” or “low-threshold calcium spike” currents) that culminates in thalamo-

cortical neurons emitting a series of spikes that impinge on the cortex at spindle frequency (Steriade, 2000, 2006, Fig. 42.9).

Delta frequency EEG oscillations may have both thalamic and cortico-thalamic origins (Steriade, 2000, 2006). Delta-frequency oscillations can arise via thalamic neurons’ intrinsic delta-frequency pacemaker property or, alternatively, when cortico-thalamic neurons excite thalamic reticular neurons that, in turn, hyperpolarize the thalamo-cortical neurons causing them to stimulate the cortex at delta frequency (Steriade, 2000, 2006).

In the transition from NREM to REM, activation of the thalamus by brain stem cholinergic neurons blocks the intrinsic oscillations resulting in a cortical “desynchronization.” This appears as a speeding and diversification of EEG frequencies along with a decrease in the amplitude of oscillations in the EEG (Steriade,

**FIGURE 42.9** Sites of REM induction. (A, left) Filled circle indicates site of injection of carbachol into peribrachial pons. Small dots indicate location of cholinergic cells and crosses location of PGO burst cells. (A, right) Injection of carbachol, an acetylcholine agonist, in the perimedial pons (magenta dot) causes short-term induction of REM sleep. Injection of the peribrachial pons (yellow dot) causes long-term induction of REM sleep. After injection of a cholinergic agonist into the peribrachial pons, ponto-geniculo-occipital (PGO) burst cell activity and PGO waves can be measured immediately in the lateral geniculate body (LGB) on the same side (ipsilateral) of the brain as the injections (B, left). Hypothesized connections among the PGO trigger zone (PB), modulatory aminergic raphe (R), locus coeruleus (LC), and paramedian pontine reticular cells (FTC) are shown. (C, left) Injections of carbachol at the PB site shown in A produce immediate PGO waves in the ipsilateral LGB. After 24 h, REM sleep intensifies (C, middle) and remains so for 6 days (C, right). FTC, FTG, and FTP are reticular tegmented nuclei. ACh are cholinergic nuclei. RN, red nucleus; IC, inferior colliculus; SC, superior colliculus; BC, brachium conjunctivum.

2000, 2006). Cholinergic desynchronization of EEG in REM and waking occurs via (1) an inhibitory effect on GABAergic thalamic reticular neurons that disinhibits their thalamo-cortical targets, and (2) by cholinergic excitatory influence on thalamo-cortical neurons that facilitates their glutamatergic excitation of the cortex (Steriade, 2000, 2006).

### REM Sleep Is Initiated in the Brain Stem

The cellular and molecular events that produce the regular alternation of REM and NREM sleep emerge under brain stem control once sleep has been achieved (Hobson *et al.*, 2000; Jones, 2005). As described in the previous section, activation of the cortex in REM sleep occurs when the intrinsic oscillations of NREM sleep

are blocked by the brain stem ascending reticular activating system's (ARAS) cholinergic reactivation of the thalamus (Steriade, 2000, 2006). A second, more ventral ascending activation pathway by which the ARAS can produce cortical activation and desynchrony involves excitation of the cholinergic neurons of the basal forebrain that project widely to the cortex and promote arousal in waking (Jones, 2005; Lu *et al.*, 2006a). The cardinal physiological features of REM include:

- EEG desynchronization
- Phasic potentials recorded sequentially in the pons, thalamic lateral geniculate body and the occipital cortex of the cat, termed ponto-geniculo-occipital (PGO) waves or P-waves in the rat (Datta, 1998)

- Rapid eye movements
- A change in hippocampal EEG from irregular rhythms to a regular theta rhythm
- Skeletal muscle atonia

The earliest cellular model of the brain stem REM sleep generator, the reciprocal interaction (RI) model, suggested that regular alternation of REM and NREM sleep results from the interaction of aminergic REM-off and cholinergic REM-on neuronal populations in the pontine brain stem (Hobson *et al.*, 1975; McCarley and Hobson, 1975, Figs. 42.10 and 42.11).

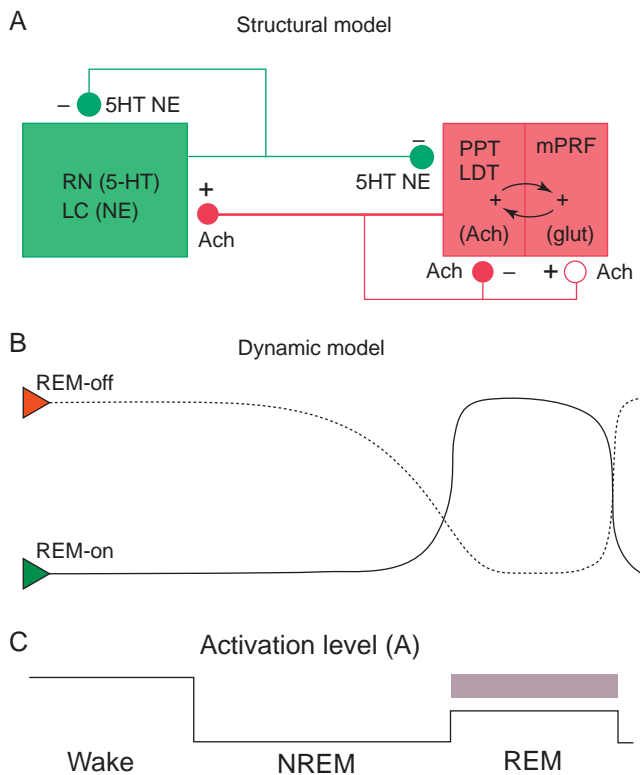

The aminergic and cholinergic neurons described in the RI hypothesis are components of the brain stem ARAS, a system that also includes large and varied populations of glutamatergic and GABAergic neurons (Hobson *et al.*, 2000; Lydic and Baghdoyan, 2005; Jones, 2005). The key cholinergic neurons supporting thalamic activation in REM reside in the laterodorsal teg-

mental (LDT) and pedunculo pontine (PPT) nuclei of the pons-midbrain junction (mesopontine tegmentum). Aminergic REM-off neurons of the LC and DR also occur in the mesopontine region. Many glutamatergic and GABAergic ARAS neurons are located ventral to the mesopontine tegmentum in the medial pontine reticular formation (mPRF). Many of these neurons bear Ach receptors (are "cholinoceptive").

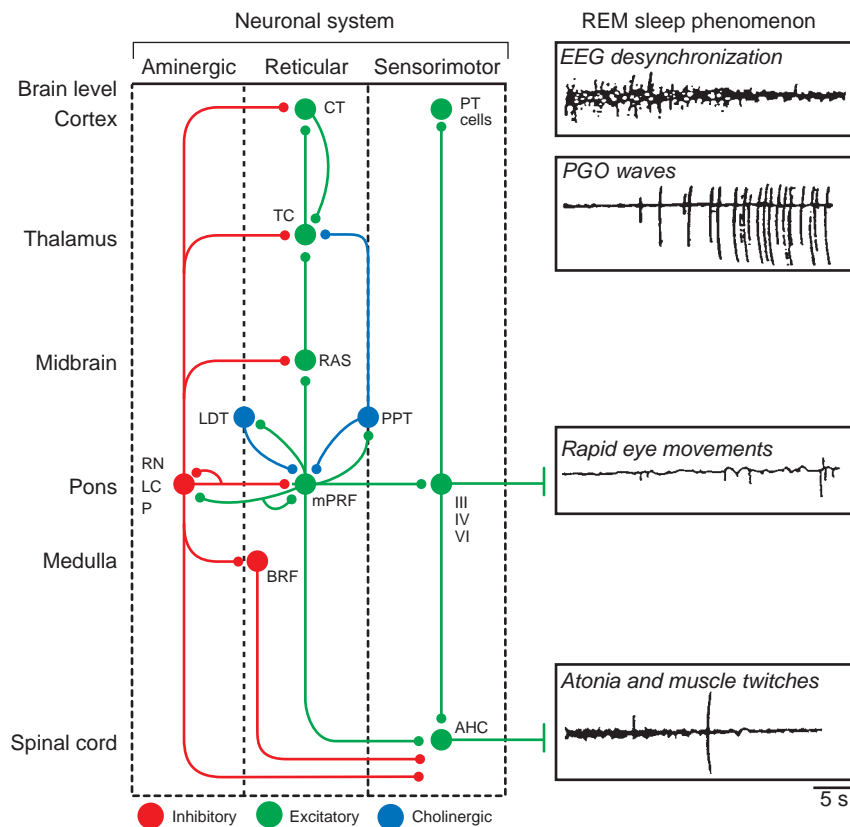

The RI hypothesis is supported by extensive experimental and clinical findings showing powerful effects of Ach and the monoamines NE and 5-HT on the REM-NREM oscillator. For example, in many regions of the pontine reticular activating system of cats, microinjection of either drugs like carbachol that mimic the action of acetylcholine (cholinergic agonists) or drugs like neostigmine that block the enzymatic degradation of naturally produced acetylcholine (acetylcholinesterase inhibitors) produces a state indistinguishable from naturally occurring REM sleep (Hobson *et al.*, 2000; Lydic and Baghdoyan, 2005). Moreover, REM sleep is reduced or blocked by microinjection of noradrenergic or serotonergic agonists into the pontine brain stem of animals as well as by systemic administration, in humans, of drugs that block the synaptic reuptake or enzymatic degradation of naturally produced monoamines such as many antidepressants (Hobson *et al.*, 2000). PGO waves result from tonic disinhibition and phasic excitation of bursting cells in the peribrachial region of the mesopontine tegmentum and, like REM sleep, they can be triggered and augmented by cholinergic stimulation (Datta, 1997).

Major roles for acetylcholine and the monoamines in REM-NREM control continue to be reported (reviewed in Lydic and Baghdoyan, 2005; Pace-Schott and Hobson, 2002), and many intermediate synaptic steps for both the activation of REM-on neurons in the mesopontine tegmentum and the suppression of REM-off aminergic nuclei also have been described. For example, mutually excitatory interactions between cholinergic and glutamatergic neurons may underlie the rapidly escalating firing of pontine reticular REM-on neurons during REM sleep (see Pace-Schott and Hobson, 2002). Similarly, during REM, inhibition of REM-off aminergic neurons in the LC and DR by brain stem GABAergic neurons may remove their inhibitory influence on REM-on cell populations (see Pace-Schott and Hobson, 2002). GABAergic inhibition by neurons of periaqueductal gray area (PAG), substantia nigra pars reticulata, dorsal paragigantocellular nucleus, or local pontine interneurons may be responsible for shutting down REM-off serotonergic and noradrenergic cells (Gervasoni *et al.*, 2000; reviewed in Jones, 2005).

Other models on the control of REM onset and offset have emphasized interactions between brain

**FIGURE 42.10** Structural and dynamic models of activation in REM sleep. (A) In the structural model, REM-on cells of the pontine reticular formation are excited by acetylcholine (ACh) or they produce excitatory signals using ACh in their synaptic terminals (or they do both). REM-off cells respond to or use NE or 5-HT as inhibitory neurotransmitters (or they do both). (B) In the dynamic model, during waking the pontine aminergic system (dashed line) is active continuously and inhibits the pontine cholinergic system (solid line). During NREM sleep, aminergic activity decreases, allowing cholinergic activity to rise. By the time REM sleep begins, the aminergic system is off and cholinergic excitation has peaked.

**FIGURE 42.11** Convergent findings on relative regional brain activation and deactivation in REM compared to waking. A schematic sagittal view of the human brain showing those areas of relative activation and deactivation in REM sleep compared to waking and/or NREM sleep, which were reported in two or more of the three PET studies published to date (Braun et al., 1997; Maquet et al., 1996; Nofzinger et al., 1997; see Hobson et al., 2000 for citations). Only those areas that could be matched easily between two or more studies are illustrated here and a realistic morphology of the depicted areas is not implied. Note that considerably more extensive areas of activation and deactivation are reported in the individual studies; these more detailed findings are reviewed in Hobson et al. (2000). The depicted areas are thus viewed most realistically as representative portions of larger CNS areas subserving similar functions (e.g., limbic-related cortex, ascending activation pathways, and multimodal association cortex).

stem GABAergic cell populations in which GABAergic inhibition plays both REM facilitatory and REM inhibitory roles. For example, Boissard *et al.* (2002) have suggested that the onset of REM in the rat is triggered by the release of neurons of the pontine sublaterodorsal (SLD) nucleus from tonic GABAergic inhibition. In addition, a GABAergic “switch” between waking and REM has been reported in the nucleus pontine oralis (within the mPRF) of cats (Xi *et al.*, 2001). Most recently, Lu *et al.* (2006b) have proposed that a GABAergic flip-flop switch, analogous to the earlier hypothalamic flip-flop switch, controls the alternation of REM and NREM sleep states in the rat via REM-off regions in the ventrolateral periaqueductal gray and lateral pontine tegmentum that project to REM-on regions in the SLD, precoeruleus, and periventricular grey mesopontine areas. Discrepancies between models proposing that REM results from brain stem GABAergic interactions and those suggest-

ing release of mesopontine cholinergic neurons from inhibition by aminergic nuclei may result from: (1) GABAergic models being derived mainly from work in the rat whereas aminergic-cholinergic models were derived in cats, and (2) hierarchical, horizontal, or redundant control by overlapping GABAergic and aminergic/cholinergic brain stem circuits paralleling the multiple overlapping ascending arousal circuits whose cholinergic, aminergic, and orexinergic components promote waking (Saper *et al.*, 2005).

### Other Brain Stem and Diencephalic Neurotransmitter Systems Participating in Behavioral State Control

Despite the prominence of cholinergic, aminergic, and amino acid (GABAergic and glutamatergic) neuronal populations in the control of the sleep-wake and REM-NREM cycles, many additional neurotransmit-

ter systems participate in the modulation sleep states. Such neurochemicals may exert their effects on behavioral state by interacting with aminergic, cholinergic, and amino acid neurons that exert a more direct "executive" control on sleep and waking states. In addition, such neurochemicals may have roles in mediating specific physiological signs of REM and NREM sleep.

### *Other Monoamines*

In addition to the prominent roles of norepinephrine, serotonin, and histamine, recent findings have begun to identify roles for a fourth monoamine, dopamine, in sleep wake regulation. Until just recently, little attention was paid to potential roles of dopamine in sleep-wake control because, unlike the other monoamines, firing rate of dopaminergic cells in the substantia nigra pars compacta (SNpc) and ventral tegmental area (VTA) did not appear to vary with behavioral state (see Hobson *et al.*, 2000). However, Lu *et al.* (2006b) have identified wake-active dopaminergic neurons in the ventral PAG that project to many of the traditional neuronal components of sleep-wake regulation. These investigators hypothesize that these neurons constitute a dopaminergic component of monoaminergic ascending wake-promoting arousal systems analogous to serotonergic, noradrenergic, and histaminergic systems in the DR, LC, and TMN, respectively (Saper *et al.*, 2005). Additional emerging evidence for a dopaminergic component to behavioral state control includes the findings that (1) dopamine concentrations in the medial prefrontal cortex (mPFC) and nucleus accumbens (NAc) are greater during REM and waking than during NREM sleep (Lena *et al.*, 2005), (2) VTA dopaminergic neurons switch to a burst firing mode in REM (Dahan *et al.*, 2007), (3) metabolism increases in the dopaminergic ventral tegmental area during REM rebound (Maloney *et al.*, 2002), and (4) mice with abnormally high brain dopamine levels display an abnormal REM-like waking that is reversible with a D2 antagonist (Dzirasa *et al.*, 2006).

Histaminergic projections of the TMN diffusely innervate the entire forebrain and brain stem (Shiromani *et al.*, 1999). Histaminergic TMN neurons show a behavioral state-dependent pattern of firing similar to LC and DR neurons (Saper *et al.*, 2001). In addition, like serotonergic and noradrenergic neurons, histaminergic neurons are tonically inhibited during sleep by GABAergic and galaninergic projections from the VLPO (Saper *et al.*, 2001).

### *Amino Acid Neurotransmitters*

The brain's most ubiquitous inhibitory neurotransmitter, GABA, is involved at many stages in the control of the sleep-wake and the REM-NREM cycle (Jones,

2005). In addition to its roles in sleep onset and maintenance, thalamo-cortical oscillations and REM facilitation/inhibition described earlier, GABAergic inhibition also controls the neurons that generate PGO waves (Datta, 1997). Another inhibitory neurotransmitter, glycine, is responsible for the postsynaptic inhibition of somatic motoneurons that results in REM atonia (Chase and Morales, 2005). In addition to its important roles in ascending reticular activation and thalamo-cortical oscillations described earlier, the brain's most ubiquitous excitatory neurotransmitter, glutamate, transmits signals from pontine REM-control regions to inhibitory glycinergic and GABAergic cells of the medulla that, in turn, suppress somatic motoneurons to produce REM atonia (Boissard *et al.*, 2002; Jones, 2005).

### *Intercellularly Diffusible Gaseous Neurotransmitter: Nitric Oxide (NO)*

NO has recently been widely implicated in sleep cycle modulation and functions primarily as an intercellular messenger, which can enhance the synaptic release of neurotransmitters such as ACh and enhance capillary vasodilation (Leonard and Lydic, 1999). NO is coproduced by cholinergic mesopontine neurons and may play a role in maintaining the cholinergically mediated REM sleep state in both the pons and the thalamus (Leonard and Lydic, 1999).

### *Neuropeptides*

Neuropeptides are increasingly seen to play diverse roles in regulation of the sleep-wake and REM-NREM cycles. As described earlier, the hypothalamic peptide galanin participates in the inhibition of wake-promoting centers during sleep onset, the hypothalamic peptide orexin promotes waking (Saper *et al.*, 2001) and cytokine peptides may play roles as endogenous somnogens (McGinty and Szymusiak, 2005). Other peptides implicated in the REM-NREM and sleep-wake cycles include vasoactive intestinal polypeptide (Steiger and Holsboer, 1997), as well as numerous hormones (Obal and Krueger, 1999) such as corticotropin releasing hormone (Chang and Opp, 2001).

### *Second Messengers and Intranuclear Events*

As in other areas of neuroscience, research on behavioral state control is now beginning to extend its inquiry beyond the neurotransmitter and its receptors to the roles of intracellular second messengers and gene transcription. For example, Bandyopadhyaya *et al.* (2006) have shown variation with prior amount of REM sleep in the intracellular concentrations of the catalytic subunit of protein kinase A (PKA), the component of PKA that enters the nucleus to phosphorylate CRE-binding protein. Similarly, manipulation of

the cAMP-PKA pathway has been shown to modify the REM sleep effects of cholinergic activation of muscarinic receptors in the mPRF (Capece *et al.*, 1997). The specific profile of genes selectively activated in different sleep–wake states is also a current area of intense investigation (Wisor and Kilduff, 2005; Tononi and Cirelli, 2001).

## Summary

Circadian and homeostatic factors together regulate sleep–wake propensity. Circadian information is provided by reliable molecular clocks in cells of the SCN of the anterior hypothalamus. SCN neurons transmit circadian information via several hypothalamic nuclei to sites where its influence is combined with information on homeostatic sleep pressure indexed by endogenous somnogenic substances such as adenosine that accumulate during waking.

A key structure in the initiation of NREM sleep is the VLPO in the anterior hypothalamus whose inhibitory GABA and galanergic neurons inhibit wake-promoting arousal systems originating in cholinergic, noradrenergic, serotonergic, and dopaminergic brain stem nuclei, the histaminergic TMN in the posterior hypothalamus, and cholinergic arousal systems of the basal forebrain and brain stem. During waking, the peptide neuromodulator orexin from cells in the lateral hypothalamus further excites these aminergic and cholinergic arousal systems and stabilizes the waking pole of a bistable sleep–wake mechanism analogous to an electrical flip-flop circuit.

The ascending arousal systems of waking and REM suppress the endogenous oscillatory rhythms generated in thalamo-cortical circuits that manifest as the slow oscillation, spindle, and delta brain waves of the EEG in NREM sleep. The slow oscillatory rhythm is generated by cortical neurons and reflects a pattern of prolonged hyperpolarization followed by burst firing that controls the timing of spindles, delta waves, and K-complexes in the NREM sleep EEG.

Aminergic, cholinergic, and orexinergic neuromodulation promotes the activated brain states of waking but cholinergic and perhaps dopaminergic arousal systems promote the activated state of REM sleep. After sleep is initiated, an ultradian oscillator located near the junction of the pons and midbrain controls the regular alternation of NREM and REM sleep stages. This alternation of states involves a reciprocal interaction between aminergic REM-on and cholinergic REM-off cell groups, the interactions of which are mediated by interposed excitatory, inhibitory, and autoregulatory circuits that utilize the amino acid neurotransmitters GABA and glutamate. Substantial species

differences may exist in mechanisms of REM-NREM control and mutually inhibitory GABAergic circuits may exert the most proximal control of sleep state alternation in rodents.

Additional neurochemicals such as the amino acid glycine and neuropeptide hormones contribute to the regulation of sleep–wake and REM–NREM cycles as well as to specific physiological signs of particular behavioral states. Contemporary neurophysiological research is elucidating the intracellular events taking place in second messenger systems and the cell nucleus. Emerging details on the molecular expression of specific sleep-related genes will undoubtedly provide an increasingly detailed understanding of causal mechanisms underlying the control of behavioral state.

## MODELING THE CONTROL OF BEHAVIORAL STATE

Two linked models—one neurobiological (McCarley and Hobson, 1975) and the other psychophysiological (Hobson and McCarley, 1977; Hobson *et al.*, 2000)—have been advanced to organize experimental findings and their implications for a theory of consciousness. According to the neurobiological model (Fig. 42.10), in waking, brain activation and open input–output gates result from a combination of continual aminergic activity and phasic (waxing and waning) aminergic and cholinergic activities. In contrast, in REM sleep the continually low level of aminergic activity and the periodic increases in cholinergic activity close input–output gates, activate the brain, and periodically stimulate the brain.

The subjective experience of waking, NREM sleep, and REM sleep can tentatively be linked to the accompanying changes in physiology (Table 42.2). Sensation and perception decline progressively during the cortical deactivation that occurs at the onset of sleep; responsiveness declines further as NREM sleep deepens. During REM sleep the brain reactivates, but presynaptic inhibition blocks sensory signals. REMs and their associated PGO waves act as internal stimuli, which take the place of stimuli from external sources. The brain stem sends information about eye movements to the thalamocortical visual system, possibly contributing to the intense visual hallucinations of dreams. Furthermore, these PGO signals also drive the amygdala, perhaps accounting for such emotions as anxiety and surprise in dreams. Interestingly, PET studies show an increase of regional cerebral blood flow in limbic structures, including the amygdala during REM sleep.

In the early days of the EEG, brain waves with frequencies greater than 25 Hz were either ignored or

TABLE 42.2 Physiological Basis of Changes That Occur during Dreaming

Function	Change (compared with waking)	Hypothesized Cause
Sensory input	Blocked	Presynaptic inhibition
Perception (external)	Diminished	Blockade of sensory input
Perception (internal)	Enhanced	Removal of inhibition from networks that store sensory representations
Attention	Lost	Aminergic modulation decreases, causing a decrease in the ratio of signal to noise
Memory (recent)	Diminished	Because of a decrease in aminergic activity, activated representations are not stored in memory
Memory (remote)	Enhanced	Removal of inhibition from networks that store memory representations
Orientation	Unstable	Internally inconsistent signals are generated by cholinergic systems
Thought	Poor reasoning, processing hyper-associative	Loss of attention, memory, and volition leads to failure of sequencing and rule inconstancy; analogy replaces analysis
Insight	Self-reflection lost	Failures of attention, logic, and memory weaken second- (and third-) order representations
Language (internal)	Confabulatory	Aminergic demodulation frees the use of language from the restraint of logic
Emotion	Episodically strong	Cholinergic hyperstimulation of the amygdala and related structures of the temporal lobe trigger emotional storms, which are not modulated by aminergic activity
Instinct	Episodically strong	Cholinergic hyperstimulation of the hypothalamus and limbic forebrain triggers fixed motor programs, which are experienced fictively but not enacted
Volition	Weak	Cortical motor control cannot compete with disinhibited subcortical networks
Output	Blocked	Postsynaptic inhibition

filtered out because of the problem of interference by 50- or 60-Hz artifacts from electrical power sources. Later, researchers were able to focus on the possibility that 40-Hz EEG activity synchronizes processing in cortical areas.

Rodolfo Llinás proposed that as the cortex is scanned by the thalamus, 40-Hz waves propagate from the frontal to the occipital poles (Kahn *et al.*, 1997). Noting that 40-Hz activity is observed in REM sleep as well as in waking, he suggested that intrinsic neuronal oscillations are important in the genesis of both states of consciousness and that the main difference between waking and dreaming arises from differences in input-output gating (Llinás and Pare, 1991). In addition to being without temporal or spatial input, in REM sleep the brain has little background aminergic activity; this lack may contribute to the declines in attention, orientation, memory, and logic that characterize dreaming and make dreams difficult to remember (Hobson *et al.*, 2000).

### Neuroimaging and Lesion Studies of Sleep and Dreaming

Functional neuroimaging studies have revealed distinctive differences in regional brain activation between the cardinal behavioral states of waking, NREM sleep

and REM sleep (for a review and original citations, see Hobson *et al.*, 2000). In brief, widespread deactivation of the forebrain and brain stem is seen following sleep onset, and activation further decreases with the increasing depth of NREM sleep from NREM stage 1 to 2 to slow-wave sleep (SWS). Subsequently in REM sleep, however, there is selective reactivation to waking or above-waking levels in brain stem, diencephalic, subcortical limbic, cortico-limbic, and selected cortical association areas. Notably however, during REM, significant deactivation of the dorsolateral prefrontal cortex relative to waking persists. Figure 42.12 illustrates the structures found to be activated or deactivated in two or more of these recent neuroimaging studies.

These findings have led to an updating of the original activation synthesis hypothesis of dreaming (Hobson and McCarley, 1977), which now emphasizes that the distinctive cognitive features of dreams result from simultaneous autoactivation of the limbic brain (with consequent dream emotionality and salience) combined with the deactivation of executive structures subserving logic and working memory (with consequent dream bizarreness and disorientation) (Hobson *et al.*, 2000).

Complementing these findings have been neuropsychological findings on brain-damaged patients by

**FIGURE 42.12** Central and obstructive sleep apnea. During waking, the respiratory oscillator of the medulla receives tonic drive from other neural structures and can respond to voluntary and metabolic signals to change breathing pattern. Muscle tone keeps the oropharynx open to the flow of air. In NREM sleep, central drive decreases, and the rate and depth of ventilation fall. If the decrease is excessive, central sleep apnea results, including a complete, albeit temporary, cessation of breathing. If the airway collapses, obstructive sleep apnea may result, with a similar cessation of breathing. During REM sleep, activation of pontine generator neurons drives the respiratory oscillator, and desynchronization may lead to breathing efforts that are too frequent or strong (hyperpnea) or that stop. During REM sleep the oscillator also becomes unresponsive to metabolic signals.

Solms (1997). In these studies, dorsolateral prefrontal damage was found to have little effect on dreaming. This is in keeping with its relative inactivity during REM and the apparent diminution of its mnemonic, orientational, and logical functioning in dreaming. In contrast, destructive lesions of multimodal parietal areas resulted in global cessation of dreaming, and lesions of the visual association cortex led to nonvisual dreaming. This is in keeping with the activation, in REM, of the supramarginal gyrus and inferotemporal cortex in some PET studies and the highly visuospatial nature of dreaming. Similarly, disconnective lesions in upper brain stem-limbic-prefrontal areas led to global cessation of dreaming in keeping with their activation in REM and the highly emotional and personally salient quality of dreaming (Box 42.2).

### Central Autonomic Control Systems Are State Dependent

Alterations in cognitive and vegetative functions are linked to changes in central modulatory systems during sleep. For example, active hypothalamic temperature control is diminished or abandoned in REM sleep (Hobson, 1989), and the sensitivity of the respiratory control system is likewise diminished. As a result, a neuron that is sensitive to temperature or  $pO_2$  during waking loses that responsiveness during REM sleep. Sleep, then, involves significant changes in the reflex

#### BOX 42.2

### REGIONAL ACTIVATION AND DEACTIVATION: IMAGING THE HUMAN BRAIN AWAKE AND ASLEEP

Not only is the brain surprisingly and strongly activated during REM sleep, but its various subregions are activated and deactivated in a pattern quite different from that of waking. The mechanism of this differential activation pattern, revealed in PET, SPECT, and fMRI functional neuroimaging studies, is unknown, but it seems quite likely that the underlying shifts in regional metabolism and blood flow are orchestrated by the neuromodulators, which play this role in the rest of the body.

Compared to waking, deep NREM sleep shows a rather global deactivation pattern in keeping with the observed EEG slowing and synchronization. However, in REM, some areas are hyperactivated (among which the pontine brain stem, the limbic system, and the paralimbic cortex are most notable), whereas others are deactivated

(among which the posterior cingulate and the dorsolateral prefrontal cortex are most notable).

These shifts in regional blood flow, and by inference regional neuronal activity, map nicely onto the observed changes in consciousness. Thus activation of the amygdala and other sub-cortical and cortical limbic structures is relevant to the domination of dream consciousness by emotion, the selective activation of only certain of the multimodal cortices is relevant to the hyper-associative quality of dreaming, whereas the inactivation of the dorsolateral prefrontal cortex seems relevant to the defects in cognition and memory. At last, the human brain and its wondrous array of conscious states is amenable to neurobiological analysis, in real time, in real people, and in patients as well as in healthy individuals.

*Edward F. Pace-Schott, J. Allan Hobson and Robert Stickgold*

control of autonomic function. Our understanding of changes in the control of vegetative and sensorimotor functions during waking and sleep can be applied to understand sleep-related dysfunctions such as insomnia (inability to sleep), hypersomnia (excessive sleepiness), and parasomnia (sleep with reflex responses to stimuli) (Hobson, 1989).

### Sleep Disorders Result from Disrupted Control of Behavioral State

When central nervous system (CNS) aminergic activity increases, the brain is shifted in the direction of hyperarousal, and stress and insomnia can result. If stress and insomnia are prolonged, the chronic sympathetic overdrive can harm cardiovascular, cognitive, and behavioral functions of an animal. Behavioral and pharmacologic interventions that decrease sympathetic output can be used to reduce this hyperarousal, allowing the restoration of more normal sleep. But pharmacologic interventions invariably additionally modify the structure of sleep itself, reducing its quality. (For reviews of sleep disorders discussed later, see Kryger *et al.*, 2005, and Hobson, 1989.)

The decrease in CNS aminergic activity (as in depression or narcolepsy) has opposite effects on cardiovascular, cognitive, and behavioral systems. As sleepiness appears, attention and cognition decline, and motor activity is impaired. Under these conditions, the cholinergic system is disinhibited, and the REM generator is triggered abnormally easily. The result is unwanted sleepiness or frank REM sleep attacks. These symptoms are decreased by aminergic agonists, such as blockers of amine reuptake, and psychostimulants, both of which boost sympathetic activity. Notably, many such drugs have both proaminergic and anticholinergic actions.

### Respiratory Dysfunction Is Common in Sleep

One of the more dramatic problems associated with sleep is an exaggeration, at sleep onset, of the normal decline in respiratory drive (Chapter 37). Also, respiratory irregularity may be provoked by the altered brain stem activity of REM sleep. This sleep-dependent disruption of respiratory function, known as central sleep apnea, involves a decrease in respiratory drive during sleep (Fig. 42.13). More commonly, especially in obese people, mechanical collapse or compression of the airway can result in peripheral (or obstructive) sleep apnea, in which ventilation decreases because of a mechanical problem in the oropharynx. In peripheral sleep apnea, central respiratory drive causes continued respiratory effort. Eventually, the increase in CO<sub>2</sub> in the brain leads to an arousal which in turn produces

increased muscle tone in the oropharynx, and the airway opens. As the person falls into deeper sleep again, the oropharynx relaxes and the airway can become obstructed again until arousal recurs. In severe cases, arousals every one to two minutes all night are common.

People with sleep apnea usually feel excessively sleepy during daytime because frequent arousal prevents deep, sustained sleep. They are often unaware of their sleep-dependent breathing pattern because they are never fully aroused from sleep. Instead, observant friends or family often describe seeing these signs of respiratory dysfunction. In a sleep laboratory, EEG, respiratory effort, and cardiovascular parameters (e.g., heart rate, blood pressure, and oxygen saturation) are measured to quantify the problem. Sleep apnea can be treated by having the person wear a mask through which air is forced gently, helping to keep the airways open. The pressure of the air fluctuates to allow regular exhalation. People with sleep apnea are treated not only to alleviate their constant drowsiness, but to prevent long-term effects of sleep apnea, such as cardiopulmonary complications.

### Motor Disturbances Can Occur during Sleep

Parasomnias that affect the skeletal motor system can occur in either REM or NREM sleep. In NREM sleep these parasomnias (e.g., sleep walking, sleep talking, tooth grinding, and night terrors) are seen mainly in young people, and reflect motor responses to the outputs of central motor pattern generators. Normally, responses to these generators are disinhibited at sleep onset and inhibited during REM sleep, when no motor commands normally are enacted. Extensive motor output in REM sleep requires the overpowering of the normal muscle atonia of REM sleep, and REM sleep behavior disorder can be a sign of degenerative brain disease in the elderly. Because of a failure to inhibit the expression of motor acts in REM, people with this disorder may literally enact their dream scenarios in their bedrooms. Given the normal lack of this active motor suppression during NREM sleep, it remains a mystery why dreams arising during NREM sleep fail to produce robust motor output.

A syndrome strikingly similar to REM sleep behavior disorder can be induced experimentally by bilateral lesions of the pontine tegmentum in cats. When in REM sleep, these animals perform stereotyped behavior sequences, such as hissing, piloerection, pouncing, and jumping. Jouvét called these “hallucinatory behaviors,” and Morrison called the phenomenon “REM sleep without atonia” (Jouvét, 1999). Because the ability of a cat to inhibit motor pattern commands during

**FIGURE 42.13** Central and obstructive sleep apnea. During waking, the respiratory oscillator of the medulla receives tonic drive from other neural structures and can respond to voluntary and metabolic signals to change breathing pattern. Muscle tone keeps the oropharynx open to the flow of air. In NREM sleep, central drive decreases, and the rate and depth of ventilation fall. If the decrease is excessive, central sleep apnea results, including a complete, albeit temporary, cessation of breathing. If the airway collapses, obstructive sleep apnea may result, with a similar cessation of breathing. During REM sleep, activation of pontine generator neurons drives the respiratory oscillator, and desynchronization may lead to breathing efforts that are too frequent or strong (hyperpnea) or that stop. During REM sleep the oscillator also becomes unresponsive to metabolic signals.

REM sleep is impaired by the lesions, they act out commands that are normally initiated during REM sleep. The instinctual aspect of these released behaviors is relevant to the psychophysiology of dreaming and has important implications for the hypothesis that REM sleep serves an active maintenance function.

**Summary**

Two models attempt to explain sleep and wakefulness. In the neurobiological model, sleep and waking are the result of a hypothalamic sleep-wake switch followed by reciprocal, phasic interactions between aminergic and cholinergic neurons and related circuitry. In the psychophysiological model, the influences of external and internal sensations are emphasized. During slow-wave sleep, thalamocortical synchronous activity diminishes responsiveness to the external world. During REM sleep, under the influence of cholinergic

projections to the forebrain, internal representations of visual information predominate. In addition to changes in levels of sensory arousal and cognitive performance during sleeping, vegetative functions such as circadian rhythm recognition, body temperature, and autonomic activity also are regulated coordinately. Disorders of sleep influence emotional and cognitive functions adversely. Prolonged sleep deprivation is lethal, ending in a septic state of immunodeficiency, strongly suggesting that sleep serves important but uncertainly mediated maintenance functions.

The brain undergoes daily, complex, systematic changes in state that profoundly alter the nature of our consciousness, behavior, autonomic control, and physiologic homeostasis. At the root of these changes is the circadian clock. Located in the hypothalamus, this clock programs rest-activity and body temperature cycles. It also gates the NREM-REM sleep cycle control system in the pons.

## BOX 42.3

### CONSCIOUSNESS IN WAKING, SLEEPING, AND DREAMING: A MODEL FOR MENTAL ILLNESS

Since the brain is continuously active across states of sleep, so is the mind. Every modality of conscious experience can be shown to be state dependent, and particularly strong contrasts are evident between waking and dreaming, the two conscious states associated with higher levels of brain activation.

These alterations in consciousness are particularly informative to neurologists and psychiatrists because they provide new ways of thinking about the brain basis of mental illness. When brain activation declines in NREM sleep, most aspects of waking consciousness also decline. But when the brain is activated again during REM sleep, it does not reinstate waking consciousness. Instead, consciousness changes in an almost qualitative manner: Perception, instead of being shaped by external forms, becomes hallucinatory. Cognition is similarly deranged. Instead of being oriented, the dreaming mind loses track

of time place and person. Instead of thinking actively and critically, the dreaming mind indulges in nonsequiturs, ad-hoc explanations, and other illogical whims. Memory, during dreams, instead of being declaratively faithful to recent history, is fragmented in its disconnection from current events and globally deficient in recalling them. Emotion, instead of being restrained and focused in response to percepts and thoughts, comes to dominate and organize dreaming consciousness often in strikingly salient ways. All these features of dream consciousness are normal and all are closely related to the changes in brain modulation. Because they are formally similar to the symptoms of the major psychoses, they suggest that mental illness may reflect genetic and environmental dysfunction of brain modulatory systems.

*Edward F. Pace-Schott, J. Allan Hobson and Robert Stickgold*

Some cellular and molecular details of the brain stem diencephalic behavioral state control system are clear: For the awake state, the noradrenergic locus coeruleus and the serotonergic raphé neurons of the pons, histaminergic and orexinergic neurons of the hypothalamus and, possibly, midbrain dopaminergic neurons must fire regularly to support alertness, attentiveness, memory, orientation, logical thought, and emotional stability. When the output of these chemical systems diminishes, drowsiness occurs. When sleep begins, the output of these systems declines further, and the brain-mind enters NREM sleep, a phase of lowered consciousness which, at times, might lapse into true unconsciousness. As NREM sleep continues, cholinergic activity increases gradually. At the NREM-REM transition, the activity of the serotonergic and nonadrenergic systems is at its nadir, and the output of the cholinergic system is increasing exponentially. This chemical switch results in the cholinergic activation and autostimulation of REM sleep. Combined with the lack of aminergic stimulation, this cholinergic overdrive contributes to the characteristic hallucination, delusion, disorientation, memory loss, and emotional intensity of REM sleep dreaming. What replaces these influences during NREM dreaming remains unknown.

Although the details of these daily changes in brain chemistry remain to be specified, consequences of their

dysfunction are becoming more clearly understood through the study of insomnias, hypersomnias, and parasomnias. Integration of data from basic neurobiology, cognitive psychology, and clinical science enables the construction of specific, testable models of how waking and sleep affect our conscious experience. These models, in turn, constitute the building blocks of a scientific theory of consciousness.

### SLEEP HAS MULTIPLE FUNCTIONS

Although it is easy to conceptualize the function of waking and to understand the adaptive value of consciousness, it has been difficult to move beyond the subjectively compelling but scientifically unsatisfactory notion of sleep as rest. But recent evidence indicates that sleep plays important roles in many physiological and cognitive systems. Evidence strongly suggests that sleep has an anabolic and actively conservative function that is related to the complexity of the mammalian brain (Table 42.1). In fact, Bennington and Heller (1995) propose that an important function of NREM sleep is to restore brain glycogen stores.

The most dramatic evidence of this homeostatic function comes from sleep deprivation studies in rats in which sleep deprivation was fatal when it persisted for four to six weeks. Early in the deprivation period,

the rats began to eat more but could not maintain their body weight. Later, they lost their ability to maintain body temperature and developed strong heat-seeking behavior, and, finally, they died. Although the cause of this death remains uncertain, it is suspected to result from overwhelming sepsis because of immunodeficiency. The study implied that the maintenance of metabolic caloric balance, thermal equilibrium, and immune competence require sleep (Rechtschaffen and Bergman, 2002).

Additional evidence links immune function and sleep. Pappenheimer found that NREM sleep in rabbits was enhanced by dimuramyl peptides of bacterial cell wall origin. NREM sleep is also enhanced by the cytokines interleukin-1 and interleukin-2, both of which are released during NREM sleep (Krueger *et al.*, 1999). But perhaps more to the point, immunizing subjects with an anti-influenza vaccine during a period when sleep was restricted to 4 hours per night reduced the normal production of anti-influenza antibodies by 57% (Spiegel *et al.*, 2002).

Contributing to the notion that sleep has an anabolic function is the abundance of sleep in early life. REM sleep predominates *in utero*, where its stereotypic pattern of motor activation and its chemical microenvironment could promote CNS development (Hobson, 1989). Sleep also plays a role in hormonal regulation. Growth and development are most likely enhanced by the release of growth hormone and gonadotropins in slow wave sleep. Such hormone release declines, along with slow wave sleep, after growth and sexual maturation are complete, around 30 years of age. Recent studies have demonstrated the importance of sleep for normal regulation of glucose and prevention of diabetes (Knutson *et al.*, 2006).

## Sleep and Memory Are Interdependent

Perhaps the clearest evidence of a function for sleep is for its role in consolidating recently formed memories (Stickgold, 2005). One of the most notable examples is the discovery, in rats, by Carlyle Smith, of "REM windows" (Smith, 1995), which are time periods after an animal is trained on specific tasks when the animal shows enhanced quantities of REM sleep and when retention of learning could be decreased by selective REM sleep deprivation. Thus, not only does REM sleep appear to be critical for the maintenance of this learning, but animals also increase their REM sleep after training, presumably by a homeostatic mechanism that regulates the amounts of different sleep stages based on the needs of the organism. Subsequent studies in humans have led to the theory that REM sleep is especially important for the consolidation of proce-

dural memories, which are defined as memories of how to do things in the absence of explicit rules, such as how to ride a bicycle or read a map. In contrast, SWS has been implicated in the consolidation of explicit or declarative memory, which includes autobiographical memories as well as general knowledge of facts. However, studies on a procedural visual discrimination task have shown a requirement for both REM and SWS on the night following training in order for next day improvement on the task to be observed (Stickgold *et al.*, 2000b). This finding supports an earlier theory based on animal studies in which a two-step process involving both REM and SWS was hypothesized. In humans, the requirement for sleep immediately following learning was shown when subjects who were sleep deprived the night following training, but who then were allowed two nights of unrestricted recovery sleep before testing, showed no significant task improvement (Stickgold *et al.*, 2000a). In addition to procedural learning tasks, REM effects have been reported in humans on learning of complex logic games, foreign language acquisition, intensive studying in general, and both REM and SWS effects have been reported for the consolidation and processing of emotional memories. In contrast, sleep-dependent consolidation of simple motor skill learning, such as for a sequential finger-tapping task, correlates with Stage II NREM sleep (Walker *et al.*, 2002).

There is also evidence that normal sleep-dependent memory consolidation is altered in patients with psychiatric disorders. Patients with schizophrenia show normal learning of the finger-tapping task during training, but no overnight improvement (Fig. 42.14; Manoach *et al.*, 2004).

## No Function for Dreaming Has Been Identified

Does dreaming also serve a function? Answering this question is not yet possible, because we do not know how to separate possible functions of the experience of dreaming from functions of the neurobiological processes that produce it. But REM sleep dream content can predict who will become clinically depressed following marital divorce or separation (Cartwright *et al.*, 1998), suggesting that dreaming may serve to modulate emotional states during waking.

Dreaming may also play a role in modifying associative memory networks. Subjects awakened from REM sleep show preferential activation of more distantly related associations than seen either during waking or during NREM sleep (Stickgold *et al.*, 1999). Such preferential activation of weak associations might explain the bizarre content of dreams during REM

FIGURE 42.14 Sleep-dependent memory consolidation. Subjects were asked to type the sequence “41324” as quickly and accurately as they could for 30sec and then reset for 30sec before doing it again. Twelve trials were performed on each of two successive days. The control subjects showed a 16% increase in speed overnight, whereas the schizophrenia patients showed none.

FIGURE 42.15 Sleep facilitates mathematical insight. Subjects are taught to reduce an eight-digit sequence to a single digit (9 at the right), through six intermediate calculations (in italics) with a standard algorithm. Unknown to the subjects, the task is designed so that the last three calculations form a mirror image of the preceding three, and thus the second intermediate calculation matches the final answer. Right: subjects who slept between training and testing were more than twice as likely to discover the insight algorithm than those not allowed sleep.

sleep, and may permit the brain to discover creative solutions to problems during sleep. Indeed, sleep has been shown to increase the likelihood of such discoveries (Fig. 42.15; Wagner *et al.*, 2004). But whether the conscious experience of dreaming is crucial for any of these sleep-dependent processes remains unknown.

**Summary**

Sleep represents a complex behavioral and neurobiological process that is conserved across much of the animal kingdom. REM sleep is similarly conserved across the class Mammalia. The complex, REM-NREM cycle suggests that these distinct neurophysiological and neurochemical brain states have evolved to subserve specific functions. One hypothesis is that the types of sleep stages and their timing across the night evolved to meet the demands of varying memory systems for

effective offline processing during sleep. Whether dreaming also evolved to permit offline cognitive and affective processing remains an open question.

# Reward, Motivation, and Addiction

## REWARD AND MOTIVATION

Motivation is the process by which animals adapt to internal or external change. Such adjustments to change may involve the integration of endocrine, autonomic, and behavioral responses. Some adjustments are part of the regulatory process of homeostasis and act through negative feedback loops to correct an internal change. Indeed, motivation used to be explained largely in terms of reductions of needs, or “drives,” such as those for sodium (salt) or water. This purely homeostatic explanation of motivation could plausibly account for ingestive and thermoregulatory behaviors, and possibly even the drug-seeking behavior generated by the state produced by drug withdrawal. However, it fails to explain satisfactorily behavior such as aggression, mating, or exploration, for which there are obvious external triggering stimuli but no identifiable deficit state. It also fails to explain what happens when homeostatic mechanisms are apparently overridden by powerful external incentives, as occurs during drug binges and during overingestion of delicious food. Instead, such behavior often is explained by attractions to external stimuli that have appetitive or rewarding properties (incentive–motivation).

In many cases, goals such as food or a sexual partner are not available, and an animal must search or forage for them. Therefore, motivated behavior is more than the simple control of consummatory responses that end sequences of motivated behavior, such as eating, drinking, and sexual mounting or lordosis. Consummatory behavior tends to be stereotyped and reflexive and is acquired early in an animal’s life. In sequences of motivated behavior, however, consummatory behavior usually is preceded by adaptive, flexible forms of appe-

titive behavior (e.g., foraging for food), which enables an animal to come into physical contact with its goal. This appetitive behavior may be simple locomotor approach responses to the goal or may include exploratory behavior and complex response sequences. In addition, appetitive behavior may occur in parallel with endocrine and autonomic responses (e.g., secretion of saliva and insulin) (Chapter 38) that prepare the animal for efficient interaction with the goal.

## Conditioning and Learning

In the absence of immediate goals, an animal usually must use past experience to predict the likelihood of an occurrence. This learning may involve classically conditioned (i.e., Pavlovian) reflexes and goal-directed instrumental (or operant) behaviors. With the latter behaviors, an outcome that increases the occurrence of a preceding behavior is a positive reinforcer. This term often is used interchangeably with the more colloquial term *reward*, which connotes a positive emotional component of positive reinforcement or pleasure. However, accurately inferring subjective states in animals is difficult, if not impossible and both reward and positive reinforcer should be used operationally. Identification of neural structures that mediate subjective phenomena, such as pleasure, may need to depend on functional neuroimaging of humans. Incentive, however, generally refers to the attractiveness of a goal, and positive reinforcement strengthens specific responses by presenting stimuli contingent on performance. For example, rats can learn arbitrary instrumental actions, such as a lever press, to gain access to positive reinforcers, such as food or drugs (i.e., self-administration behavior) (Fig. 43.1) or to

**FIGURE 43.1** Intravenous self-administration by rats. (Top) Drawing illustrating the setup for intravenous self-administration of cocaine by rats. (Bottom) Event records for different unit doses of cocaine show a dose-response relationship relating dose of cocaine to number of infusions. Rats implanted with intravenous catheters and trained to self-administer cocaine with limited access (3h per day) show stable and regular drug intake over each daily session. No obvious tolerance or dependence develops. Rats generally are maintained on a fixed-ratio (FR) schedule of drug infusion, such as FR-1 or FR-5. In an FR-1 schedule, one lever press is required to deliver an intravenous infusion of cocaine; in an FR-5 schedule, five lever presses are required to deliver an infusion of cocaine, and so on. With an FR schedule, rats appear to regulate the amount of drug self-administered. Lowering the dose from the training level of 0.75mg/kg per injection increases the number of self-administered infusions. Raising the unit dose decreases the number of infusions. Pretreatment with the dopamine receptor antagonist SCH 23390 also increases the number of self-administered infusions. Reprinted with permission from Caine *et al.* (1993).

stimuli associated with these primary reinforcers—conditioned reinforcers. Schedules of reinforcement vary the relationship between activity and positive reinforcement. Thus, an animal's degree of motivation can be assessed by its capacity to work for a goal.

Another measure of motivation often involves the choice an animal makes (e.g., between actions that

produce one stimulus associated with reward over another stimulus that is not associated with reward). Conditioned place preference is a commonly used procedure based on this principle in which choice is made between two environments, only one of which is linked to reward. A distinctive location is associated with a reinforcer such as food or a drug. Following several

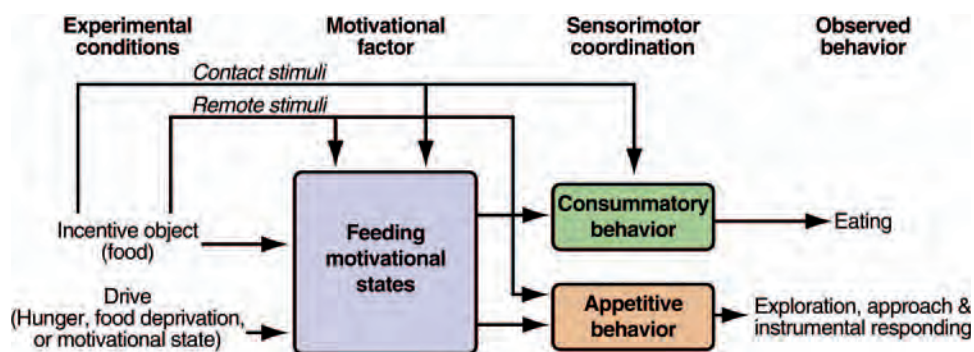

FIGURE 43.2 Theory of incentive-motivation, as applied to feeding. Note that drive (internal stimuli) and food (external stimuli) separately affect central motivation to feed. Also, incentive (i.e., food) and discriminative (i.e., sensorimotor) influences exert their effects separately to control consummatory behavior (when food is contacted) and appetitive behavior (when food remains remote). Modified with permission from Robbins (1986).

learning trials, a test trial is conducted in the absence of the goal itself. In the test, the preference for that place (as measured by the time spent there) relative to another place without that association is taken as an index of the incentive properties of the goal. Negative reinforcement, as distinct from positive reinforcement, is defined by the removal or postponement of an aversive event, the process that increases the probability of a preceding response and that may lead to a positive emotional state sometimes associated with relief. Negative reinforcement should not be confused with punishment. Punishment is defined as the suppression of instrumental actions with which it is associated.

Apparently motivated behavior can sometimes be shown to be resistant to motivational changes (e.g., satiety or other forms of devaluation of the goal such as lithium-induced illness). The assumption then is that it has acquired some habitual properties, based on the association between stimulus and response (S-R), rather than between the instrumental action and goal outcome. Such S-R “habits” may predominate after certain forms of training, particularly if prolonged (Dickinson 1994; Yin *et al.*, 2004).

The complexity of motivated behavior (Fig. 43.2), from selection of voluntary actions based on past experience to reflexive control of consummatory behavior, involves coordination of several levels of neural control, including the neocortex, older areas of the cortex often grouped as the “limbic system” (including the amygdala), the extrapyramidal motor system, integrative centers (e.g., the hypothalamus), and the basic motor mechanisms of the brain stem.

### The Hypothalamus Plays a Role in Motivation

Hypothetical motivational centers were based on early concepts of brain stem centers for fundamental

processes, such as respiration (Chapter 37). Though the construct of *brain centers* eventually fell out of favor, the original concept of homeostatic centers led many investigators to approach motivation as a search for specific neural or hormonal signals that could trigger neurocircuitry to initiate the appropriate behavioral responses. Such models could explain the efficient integration of many different signals to produce coordinated sequences of behavior. The hypothalamus is an ideal key structure in a circuitry for such integrative functions, given its rich blood supply and exposure to cerebrospinal fluid (and thus access to a variety of chemical signals and the capacity also to deliver them), control over the pituitary, and neural connections (through brain stem and other centers) with visceral afferent information (e.g., taste and olfaction), autonomic and somatic motor outflow. The concept of mutually inhibitory centers for the initiation (hunger) and suppression (satiety) of feeding arose from such a view (Chapter 34) (Box 43.1).

### Hypothalamic Contribution to Other Forms of Motivation

On the basis of the criteria just described, the list of hypothalamic motivational centers originally was extended to include behaviors as diverse as drinking, thermoregulation, aggression, and sex (Chapter 34). Thus, for example, thermoregulatory behavior, such as reflexive shivering, panting, and grooming, is impaired by lesions of the preoptic region of the hypothalamus and is elicited by cooling or warming of this region (Satinoff, 1982). Defensive (affective) aggression and accompanying autonomic changes, such as piloerection, are produced by electrical stimulation of the ventromedial hypothalamus, whereas predatory (“quiet”) aggression is produced by electrical stimulation of the

## BOX 43.1

### LOGIC OF METHODOLOGY USED IN BEHAVIORAL NEUROSCIENCE

Theorists (e.g., Hoebel, 1974) have defined principles for identifying the involvement of particular brain regions in motivational (and other behavioral) functions. For example, electrophysiological, neurochemical, or metabolic activity may be observed in a structure correlated with a behavioral response of interest, which suggests an involvement of that structure with the function under study. However, this correlative relationship does not establish whether the functioning of that region is causally important for the behavior. This issue may be addressed by an intervention that disrupts (impairs or improves) the function under study. For example, if the function is lost following selective lesioning, this suggests that the brain structure is implicated in that function. Similarly, if the function is enhanced following a boosting of neurotransmission in that region (e.g., via mild levels of electrical or chemical stimulation through implanted electrodes or cannulae), this is similarly converging evidence of a causative role. However, it is important to realize that the use of these techniques is each associated with interpretative problems, and their effects must be critically appraised. For example, the designation of the lateral hypothalamic region as a “feeding center” was based on the following:

1. Electrolytic lesions produced profound aphagia (abstention from eating).

2. Electrical stimulation of the brain through electrodes implanted in the lateral hypothalamus induced eating in sated rats (Hoebel, 1974).
3. Infusions of the neurotransmitter norepinephrine into the hypothalamus also induced eating in sated rats (Leibowitz, 1980).
4. Electrophysiological recording showed that when monkeys were deprived of food, individual neurons in the lateral hypothalamus were sensitive to the sight and taste of food (Rolls, 1985).

Although many of these experimental observations have remained valid, subsequent evidence has suggested that the lateral hypothalamus has a much more specific role in feeding motivation, as a result of using improved techniques (see main text). Moreover, many of the effects associated with diminishing and increasing activity within the lateral hypothalamus have been shown subsequently to depend upon coincidental influences on axons within the medial forebrain bundle that merely passes through the lateral hypothalamus (e.g., between midbrain and striatum or between prefrontal cortex and brainstem) and had little to do functionally with the lateral hypothalamus itself. Only through the use of several neurobiological techniques providing converging evidence can the relationships between brain and behavior become more certain.

lateral hypothalamus in a number of species (Flynn *et al.*, 1970).

A particularly well-studied example is that of sexual motivation. Some hypothalamic nuclei contain high concentrations of steroid receptors (e.g., for estradiol and testosterone), especially the medial preoptic area and the ventromedial hypothalamic nucleus. In male rats, copulatory behavior is abolished by medial preoptic area lesions (Heimer and Larsson, 1966–1967), whereas electrical stimulation of this region elicits copulation. In female rats, lordosis is blocked (and aggression toward males increased) by lesions of the ventromedial hypothalamic nucleus. Lordosis also is induced by electrical stimulation of this region (Pfaff, 1982). Most of these responses are hormone dependent. In ovariectomized females, proceptive (“ear wiggling,” hopping, and darting) and receptive (lordosis) behaviors can be elicited by implanting

estradiol into the ventromedial hypothalamic nucleus. Similarly, the sexual behavior of castrated males can be restored by implanting testosterone into the medial preoptic area. This hormone dependence underlines the interaction between external (environmental) and internal (plasma steroids) states in inducing motivated responses. Also, sex hormones influence the organization of sexually dimorphic brain development (e.g., development of the sexually dimorphic nuclei in the preoptic region), as well as sexually dimorphic behavior. Maternal behavior also is dependent on hormones and is impaired by lesions of the medial preoptic area. Thus, it seems clear that the hypothalamus plays a central role in the regulation of sexual behavior.

The intermingling of hypothalamic neural mechanisms controlling thermoregulation, maternal behavior, feeding, and mating suggests that these behaviors

share controls in many circumstances. In summary, a wide variety of motivational states expressed as easily elicited, sometimes stereotypical and species-specific behaviors are represented within the hypothalamus and related structures.

### Hypothalamic Role in Consummatory Behavior

Many studies of the role of the hypothalamus in motivation have concentrated on measuring consummatory rather than learned instrumental behavior, a research strategy that may lead to misleading conclusions about motivational changes in general. For example, rats with preoptic lesions will not respond to thermal stress with reflex mechanisms such as shivering, adjustment of food intake, nest building, or changes in locomotion. However, they will learn to press a lever for hot or cool air and can achieve thermoregulation by this means (Carlisle, 1969). Similarly, male monkeys with preoptic lesions still show motivated behavior (e.g., they will masturbate in the presence of females), but are unable to mount and intromit. Moreover, male rats with preoptic lesions still show displacement behaviors and locomotor excitement in the presence of a receptive female, as well as lever pressing to gain access to the female, but cannot perform the consummatory behavior of copulation.

This dissociation between consummatory and instrumental behaviors is important because damage to a component of the limbic system, the amygdala, is known to produce the opposite pattern of effects—unimpaired mounting but reduced instrumental behavior (Everitt, 1990). These examples show that hypothalamic mechanisms operate mainly at the level of controlling consummatory rather than learned instrumental behavior leading to a goal. Behavioral flexibility illustrated by learning appears to require recruitment of additional neural systems, including the amygdala (see later).

### The Lateral Hypothalamic Syndrome

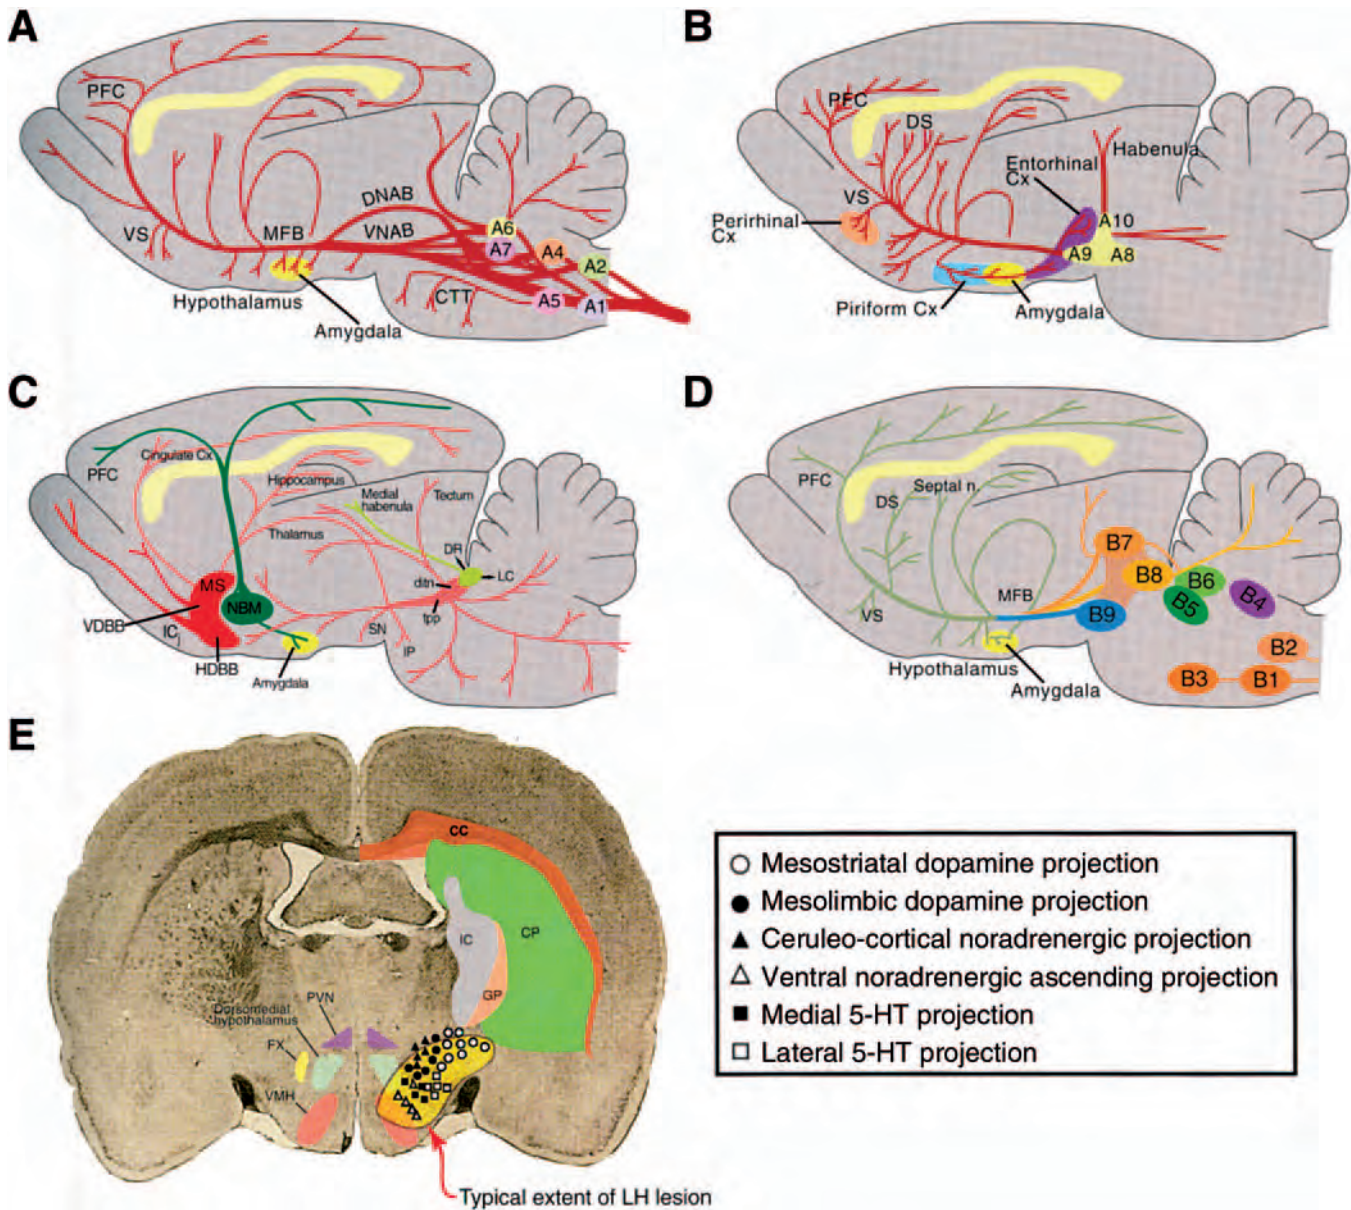

Electrolytic lesions of the lateral hypothalamus cause dramatic deficits in food intake. However, not only do such lesions affect more than simply feeding behavior, they also destroy far more than the lateral hypothalamic region itself, mainly by interrupting ascending and descending fibers in the medial forebrain bundle (Fig. 43.3). Thus, the effects of lateral hypothalamic lesions on eating were unlikely all to be caused by damage to a lateral hypothalamus “feeding” center. For example, the nigrostriatal dopamine pathway courses through the lateral hypothalamus

without synapsing there. Injection of a catecholamine-selective neurotoxin, 6-hydroxydopamine (6-OHDA), into the vicinity of the lateral hypothalamus reproduced most of the classic lateral hypothalamic syndrome (Ungerstedt, 1971a). The injected rats suffered large depletions (>90%) of dopamine from the striatum. They were cataleptic and had difficulty initiating head, limb, axial, and oral movements. Further experiments showed that the syndrome could be produced by injection of 6-OHDA at any of several points along the nigrostriatal dopamine pathway between its origin in the substantia nigra and its termination in the caudate-putamen. Thus, dopamine depletion at sites well away from the lateral hypothalamus reproduced much of the lateral hypothalamic syndrome. 6-OHDA-induced lesions of the mesolimbic rather than the nigrostriatal pathway minimally affected ingestion but did affect other behaviors, such as locomotion and exploration, that may accompany feeding (Koob *et al.*, 1978). Therefore, both consummatory and appetitive behaviors are affected by dopamine depletion, although probably in different regions of the forebrain.

#### *Lateral Hypothalamic Syndrome Is Similar to, but Not the Same As, the Syndrome Produced by 6-Hydroxydopamine Lesions*

Recovery from the lateral hypothalamic syndrome and the syndrome produced by 6-OHDA is similar (Marshall and Teitelbaum, 1977). At first, animals show adipsia (absence of drinking), aphagia (absence of eating), sensorimotor neglect (lack of response to stimuli), and akinesia (dearth of movements). Recovery from sensorimotor neglect parallels recovery from aphagia in both syndromes. (Recovered rats do not respond normally to physiological challenges, such as hyperosmolality.) Stricker and Zigmond (1976) explained this recovery as intrinsic recovery of function in dopaminergic systems. They proposed that changes in dopamine turnover and reuptake, as well as increases in the number of dopamine receptors, combine to minimize the impact of a lesion. In fact, in animals recovered from 6-OHDA lesions, aphagia and adipsia can be reinstated by drugs that block the synthesis of catecholamines or that block dopamine receptors. These studies led to the hypothesis that the entire lateral hypothalamic syndrome is caused by a deficit in behavioral activation and results from depletion of brain dopamine rather than damage to lateral hypothalamic cells.

Despite these similarities, subtle differences between the two syndromes cannot be explained by this dopamine hypothesis. For example, 6-OHDA-lesioned rats, unlike animals with lateral hypothalamic lesions, are

**FIGURE 43.3** Ascending monoamine neurotransmitter systems. Figure shows schematic sagittal (A–D) and coronal (E) sections through the lateral hypothalamus of a rat brain. Modified from Robbins (1986), with permission.

not somnolent (drowsy), are less finicky about food, and have fewer deficits in thermoregulation, taste aversion, learning, and oral motor performance. However, the most compelling difference is that rats with lateral hypothalamic lesions and the full syndrome have only 50% depletion of striatal dopamine, whereas 6-OHDA-lesioned rats (even with less than the full syndrome) have greater than 90% depletion of striatal dopamine. Therefore, damage to the lateral hypothalamus itself or to fibers of passage, in addition to those of the ascending dopamine system, apparently contributes to the lateral hypothalamic syndrome.

#### *Cell Body Lesions in the Hypothalamus Produce a Less Severe Lateral Hypothalamic Syndrome*

The neurotoxins kainic, ibotenic, and quisqualic acids are structurally related to the excitatory neurotransmitter glutamate. They bind to various subtypes of glutamate receptors and essentially stimulate neurons to death. These excitotoxins can be used to produce lesions of cell bodies while sparing fibers of passage. Electrolytic and mechanical lesions, in contrast, damage soma and fibers. Despite sparing striatal dopamine, such cell body lesions lead to severe problems with eating, followed by long-lasting deficits in homeostasis (Winn *et al.*, 1984). However, there are no signs of akinesia or sensorimotor neglect. Hence, at least two factors are required to explain the lateral hypothalamic syndrome: damage to the lateral hypothalamus disrupts homeostasis and striatal dopamine loss disrupts the initiation and execution of feeding and related behaviors. Neurons in the lateral hypothalamus containing the neuropeptide orexin project directly to the dopamine neurons in the ventral tegmental area and may therefore provide a neuroanatomical and functional link between regulatory and incentive motivational components of ingestive behavior.

#### *Animals with Dopamine Denervation Syndrome Show Rotation and Sensorimotor Neglect*

A central question for research in this area is what is the precise nature of the contribution by the dopamine system to motivation? Some clues to answering this question were provided by experiments in which rats received unilateral 6-OHDA lesions of the nigrostriatal system. The rats rotated toward the side of the lesion following treatment with a dopamine-releasing drug, such as D-amphetamine (Ungerstedt, 1971b). Presumably, this rotation occurred because more dopamine is released on the intact side than the lesioned side of the brain and because any output pathway from the striatum influences, via crossed

pathways, the opposite side of the body. Of even greater interest, the direct dopamine receptor agonist apomorphine caused the rats to turn away from the side of the lesion so long as the lesion was extensive. This rotation could be explained by supersensitive dopamine receptors on the lesioned side. These studies of drug-induced movement have been important in identifying mechanisms of receptor regulation that might contribute to recovery from motivational deficits following dopamine denervation. However, they do not by themselves answer the central question posed earlier of the precise contribution of dopamine to motivation.

More relevant to this question is that unilateral lesions of the lateral hypothalamus or nigrostriatal dopamine system also produce polymodal sensorimotor neglect, measured by responses to contralateral somatic, auditory, and olfactory stimuli—a syndrome initially attributed to sensory inattention (Marshall and Teitelbaum, 1977). A more detailed analysis suggests that the fundamental deficit is a failure in initiating responses rather than attending to stimuli (Box 43.2 and Fig. 43.4). This leads to the conclusion that the nigrostriatal dopamine system contributes to *activation*, energizing the vigor of behavioral output (Chapter 31).

#### **Mesencephalic Dopamine Mediates Activation of Behavior**

Animals with lesions of the nigrostriatal system retain the capacity for movement; they do not have an irreversible motor deficit. However, they have great difficulty in starting that movement without an intact dopamine system. It is instructive to compare this with the problems that patients with Parkinson's disease have with movement initiation, since they too have a severe deficit in nigrostriatal dopamine (Chapter 31). To identify the circumstances in which the dopamine system normally becomes active, *in vivo* neurochemical techniques, such as microdialysis and voltammetry (Phillips *et al.*, 1991), have been used to monitor the release of dopamine in animals exhibiting particular behaviors. In addition, researchers have examined the firing of dopamine cells in response to particular stimuli (Schultz *et al.*, 1995). For example, dopamine cells have been identified in the ventral tegmental area that respond to rewards such as food (Fig. 43.5). However, if the food is reliably predicted by a conditioned stimulus, then, as a consequence of learning, the firing is initiated instead in response to the previously neutral stimulus. This and other findings support the theory that the dopamine cells provide an *error prediction signal* that enables reinforcement learning

## BOX 43.2

## SEPARATION OF SENSORY AND RESPONSE FACTORS IN THE DOPAMINERGIC SYNDROME OF NEGLECT

Sensory and motor aspects of the neglect syndrome were separated in the following way (Carli *et al.*, 1985). Rats were trained to detect brief flashes of light presented to either side of the head. In one case, they were trained to respond where the light was. In the alternate case, rats were trained to respond in a location away from the side of the light (Fig. 43.4). Rats with dopamine depleted from one side of the striatum could not respond properly toward

the contralateral side, whether or not the stimulus was presented on that side. Measurement of reaction time showed that the problem was in initiation, rather than completion, of the movement. Consistent with these data, dopamine-depleted rats could detect a contralateral stimulus and respond to it with an unlateralized response. Thus, their deficit was in initiation of movement in response to stimuli rather than in detection of the stimuli.

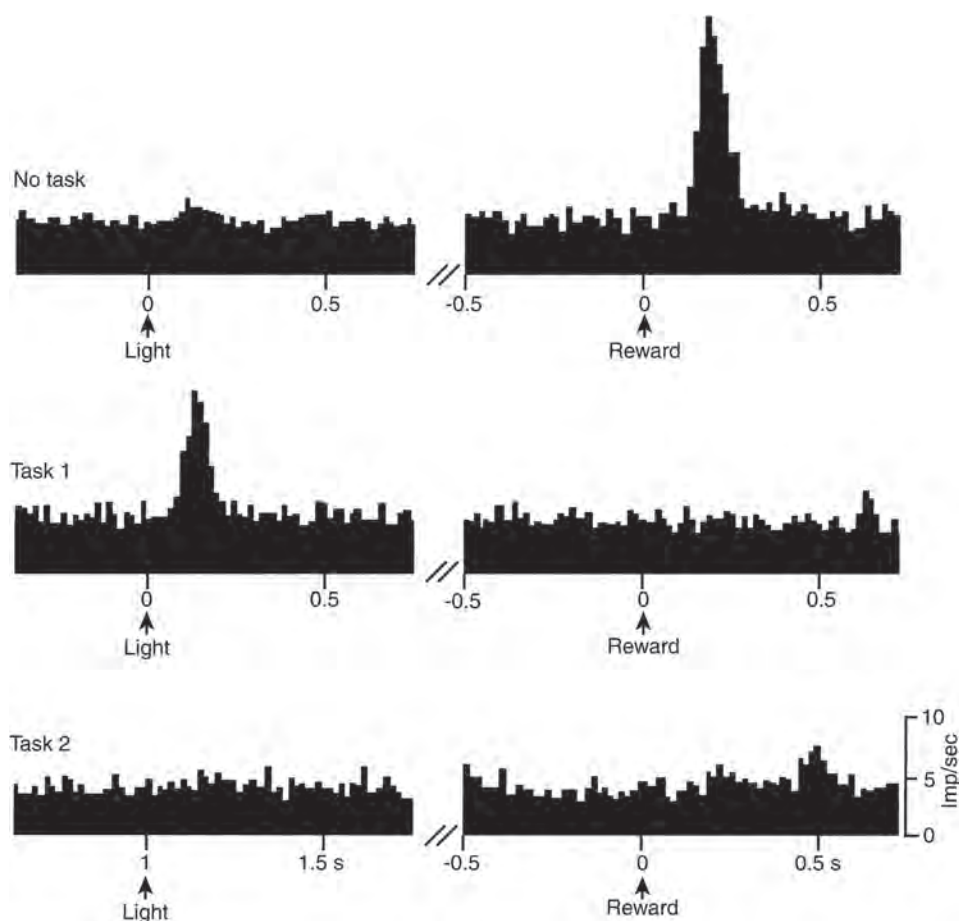

**FIGURE 43.4** Distinguishing between sensory and response factors. Rats were trained to move toward the same or opposite side on which a brief (0.2s) visual stimulus was presented. If a rat did not respond to the stimulus, it remained in a central location. After training, unilateral striatal lesions (oval) were made. Rats then were observed for their ability to respond to stimuli presented ipsilateral or contralateral to their lesions. Based on the responses of lesioned rats to stimuli, conclusions were drawn about the sensory and motor nature of the deficits caused by striatal lesions. (B) The hypothetical pattern of behavioral results obtained in the different test conditions following unilateral dopamine depletion is shown. Data were, in fact, consistent with a deficit in responding to contralateral space (i.e., motor neglect). From Robbins and Everitt (2003), with permission.

by networks in the striatum to influence appetitive behaviors.

### Electrical Stimulation of the Brain Can Be a Positive Reinforcer

Olds and Milner (1954) discovered that rats learned new responses when their learning was positively reinforced by electrical stimulation of the brain. That finding affirmed the importance of incentive factors in instrumental behavior. The best natural parallel appeared to be behavior in response to large incentives by animals

in low states of drive (e.g., chocolate milk in undeprived rats). However, any attempt to directly equate rewarding brain stimulation with subjective feelings of pleasure and hedonism is limited because the individuals used as subjects in human intracranial self-stimulation (ICSS) experiments often suffer from schizophrenia or intractable pain, and they frequently had difficulty verbalizing their responses. Measurement of the strength of reinforcers in microamperes (Box 43.3; Fig. 43.6) promised a pragmatic, as well as objective, new approach to the psychophysics of an operational hedonism. However, its greatest contribution was to enable

**FIGURE 43.5** Responses of dopamine neurons to unpredicted primary reward (Top) and the transfer of this response to progressively earlier reward-predicting conditioned stimuli with training (Middle). (Bottom) the record shows a control baseline task when the reward is predicted by an earlier stimulus and not the light. From Schultz *et al.* (1995), with permission.

the anatomical mapping of the central reward or reinforcement mechanisms of the brain (Phillips, 1984).

### Catecholamine Hypothesis of Rewarding Brain Stimulation
